If implemented in a robust fashion, the NFMA's diversity mandate will serve as a precautionary and proactive approach to wildlife conservation. In contrast, the ESA provides a more reactive and crisis-based approach to decision making, since the law's protective measures are usually not initiated until a jeopardized species is listed, and by that time, it is already in the proverbial emergency room. Federal wildlife agencies take an average of 11 years to list species (Greenwald et al. 2006), frequently after their long-term viability is in doubt (Wilcove et al., 1993, Neel et al. 2012, Rylander 2012). Waiting until a species is on the brink of extinction before taking protective measures creates unnecessary risks to a species and increases the controversies, costs, and restrictions associated with their recovery. Furthermore, funding is inadequate to meet the needs of species that are already listed, are candidates for listing, or have been petitioned for listing (Scott et al. 2010). Strong wildlife provisions under the NFMA could provide an earlier, proactive response to species declines, lessening the trend for more listings under the ESA. Allowing populations to decline towards listing is not good policy ecologically, politically, or economically. It will only reduce management flexibility for states, private citizens, and federal agencies and will further burden managers implementing the already underfunded ESA.

CONCLUSIONS

Given clear guidance in the Directives and sufficient funding, the 2012 planning rule has the potential to be a highly effective framework for wildlife conservation on National Forest System lands. It commits the Forest Service to a formal adaptive management process, adopts a landscape perspective as the primary context for forest planning, strives to find an appropriate balance between coarse- and fine-filter approaches to the assessment of biological diversity, and codifies the need to monitor focal species at multiple spatial scales. These are all significant advances that signal the Forest Service's commitment to a new planning rule that is responsive to the status and trends of ecological systems, as well as the expectations of the nation for the wise stewardship and conservation of public lands and resources.

Although we are confident that the rule can be implemented so as to effectively conserve wildlife populations, we are concerned about the ambiguity of the plan's diversity provisions and the level of discretion permitted when interpreting and implementing the plan's most fundamental actions: identifying focal species, monitoring status and trends, establishing triggers for adaptive management, and taking action to sustain viable populations. Effective implementation of the rule will require a commitment to direct monitoring of focal species, species of conservation concern, and ESA species, as well as a commitment to maintaining their viability. Without this commitment, the provision to sustain biological diversity is incoherent and unlikely to be effective. Triggers will have to be established for monitoring of species to signal when a review of management approaches is necessary. Without an assessment of the effects of management actions via monitoring, the agency cannot fulfill its obligation to manage adaptively. When private land development or other more distant factors affect the viability of species, the USFS should place more, not less, emphasis on providing for viable populations to the extent practicable. The design of monitoring programs, determinations about the inherent capability of the land, and selection of focal and species of conservation concern should be based on the best available scientific information.

The language of the new rule is more discretionary than the 1982 rule, and it removes the requirement to maintain viable populations of all vertebrate species. Although this is unquestionably a significant change in regulatory language, some might argue the 2012 rule merely codifies the way the USFS has managed for diversity since 1982. In practice, management indicator species seldom have been monitored directly in a way that allowed for a clear understanding of their response to management actions, and the USFS has been managing for Regional Forester Sensitive Species by relying primarily on habitat measurements as proxies for the species' current status. In effect, the 2012 rule simply makes it more explicit that this relaxation of the standards established in the 1982 rule will be the USFS's accepted standard for managing for diversity—to focus primarily on coarse-filter approaches, with the expectation that currently abundant species will remain abundant, and that sensitive but stable wildlife populations will, by and large, persist. The problem with this approach is that the NFMA includes clear requirements to provide for a diversity of plant and animal species, not just a range of ecological conditions that may or may not support diversity. In the end, habitat is a meaningless concept if it is never occupied by actual individuals of the species in question.

With the new rule, the USFS faces a new set of decisions that it can address from a position of power, with greater discretion over its approach to wildlife, and forest management in general. It has the opportunity to improve upon past efforts to conserve wildlife and biological diversity, or it could retreat from the responsibilities established in the NFMA and the 1982 rule. At this juncture, the USFS and the broader community of foresters and wildlife managers should pause to consider whether a relaxation of standards—most notably with respect to population viability—and the consequent lessening of agency responsibility and authority is in the best interest of the nation or the agency itself. We respectfully argue that conservation of the nation's biological wealth, including the persistence of viable populations of wildlife species, is an important service that a strong and professional USFS can and should provide to the American public. To the extent that the agency uses its new discretion to lessen its responsibility to wildlife and its exposure to controversy and criticism, the 2012 rule is likely to represent a retreat from an essential public responsibility and a blow to the wildlife profession. But to the extent that the agency signals its leadership on these issues by voluntary committing itself to a nationwide, science-based, and outcome-oriented program of adaptive management of both forest ecosystems and their full complement of species, the 2012 rule will signal a new era of leadership, where increased discretion is used to elevate intent and expectations, accept greater responsibility, and provide energetic leadership in the conservation and management of the nation's public lands and wildlife.

Review and assessment of LANDFIRE canopy fuel mapping procedures

Joe Scott

4/29/2008

Executive Summary

The LANDFIRE procedures for quantifying and mapping canopy fuel characteristics follow generally accepted scientific procedures in the fields of fuel science and remote sensing. Accuracy of LANDFIRE canopy fuel products is low, but consistent with constraints imposed by the very large (national) extent of the effort and the high inherent variability of the characteristics being mapped. Other canopy fuel mapping efforts have achieved greater accuracy than LANDFIRE's products, but at greater cost per acre mapped, and by employing methods that can't be applied at LANDFIRE's extent. The problem of low map accuracy of LANDFIRE canopy fuel products is a greater problem for project-level geospatial fire analyses than for the national-level analyses which LANDFIRE was designed to support. Insufficient accuracy can be resolved by end users through a routine process of critique and calibration (refinement using local information) and refreshing (to account for changes in the landscape since the effective date of LANDFIRE products). Work is now underway to develop a standard procedure for critiquing and calibrating LANDFIRE data layers and to refresh the LANDFIRE data to the present time. These efforts will improve accuracy for both project- and national-level analyses.

Artificial seams in LANDFIRE data products may exist both within and between map zones. The problem of data seams is very difficult to resolve once the data have been published by LANDFIRE, but are unavoidable given the scale and constraints of the project. The utility of LANDFIRE data for national-level analyses is not significantly compromised by these seamlines, but regional- and project-level analyses may suffer from the difficult-to-remove seams.

This report is organized around seven potential shortcomings or problems with canopy fuel related LANDFIRE data products:

- canopy cover values are too high,
- data discontinuities exist within and between map zones,
- canopy bulk density values are too low for use in FARSITE,
- canopy base height is too high to generate crown fire,
- treelist data sources may not be best for canopy fuel calculations
- alternative canopy fuel calculation programs may produce different results
- Refreshing and calibrating LANDFIRE data is needed

Canopy Cover values too high

The canopy cover values used in the LANDFIRE process were obtained from the National Land Cover Dataset (NLCD). The NLCD dataset was produced using a Classification and Regression Tree (CART) analysis relying on a method combining satellite remote sensing and field data. Unfortunately, there are several cover-related quantities measured by ecologists and used by fire modelers; the different quantities are frequently interchanged, erroneously.

As used in fire modeling software and envisioned by fire behavior specialists, canopy cover is the proportion of the forest floor covered by the vertical projection of tree crowns. Some field methods estimate this quantity without bias, but the most common field measurement technique uses a spherical densitometer that actually measures a quantity sometimes called canopy *closure*—the proportion of the sky hemisphere obscured by vegetation when viewed from a single point. Canopy closure is usually a higher value than canopy cover; canopy cover rarely exceeds about 70 percent, whereas canopy closure often approaches 100 percent. Refer to the FireWords glossary of fire science terminology (Scott and Reinhardt 2007) for more details (available at www.fs.fed.us/fmi/downloads/firewords.html). It is not clear if this is the reason for the discrepancy between the NLCD canopy cover values and on-the-ground experience. Nonetheless the canopy cover values produced by NLCD are acknowledged by the LANDFIRE developers to be too high relative to the quantity used by existing fire models.

Canopy Cover is a key LANDFIRE variable because it is used as an independent variable for estimating a wide range of dependent variables like fuel model and canopy bulk density. As directly used in fire modeling programs, canopy cover is used to estimate wind adjustment factor and fine dead fuel moisture. The wind adjustment factor sub-model in fire modeling systems is relatively insensitive to the magnitude of apparent errors in the canopy cover maps. The dead fuel moisture model, however, is more sensitive to errors in canopy cover. In an unpublished analysis, LANDFIRE's Matt Reeves[1] found that correcting the apparent canopy cover error using an alternative approach resulted in a dead fuel moisture decline of roughly 2 percentage points across example landscapes. This change in fuel moisture led to modest changes in potential fire behavior as simulated with FlamMap[2], but a factor-of-two increase in fire growth using FARSITE[3], a significant increase.

---

[1] Matt Reeves is a GIS Specialist and leads the LANDFIRE Fuels Team, stationed at the Missoula Fire Sciences Laboratory.

[2] FlamMap is software that maps potential fire behavior across a landscape for a single specified weather condition, and has features that allow simple fire growth simulation, identification of fire travel paths, and locating fuel treatments. Available at www.firemodels.org

[3] FARSITE is software that simulates the growth of one fire for one projected weather scenario. Available at www.firemodels.org.

Moreover, canopy cover mapping errors may lead to significant indirect fire modeling effects. Because canopy cover is a keystone variable, these indirect effects are difficult to quantify. If canopy cover is overestimated, LANDFIRE may subsequently map the incorrect fuel model, incorrect CBD, incorrect CBH, etc., all of which can strongly affect fire modeling outputs in a geospatial fire analysis. Using the current LANDFIRE fuel mapping procedure, Tobin Smail[4] believes these indirect effects may be small, because they are so heavily calibrated by end users before publication of the data.

Unfortunately, most of the direct and indirect effects of overestimating canopy cover tend to under-predict fire behavior; the effects are not necessarily compensating. For example, overestimating canopy cover in forested areas can lead to slight underestimation of midflame wind speed, slight-to-moderate overestimation of dead fuel moisture content, choosing a too-benign fuel model (one with little or no live fuel, for example). Together, these factors conspire to underestimate surface fire behavior. Overestimating canopy cover can potentially lead to overestimating canopy bulk density in the LANDFIRE process, which in some cases can partially balance the underestimation.

Because it is used as an independent variable, the importance of an accurate canopy cover layer in the LANDFIRE process should not be underestimated. Matt Reeves reports that a newer type of FIA plot allows independent calculation of canopy cover for FIA plots installed since 2005. This new method appears to agree well with the unbiased (but infrequently used) line-intercept field method of estimating canopy cover, whose values correlate very well with what is expected in the fire behavior models, without manipulation. If enough of such plot data is available, it may be possible for LANDFIRE to generate canopy cover maps using this new approach, with significant improvement in fire modeling. Such improved canopy cover maps may also affect dependent LANDFIRE maps such as CBD.

[4] Tobin Smail is a LANDFIRE fuel specialist based at the Missoula Fire Sciences Lab.

Seamlines within and between map zones

LANDFIRE data is “gapless” because it maps fuel and vegetation characteristics across all ownerships across the U.S. That is a critical feature because important aspects of geospatial fire analysis (fire growth modeling and mapping potential fire behavior and effects) require gapless coverage of not only the analysis area but of a large buffer around the area as well. However, despite using a consistent methodology across the U.S., LANDFIRE data is not “seamless” in the sense that obvious artifacts of the mapping process are evident in surface and canopy fuel layers. Seams in LANDFIRE maps can arise from two sources. First, a seam can exist along map zone boundaries, even if the satellite imagery were the same in both map zones, because different protocols and different fuel and fire experts can be used in each map zone. Second, a seam may exist *within* a map zone due to the developers’ need to stitch satellite scenes into a composite image for a whole map zone. This procedure is similar in nature to stitching together digital photos to make a panorama—if the exposure is not the same for each photo, then the boundary between photos becomes obvious in the final panorama. In the LANDFIRE process, if those separate satellite images are of similar quality (captured during times of similar atmospheric conditions, for example) then the compositing process works well and a seam may not be created. However, the separate images may differ in many respects (primarily atmospheric conditions) such that the information contained in one image may differ from another image for the same pixel. The CART analysis assumes that all variation in the images is due to on-the-ground differences, not atmospheric differences unrelated to actual differences on the ground. When used in subsequent CART analyses, the boundaries where the two images were merged can become a noticeable data seam where the map indicates a strong change in value that is not actually present on the landscape. This is a difficult problem to reconcile; there is no easy way to remove such a seam—it’s in the base imagery that the data layers are built upon, and it runs along an artificial (satellite image) boundary. Such data seams can also exist in the inherited NLCD canopy cover data used in the LANDFIRE fuel mapping process, but those seams are generally “hidden” along natural terrain features such as rivers and major ridgelines where changes in vegetation structure are not uncommon. Despite being hidden, such seams can produce disconcerting data discontinuities in the final map.

For example, Charley Martin[5] provided this LANDFIRE CBD data for southern Oregon, which shows the distribution of CBD values in a small watershed that crosses a map zone boundary (figure 1).

[5] Charley Martin is a Fire Ecologist with the Bureau of Land Management’s Medford District, Oregon. Charley has been closely involved in LANDFIRE’s calibration workshops and participated in a separate project to assess accuracy of LANDFIRE fuel maps.

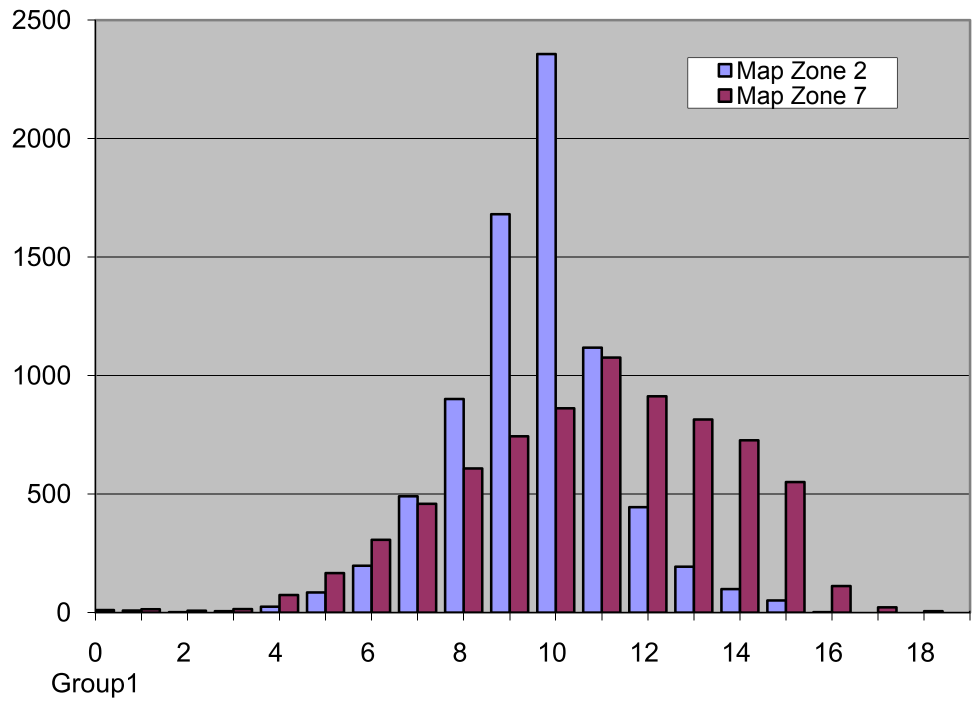

Figure 1 -- Distribution of CBD values (kg/m3 * 100) for a southern Oregon watershed that crosses two map zones .

The expectation, based on field experience in the watershed, is that the distributions should have the same shape. Information such as this can help in a calibration exercise designed to force the map zones into similar distibutions, but there is no way to know which distibution is "correct". The following map (figure 2) shows the nature of the data discontinuity on the CBD map. Similar data seams are evident in nearly all LANDFIRE maps for this watershed.

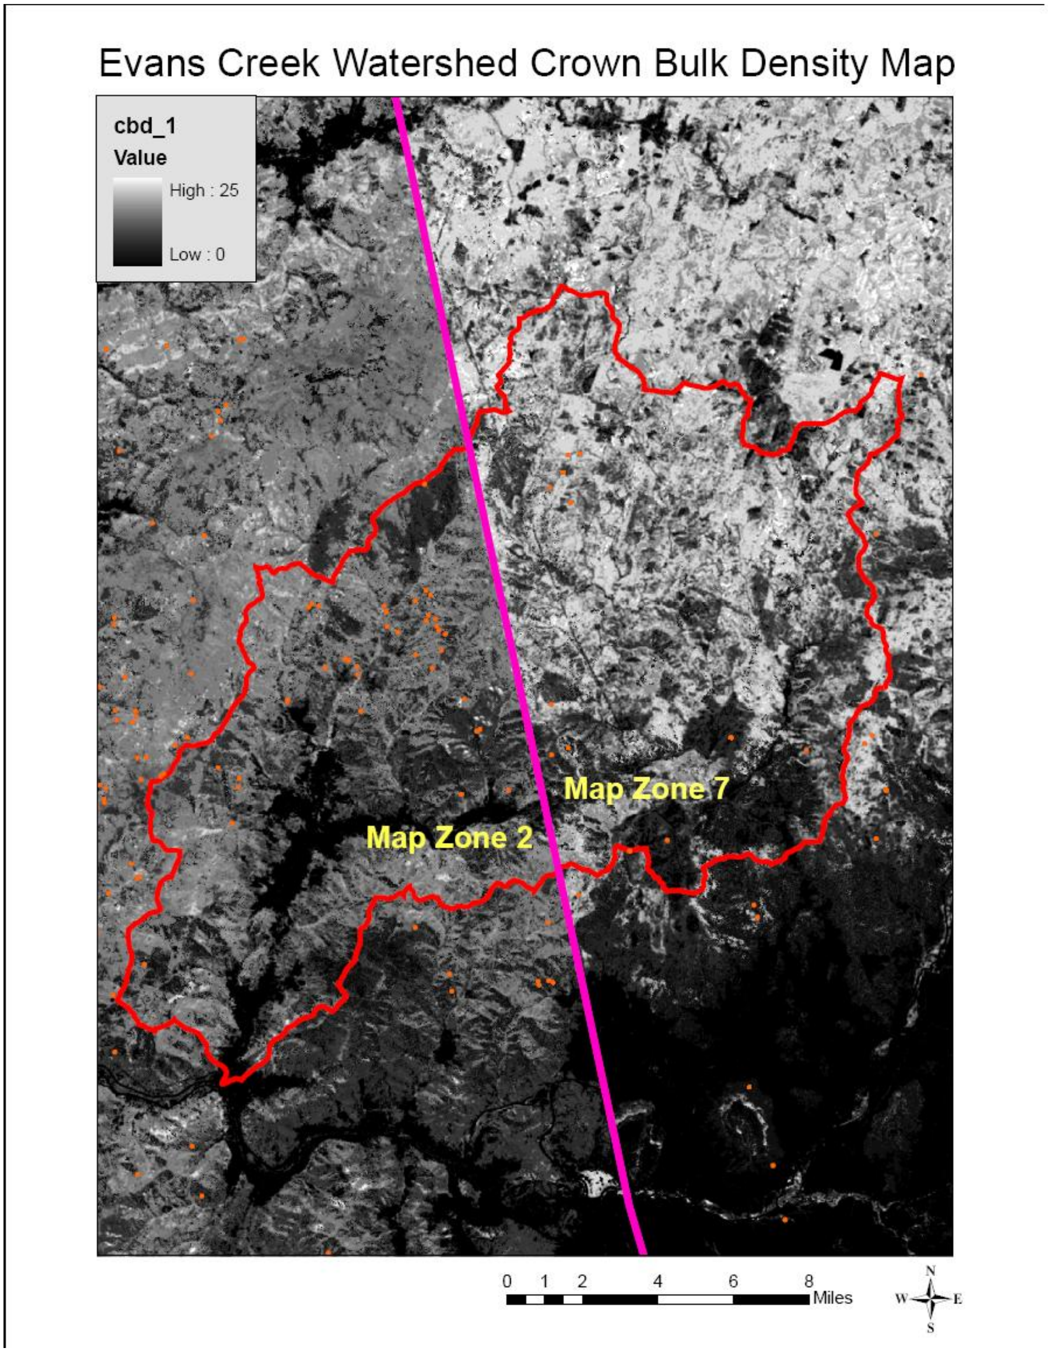

Figure 2 -- LANDFIRE map of CBD in a watershed crossing the map zone 2/7 boundary. CBD is shown as higher in the Map Zone 7 portion of the watershed; on-the-ground experience does not support that result.

Rick Stratton[6] of Systems for Environmental Management[7] is currently working on a procedure for calibrating and updating LANDFIRE data for use in some fire modeling

[6] Rick Stratton is a Fire Modeling Specialist with Systems for Environmental Management, based at the Missoula Fire Sciences Lab.

systems. Fire Program Analysis (FPA) and the USDI National Park Service are co-funding that work. The current in-preparation version of Stratton's work does not yet suggest a method for mitigating seams. Charley Martin, with the BLM in Oregon, is trying an approach that smoothes the data on both sides of the seam to reduce its effect. Such an approach is visually appealing on a map, but does not effectively deal with the problem.

Alternative approaches to using remote sensing imagery in creating the LANDFIRE data layers may reduce the intensity or extent of seams. An alternative approach, which avoids seamlines by conducting the mapping and analysis one strip (satellite image) at a time, rather than one map zone at a time, is being used to generate LANDFIRE maps in Alaska. This approach requires that field data be well-distributed across the area, because sufficient field data must exist within each image, not just the map zone. Assuming such data exist, this approach may work well to avoid seamlines and improve accuracy.

Seamlines in LANDFIRE data primarily affect project-level analyses, but regional- and national-level analyses may also be affected. Even a national analysis like FPA is broken into smaller units (FPUs and FMUs) for analysis and comparison. If the analysis unit is small compared to the map zone or satellite imagery, then the potential exists for the data discontinuities to affect results. The larger the analysis area, the smaller the effect seamlines will have on the results.

[7] Systems for Environmental Management (SEM) is a private, nonprofit research and education foundation based in Missoula Montana. In conjunction with federal partners, SEM has developed a host of fuel, weather and fire behavior modeling software and procedures, which are available at www.fire.org.

CBD too low for crown fire in the FARSITE family

Users of the Mark Finney's[8] family of geospatial fire analysis programs (FARSITE, FlamMap, FSPro[9], FSIM[10]) have long noted that values of canopy bulk density (CBD) produced by treelist methods are too low to generate the expected amount of crown fire in their simulations. LANDFIRE has used a prototype of FuelCalc, which applies a treelist method for estimating CBD, to generate its CBD map, so the complaint has been extended to LANDFIRE CBD maps. A general rule-of-thumb was developed to cope with this apparent disconnect: double the LANDFIRE treelist-generated values for use in Finney's geospatial programs to achieve the expected results.

Early CBD mapping procedures (Selway-Bitterroot, Gila wilderness areas) were developed before any plot-level methods of estimating CBD had been developed. Instead of relying on observed CBD at plots, the early efforts instead populated CBD by working backward from expected fire behavior to determine the CBD values that produce that behavior using a given fire model. Given the lack of plot-level CBD observations available at the time, the approach was reasonable. Nonetheless, that procedure produces a value that is good only for the particular fire model used. In this case, the fire model used, FARISTE, produces fire behavior quite different than all others developed since then (except FARSITE's geospatial relatives).

Since those initial mapping efforts, our ability to estimate CBD has improved considerably, and is codified in FuelCalc[11], Fuels Management Analyst Plus (FMAplus[12]), and the Fire and Fuels Extension to the Forest Vegetation Simulator (FFE-FVS), all of which use a treelist approach. Such methods are based on decades of biomass research. The CBD algorithm in FuelCalc was conservatively designed to over-estimate rather than under-estimate CBD (by using the highest CBD found in any 11-ft layer of a canopy as the value for the whole plot, which is commonly more than twice the average bulk density). Comparison of predicted CBD with meticulously observed CBD (Scott and Reinhardt 2005) has generally verified the utility of the approach for estimating CBD in various stand structures. The values the treelist method produces fall squarely in the

---

[8] Mark Finney is a research forester at the Missoula Fire Sciences Lab. Mark is the developer of a suite of geospatial fire modeling software tools, including FARSITE, FlamMap, FSPro, and FSim.
[9] FSPro is online software that simulates the likelihood of fire spread across a landscape by simulating fire growth under a large sample of possible future weather scenarios. FSPro is an integral component of the Wildland Fire Decision Support System (WFDSS).
[10] FSIM is prototype software that simulates the likelihood of fire growth and behavior across a landscape for a sample of possible weather conditions and for a sample of possible escaped-fire frequencies and locations. FSIM simulations are being considered for use in FPA, and are also used in prototype quantitative wildland fire hazard and risk assessments.
[11] A prototype version of FuelCalc designed by Elizabeth Reinhardt at the Missoula Fire Sciences Lab was used by the LANDFIRE fuel staff. A more complete version of FuelCalc is currently under development.
[12] FMAplus is commercially available software produced by Don Carlton of Fire Program Solutions LLC, available at www.fireps.com.

range of values that Agee's (1996) analysis found would lead to crown fire. The treelist methods generate CBD values work well in all fire modeling software programs except Finney's geospatial family, including BehavePlus[13], FMAplus and NEXUS[14]. FlamMap and FARSITE offer users a choice of crown fire modeling methods to use: the original "Finney (1998)" method, and a method similar to that used in NEXUS, which is labeled "Scott and Reinhardt (2001)" in those programs (figure 3).

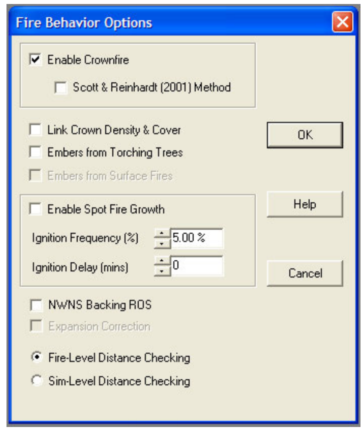

Figure 3--The *Model | Fire Behavior Options* dialog box in FARSITE, showing the checkbox that allows calculation of crown fire similar to the method described in Scott and Reinhardt (2001).

Users have generally found that using LANDFIRE or other treelist-generated CBD data with the crown fire option set to "Scott and Reinhardt" produces very reasonable results for crown fire occurrence, but not when using the "Finney 1998" default setting.

Scott (2006) suggests that the significant difference in fire model outputs (fire type, crowning index, etc.) between Finney's geospatial fire models and the others can be attributed to an error in modeling logic made initially in the Canadian Forest Fire Behavior System and subsequently used in Finney's programs. The error in modeling logic had little practical effect as implemented in the Canadian prediction system, so it went unnoticed; the same logic error when implemented in the U. S. system, however, has led to great differences in predicted fire behavior. See Scott (2006) for a detailed discussion of this topic.

The problem that LANDFIRE-generated CBD may be too low for use in Finney's geospatial fire models is best addressed by the fuel and fire modeling community, not by LANDFIRE. For users who wish to use those programs in their default setting (or those using FSPRO and FSIM, which do not yet have an option to use the Scott and Reinhardt 2001 method), the current rule of thumb may be appropriate. Otherwise,

[13] BehavePlus is software that allows simulation of fire behavior and effects for a specific point in space and time. Available at www.firemodels.org
[14] NEXUS is software that allows simulation of crown fire potential for a specific point in space and time. Available at www.fire.org

many users report that using the “Scott and Reinhardt” switch with LANDFIRE CBD maps produces acceptable results.

CBH too high for crown fire

At first glance this issue appears similar to the above issue with CBD, but in reality it is much more difficult to address. Unlike CBD, CBH is difficult to define in such a way that it can be measured in the field or estimated from a treelist. Moreover, CBH is not strongly correlated with other stand characteristics, making it difficult to produce reliable maps using the LANDFIRE approach (or any mapping approach, for that matter). For example, within any given forest type, CBH can be low in areas with low canopy cover, because there may have been little self-pruning in such a low-density stand, or CBH can be high if the stand has low cover because it was thinned. The LANDFIRE procedure can only broadly distinguish those cases.

Such difficulties led to the development of an alternative method of estimating CBH based on expert opinion. (Note that this is a similar approach taken for the Selway-Bitterroot and Gila mapping projects when faced with a lack of available CBD data.) The fuel and fire behavior experts did not offer their opinion of CBH directly, but instead were asked to identify the weather conditions that typically lead to torching (because CBH is used to predict when torching will occur). From that information, along with the fuel model and canopy cover already assigned, the CBH that leads to torching is then identified by working backward through the crown fire initiation model. This expert opinion CBH therefore depends on the fuel model and canopy cover for the area, as well as the weather conditions identified by the experts. Any errors in mapping of those layers, and any changes or adjustments made by users to those layers invalidate this CBH estimate—transition to torching would no longer take place at the identified threshold.

Fortunately, unlike with CBD, all point-based and geospatial fire models, regardless of developer, use CBH in the same way, so estimates of CBH made this way are valid in all U.S. fire modeling programs.

The difficulties with estimating CBH to simulate transition to crown fire cannot be resolved by LANDFIRE. The fire modeling community may need to find a different approach that is more amenable to mapping and less dependent on surface fire behavior (see Cruz and others 2004).

In most fire modeling systems, especially in Finney's geospatial models, the downside of conservatively estimating a low CBH is small compared to the downside of estimating a CBH that is too high. Until fire modeling uses a different approach, a stop-gap measure that LANDFIRE could employ is to modify the FuelCalc procedure for estimating CBH to identify the height of the lowest biomass of any density. Responsibility for this task lies not with LANDFIRE but with the fuel and fire behavior modeling community.

Treelist data sources

LANDFIRE has gathered treelist data from a variety of sources that use a variety of inventory methods. Two tree inventory methods are generally used: fixed-area plots and variable-radius plots (some tree inventories combine both methods). The treelist-based calculation methods used by LANDFIRE in FuelCalc are designed to be used with fixed-area plots of approximately 0.1 ac in size. The developers of that method felt that variable-radius plot may not adequately represent stand structure of a plot because it emphasizes sampling of large trees at the expense of small trees. For canopy fuel estimation, the contribution of a large number of small trees can be much more important than a small number of large trees, so it is important to have as much information as possible for those trees. Moreover, the trees sampled at a variable radius plot can be very far apart from each other, so their individual crown characteristics may not necessarily reflect growing conditions near the plot center.

Nonetheless, a large amount of treelist data available to LANDFIRE is of the variable-radius or hybrid plot type. The magnitude of potential problems with using variable-radius plots is unknown. In theory, the CBD predicted for a variable radius plot is probably slightly lower than if a fixed-area plot had been established at the same location, but this is impossible to know without research comparing the two approaches at the same plot.

For this report, a comparison of fixed-radius and variable-radius plot types was conducted using a dataset for a single even-aged ponderosa pine/Douglas-fir stand in western Montana. The dataset consisted of a complete list of tree attributes, including (X,Y) coordinates, of every tree on a square, 100 x 100 m (1-ha) plot. (The plot was established in 2006 by Elizabeth Reinhardt[15] to eventually test the use of upward-looking LIDAR for estimating canopy fuel characteristics.) From this complete dataset we established four virtual sample points within the megaplot, each located 25 meters from the edge. At each of these sample points we identified which trees would be counted in fixed- and variable-radius plots of different sizes. We then computed the average canopy fuel characteristic across the four sample points for each plot size. The results are summarized below. The results for a one-tenth-acre fixed-radius plot are shown in bold for emphasis. Plot sizes are listed in descending order of “size”; plots at the top sample a larger number of trees than plots at the bottom.

[15] Elizabeth Reinhardt is a research Forester at the Missoula Fire Sciences Lab. Elizabeth has led or participated in the development of several fuel, fire behavior and fire effects modeling systems, including FOFEM, FFE-FVS, NEXUS, and FuelCalc.

Table 1 -- Mean canopy characteristics (n = 4) for various plot types and plot sizes. The highlighted row indicates the plot type and size recommended by the developers of FuelCalc.

Fixed-radius Plots							
Plot Id	CBD (kg/m3)	CFL (t/ac)	CBH (ft)	SH (ft)	CC (percent)	Basal Area (ft2/ac)	Trees Per Acre
0.50 ac	0.054	3.0	22	86	38	102	278
0.25 ac	0.058	2.9	23	85	38	110	239
0.20 ac	0.058	2.8	23	85	38	105	253
0.10 ac	**0.065**	**3.1**	**22**	**83**	**39**	**109**	**298**
0.05 ac	0.086	4.0	29	85	46	143	310
0.02 ac	0.099	4.2	42	85	53	173	183
0.01 ac	0.148	6.2	38	72	58	239	233
Variable-radius Plots							
	CBD (kg/m3)	CFL (t/ac)	CBH (ft)	SH (ft)	CC (percent)	Basal Area (ft2/ac)	Trees Per Acre
BAF10	0.065	2.9	39	87	37	115	110
BAF20	0.088	3.7	38	84	45	135	151
BAF30	0.104	4.3	37	85	49	157	150
BAF40	0.110	5.0	37	86	56	190	207
BAF50	0.109	4.8	38	85	51	175	170
BAF60	0.130	5.7	38	86	57	210	204

Plot size appears to matter significantly for the fixed-radius plots—CBD ranged from 0.054 kg/m3 for the half-acre plots to 0.148 kg/m3 for the hundredth-acre plots, a factor of three difference (for the very same plot centers). These averages mask the increasing variability as plot size decreased—CBD at the four half-acre plots ranged from 0.046 to 0.065 kg/m3, whereas the hundredth-acre plots ranged from 0.000 to 0.366 kg/m3. This situation resulted in increasing CBD values with decreasing plot size, but that is unlikely to be a universal truth. In fact, one of the four plots was located such that many trees were found on the hundredth-acre plot, whereas the others had few or none.

The variable radius plots did not tend to underestimate CBD compared to the fixed-radius plot, an unexpected result. In fact, the BAF10 (variable-radius plot with 10-factor prism), a common BAF used in vegetation sampling, produced an estimate of CBD similar to the tenth-acre plot. In fact, larger BAFs, which sample fewer trees but puts more weight on each, tended to increase the estimated CBD. While very encouraging, this result applies to this one even-aged stand; a similar result may not be found for more complex fuel structures.

Canopy fuel load, canopy cover, and stand height estimated from variable-radius plots was also similar to the fixed-radius plots.

Canopy base height estimates differed significantly between the fixed-radius plots and the variable-radius plots, which predicted much greater CBH. This is likely due to the fact that the variable-radius plots do not adequately sample small trees, so tend to under-predict biomass in the lower part of the canopy. This effect would be even greater in more complex stand structures than present in this analysis. A hybrid plot with both variable- and fixed-radius plot elements could mitigate this effect.

Finally, the variable-radius plots underestimated tree stem density relative to the fixed-radius plots, again due to the under-sampling of small trees.

In summary, this analysis supports the conclusion that variable-radius plots under-sample small trees. That is, in fact, the purpose of that plot design. For this even-aged stand, the under-sampling of small trees led to underestimation of CBH, but not CBD, CFL, or SH. Only a more exhaustive analysis with other stand structures will confirm or refute this result.

Canopy fuel calculation programs

LANDFIRE used a customized-prototype version of FuelCalc coded by Larry Gangi[16] to estimate CBD and CBH. Other fuel analysts have used the Fire and Fuels Extension to FVS or Fuels Management Analyst Plus for making the same estimates. The canopy fuel calculations in FuelCalc and FFE-FVS[17] were designed by Elizabeth Reinhardt, and FMAplus was also patterned after those programs. All three programs use the same general approach to estimating CBH and CBD, but there are slight differences in the equations used in each tool, and slight differences in certain parameters and internal models. For example, the user has control over whether any of the biomass of broadleaf tree species is factored into the CBD and CBH estimates. In theory, differences in output generated from these three programs should be small.

As a quick test of this assumption, Charley Martin's dataset of 700 FIREMON[18] plots was run through both FuelCalc and FMAplus. The resulting differences between the programs were larger than expected—FMAplus consistently over-predicted relative to FuelCalc (Figure 4).

[16] Larry Gangi is a computer programmer with Systems for Environmental Management. Larry has also served as software developer for the FOFEM and FireMon software tools.
[17] FFE-FVS is software to simulate vegetation growth and quantify fuel characteristics over time. Available at www.fs.fed.us/fmsc/fvs/description/ffe-fvs.shtml.
[18] FIREMON is software to catalog and monitor fuel and vegetation characteristics. Available at www.fire.org

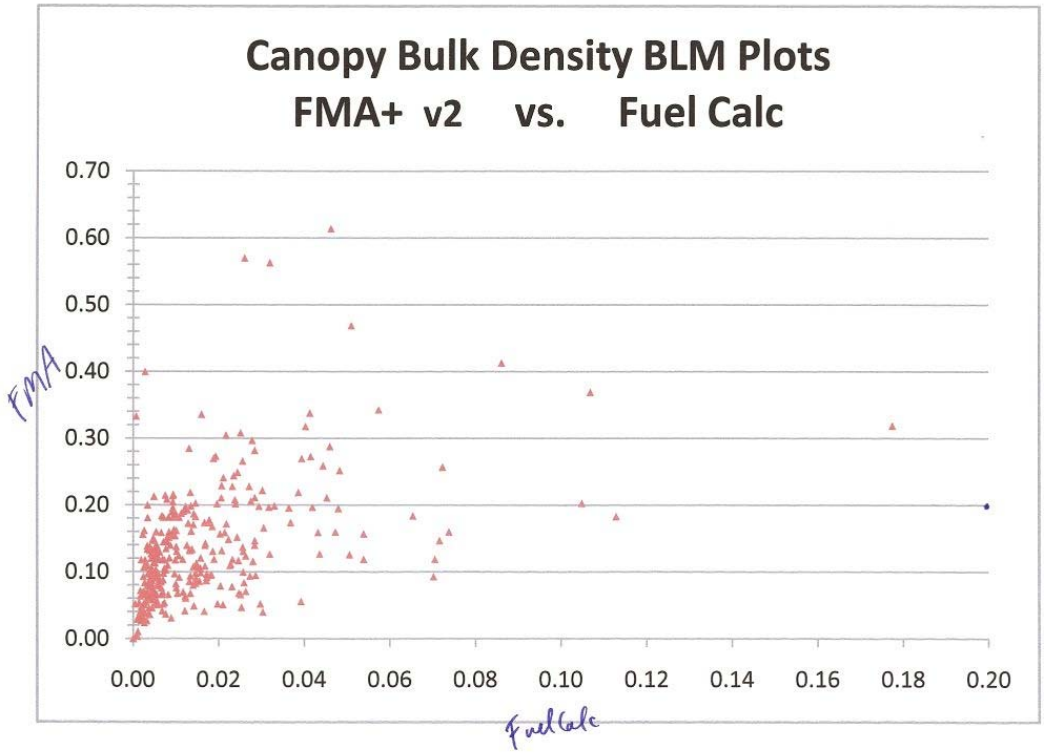

Figure 4 -- Predicted CBD (kg/m3) for FMAplus (Y-axis) and FuelCalc (X-axis). FMAplus overpredicts relative to FuelCalc, but it is not possible to know which is closest to "observed".

It is impossible at this point to know which is more accurate or reliable, but the FMAplus CBD values did not seem unreasonably high. (I don't have enough experience with the vegetation and fire behavior in the study area to confirm that conclusion, though.) It is possible that FMAplus is over-emphasizing the contribution of broadleaf species to canopy bulk density, or that FuelCalc is under-emphasizing those species.

I have forwarded this finding to Elizabeth Reinhardt, lead developer of FuelCalc, for further investigation. At this point I surmise that the FuelCalc-FMAplus comparisons were not apples-to-apples; user settings controlling different aspects of the calculation may not have been equal. FuelCalc remains the standard government application for quantifying canopy bulk density; LANDFIRE can rely on its output in mapping efforts.

The fuel and fire behavior modeling community should investigate this issue by thoroughly analyzing the outputs from a common set of treelist inputs for a variety of calculation tools. Any differences in output should be explained, and recommendations for resolving differences among the various programs should be provided.

Refreshing and calibrating LANDFIRE data

Two important limitations result from LANDFIRE's national extent: early date of validity (*ca*. 1999), and poor project-level accuracy for some fire planning applications. Refreshing data to the current year is a critical task before applying LANDFIRE's spatial data for any analysis, whether national-, regional- or project-level in extent. Improving local-level accuracy is important for project-level planning, but is not required (and may in fact hinder) regional- and national-level analyses by mixing adjusted and unadjusted data. LANDFIRE and others are addressing these issues by publishing procedures for calibrating and adjusting LANDFIRE data using a variety of *ad hoc* software tools.

To address the first limitation, LANDFIRE has developed a data-refresh plan to reflect landscape changes due to fire biennially. To jump-start the process, NIFTT[19] has conducted and nearly completed a Rapid Refresh of LANDFIRE data—a first-cut refreshing of LANDFIRE data to reflect landscape changes between 1999 and 2007. The products of this effort are expected to be replaced by a more thorough refreshing on a two-year cycle. In addition, the entire LANDFIRE mapping process will be repeated on a 10-year cycle. This procedure should ensure that high quality, up-to-date landscape data is always available. See the LANDFIRE Operations and Maintenance Business Case and Plan at http://www.landfire.gov/documents_updatedprod.php for more information.

Two separate efforts are underway to address the adjustment of LANDFIRE data to meet the needs of project-level analysis. One effort, co-funded by FPA and the National Park Service, is being carried out by Rick Stratton of Systems for Environmental Management. The product of that effort will be a document describing a process for critiquing and adjusting LANDFIRE data. A draft of this document will be available soon.

Second, NIFTT is continuing development and training of software tools and developing a training package designed to help users to download and prepare LANDFIRE. Two tutorials are available, and a course is being developed.

The DataPrep tutorial shows users how to prepare LANDFIRE data for use in NIFTT tools. This tutorial does not address adjustment or calibration of spatial data; it simply instructs users on how to download, clip, and re-project LANDFIRE data for use in a project-level analysis.

The LANDFIRE Data Access Tool tutorial describes the use of this tool for obtaining LANDFIRE data. This tutorial also does not address calibration and adjustment of the data itself.

[19] NIFTT is the National Interagency Fuel Technology Transfer team, co-funded by LANDFIRE and the National Interagency Fuel Coordination Group.

Finally, a course titled “GIS Tools for Wildland Fire and Fuels Planning” is under development. The course will teach students to download and edit LANDFIRE data for use in NIFTT’s GIS tools.

The combination of the NIFTT courses and tutorials and Stratton’s NPS/FPA-funded process for critiquing and editing LANDFIRE data should be enough guidance for most users.

Discussion

At times during their development process, LANDFIRE faced the choice of producing data that was consistent with biological science (for example, producing CBD values based on methods derived from the biomass literature) or producing data specifically adjusted so that could be consumed by a fire behavior modeling tool (CBD values manipulated so they work better in FARSITE). The LANDFIRE philosophy for the current effort was to base all data maps on the best available biological science, knowing that adjustment would be required for certain models. This is the only scientifically supportable approach. Should LANDFIRE's best biological estimate of a certain quantity end up not working well in a fire model, a quick investigation would indicate whether the problem was with the data, with the model, or with the fire modeling science. LANDFIRE should take steps to adjust any data layers it produces that are not consistent with scientifically valid field data, as they did for canopy cover values. In other cases, the fuel and fire modeling community may need to make accommodations in their fire models for the biologically estimated data.

Although users may need to critique and calibrate LANDFIRE data for use in project-level analysis, the goal of producing a nationally-consistent dataset is met without such effort. The scope of a critique and editing effort should be tied to the extent of analysis to be conducted. A national-level analysis would require a nationally consistent critique and calibration effort – LANDFIRE has already accomplished this task. A mid-scale analysis (state or region, for example) should have a critique and calibrate effort at the same scale, or none at all – mixing base LANDFIRE data for some areas with critiqued and calibrated data for others may lead to spurious results.

LANDFIRE's success at producing biologically based fuel and vegetation maps has created a situation where fire modeling difficulties can be addressed by the fire modeling community. Before LANDFIRE, without consistently created maps, fire modeling errors were always attributed to problems with the data, with no consideration for problems with the model. Geospatial fire modeling systems have been developed with a very rigid fire behavior model—no way to accommodate model error. (FARSITE has model-side spread rate adjustment factors, but other geospatial fire modeling tools do not). As a result, calibration of the fire model has always focused on changing the underlying data. When based on reliable fuel maps and weather data, many FARSITE simulations under-predict fire growth and behavior. The approach to improve simulation accuracy has been to adjust the data: reduce canopy base height, increase canopy bulk density, increase wind speed, etc. Unless there is specific evidence of a data accuracy problem, adjusting the data to suit the model is not the best approach to calibration. Instead, the fire modeling community should focus on adjusting parameters in the fire model itself. Few such adjustment factors currently exist in geospatial fire models, especially the emerging FSPro and FSIM.

Conclusion

LANDFIRE has done an admirable job integrating emerging fuel and fire modeling technologies into their mapping efforts. Given the large extent of the project, high inherent spatial variability of the characteristics being mapped, emerging (and sometimes contradictory) nature of the fuel and fire modeling technologies involved, and time constraints, no better map products could have been produced. More accurate, seamless maps can be produced at greater cost and smaller scale than required by LANDFIRE's mission. Most remaining problems with LANDFIRE data for local-level projects can be addressed through a process of calibration and adjustment. Both FPA and LANDFIRE are funding the development of procedures for accomplishing that task.

Two significant problems can potentially be addressed by LANDFIRE. First, LANDFIRE can explore whether the new canopy cover estimation techniques developed for recently placed FIA plots can be used to generate a LANDFIRE-produced forest canopy cover map to replace the inherited NLCD maps. The adjustment of this map will significantly improve fire modeling by facilitating better estimates of wind adjustment and dead fuel moisture, both of which depend on forest canopy cover. Second, in an effort to reduce data discontinuities caused by seamlines, LANDFIRE can consider strip-based mapping for any future efforts (as opposed to the present zone-base). LANDFIRE mapping for Alaska is already planning to use strip-based approach, and will serve as a good test of that approach.

Abstract: While the use of timber harvests is generally accepted as an effective approach to controlling bark beetles during outbreaks, in reality there has been a dearth of monitoring to assess outcomes, and failures are often not reported. Additionally, few studies have focused on how these treatments affect forest structure and function over the long term, or our forests' ability to adapt to climate change. Despite this, there is a widespread belief in the policy arena that timber harvesting is an effective and necessary tool to address beetle infestations. That belief has led to numerous proposals for, and enactment of, significant changes in federal environmental laws to encourage more timber harvests for beetle control. In this review, we use mountain pine beetle as an exemplar to critically evaluate the state of science behind the use of timber harvest treatments for bark beetle suppression during outbreaks. It is our hope that this review will stimulate research to fill important gaps and to help guide the development of policy and management firmly based in science, and thus, more likely to aid in forest conservation, reduce financial waste, and bolster public trust in public agency decision-making and practice.

---

1. Introduction

Insect outbreaks are increasing in size and severity on a global scale [1]. In North America alone, three massive insect outbreaks occurred within the last two decades, all involving native bark beetles in conifers [2]. Of these, the mountain pine beetle (*Dendroctonus ponderosae*) outbreak is an order of magnitude larger than any previously recorded. A variety of factors, natural and anthropogenic, converged to result in these dramatic events [2]. Each outbreak has not only had severe ecological effects, but each has also triggered human responses that, for better or for worse, have resulted in additional impacts along with massive expense [3]. Predictions are that outbreaks of bark beetles will become more frequent and severe in the future [4,5] indicating an imperative need to critically assess the efficacy and impacts of our approaches to their management.

Outbreaks of bark beetles are not new. They have been occurring for millennia and have played a major role in shaping coniferous forest ecosystems of the world. While considerable research has been conducted on controlling bark beetles, massive gaps in knowledge remain. In particular, there is a disturbing dearth of rigorous replicated empirical studies assessing the effects of various management strategies, particularly timber harvest treatments, for bark beetle outbreak suppression. Even fewer studies have focused on how such treatments meet explicit goals or affect forest structure, function and future outbreak dynamics [6]. Particularly pertinent at this time, there is a lack of information to address forest adaptation to climate change in light of increasingly "out of historic norm" behavior of bark beetles. Despite this, there is a widespread belief in the policy arena that timber harvesting is an effective and necessary tool to address beetle infestations. That belief has led to proposals for, and enactment of, significant changes in federal environmental laws to encourage more timber harvests. Our question is, does that belief have a sound grounding in current science?

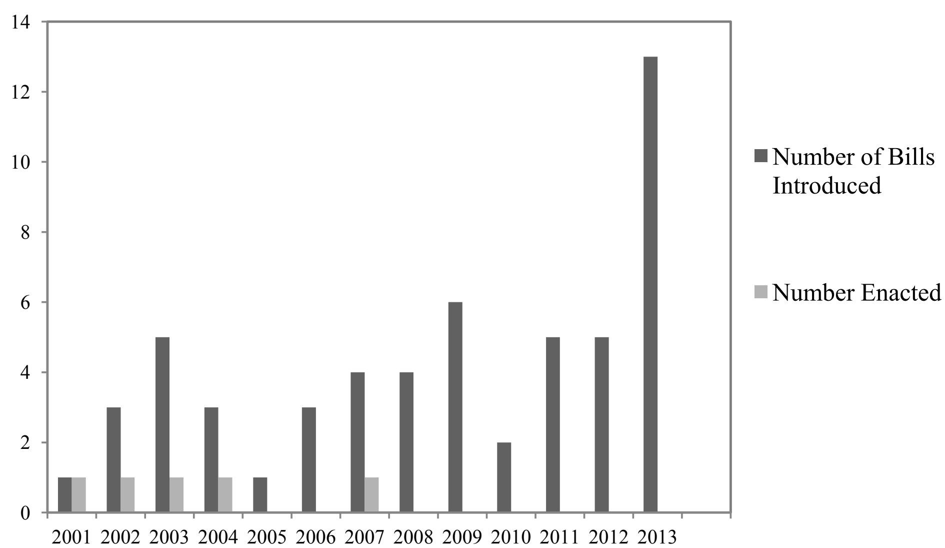
In this review, we focus on mountain pine beetle as an exemplar to critically evaluate the state of science behind the use of timber harvest treatments for bark beetle suppression during outbreaks. The mountain pine beetle was chosen because it is the most studied, most intensively managed, and most aggressive of the irruptive bark beetles. It has also responded strongly to climate change, resulting in a recent massive outbreak of unprecedented size that, in turn, has initiated numerous human responses, mostly involving implementation of timber harvests. It has also initiated many policy changes with many more currently in the pipeline.

We begin with an overview of the current policy situation. We then briefly review the biology of mountain pine beetle to form a foundation for understanding the factors that initiate and maintain outbreaks and how anthropogenic factors are contributing to current problems. We then describe the primary timber harvest treatments used to suppress bark beetle outbreaks and examine how well relevant science and ecological principles support their use. We conclude with a discussion on how well policy reflects the actual state of current science and identify where significant gaps between science and practice occur particularly in light of climate change. We also discuss the need to use advanced tools, including genetics and remote sensing, to adapt old practices to new situations-particularly in the realm of climate change adaptation. It is our hope that this review will stimulate research to fill important gaps and to help guide the development of policy and management firmly based in science, and thus, more likely to aid in forest conservation, reduce financial waste, and bolster public trust in public agency decision-making and practice.

2. The Current Policy Situation

There have been many recent proposals to streamline, reduce, or eliminate perceived legal obstacles to implementing timber harvests to address beetle epidemics on federal public lands (Figure 1). Between the 107th Congress (January 2001) and the 113th Congress (present), we found 55 bills that were introduced where at least one goal of the legislation was to increase timber harvests in order to respond to beetle infestations (Figure 1). Most of these proposals focused on the US Forest Service, which manages the majority of forests on federal public lands.

Figure 1. Number of bills involving timber sales that included bark beetle control that were introduced and/or enacted from 2001 to 10 July 2013.



Some of these proposals have been enacted. By far, the most important legal change has been the Healthy Forest Restoration Act of 2003 (HFRA). HFRA reduced the level of environmental analysis required for certain timber projects under the National Environmental Policy Act (NEPA), specifically by limiting the number of alternatives that the Forest Service was required to analyze. It also significantly restricted the ability of members of the public to challenge certain timber projects in court (by making participation in the agency's administrative process a precondition for filing suit). Further, it sought to streamline the Forest Service's internal administrative process for considering citizen challenges to certain timber projects. HFRA applies nationally to all National Forest System and Bureau of Land Management lands, and has resulted in forest treatment projects on an average of 220,000 acres of federal land per year since its enactment [7]

HFRA authorizes this streamlined process for timber projects on "Federal land on which…the existence of an epidemic of disease or insects, or the presence of such an epidemic on immediately adjacent land and the imminent risk it will spread, poses a significant threat to an ecosystem component, or forest or rangeland resource, on the Federal land or adjacent non-Federal land" [8,9].Moreover, while other types of HFRA projects in old growth forests are subject to limitations intended to protect old growth structure and large trees, timber projects to address insect epidemics can occur in old growth forests without those limitations [10,11].

HFRA also sets up a special experimental management process to develop better management methods for beetle infestations. After a long list of findings by Congress about the risks of beetle infestations in US forests, Congress authorized up to 250,000 acres of "applied silvicultural assessment and research treatments" on National Forests that would be categorically excluded from NEPA; these treatments could include timber harvesting [12,13]. HFRA section 401(b)(3) [14] requires that these applied silvicultural assessments and treatments must be peer reviewed by non-agency scientists.

HFRA is not alone. Another enacted bill created exemptions from environmental laws to allow timber harvest projects in a geographically limited area. As part of a massive supplemental appropriations act to address recovery from the September 11, 2001 terrorist attacks, Congress exempted a series of timber harvest projects in the Black Hills of South Dakota from any and all environmental laws; the law specifically stated that the projects were intended to reduce both fire risk and beetle infestations [15].

Other recent enactments create additional incentives for timber harvests intended to address beetle infestations. Congress permitted state forestry agencies to perform beetle control timber harvest projects on federal lands in Colorado and Utah under what is called "Good Neighbor Authority" [16]. These state forestry agencies must also implement "similar and complementary" services on state land adjacent to federal land in order to use the authority. Additionally, in the 2008 Farm Bill, Congress expanded subsidies for the production of "renewable biomass" energy to include timber produced from projects intended to reduce or contain disease or insect infestation [17].

There have been many more recent proposals for additional changes. Congress has considered multiple bills to expand the scope of HFRA. One proposal would require the Forest Service to implement at least one insect and disease control pilot project in at least one subwatershed in every national forest in a state that is "subject" to an insect or disease epidemic [18–24].Congress has also considered many other changes to encourage timber harvesting to control beetle infestations besides expanding HFRA. Some proposals would expand the exemptions to the Forest Service's Roadless Rule (which prohibits commercial timber projects and road construction in unroaded areas of National Forests) in order to allow more timber projects that are intended to address beetle infestations; some of these projects would be exempt from judicial review [25–27].

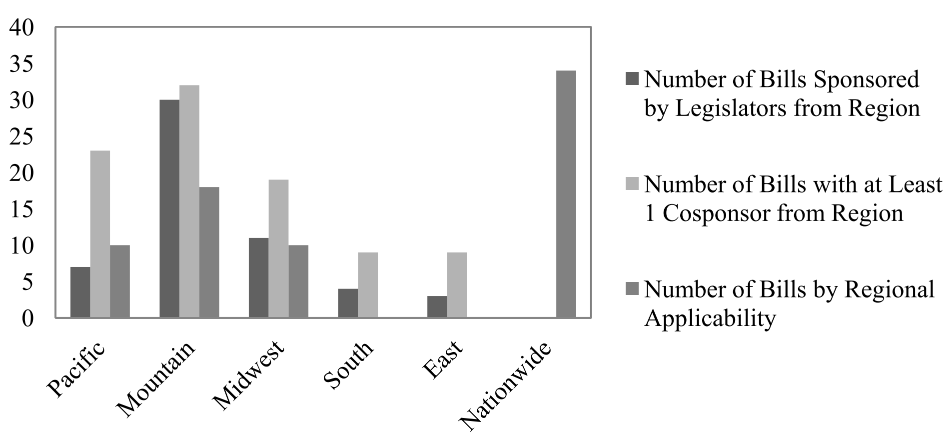
Congress has considered giving additional benefits under the Clean Air Act for "renewable biomass" produced from timber projects on federal lands, including projects intended to control beetle infestations [28,29], giving grants and other subsidies for beetle control timber projects [30], extending the Good Neighbor Authority to more states [31–33], and reducing or eliminating the fee that private timber contractors pay for timber contracts in exchange for agreements to implement restoration work, such as culvert removals, road improvements, or invasive weed removal, if the project provides insect control and other forest management benefits [26]. Finally, two bills have proposed that designation of additional federal lands as protected wilderness be paired with exemptions of beetle-related timber projects from environmental laws [34,35].

Throughout this policy debate, members of Congress and major stakeholders have regularly stated that timber harvest on federal lands is a necessary component of efforts to fight beetle infestations and control outbreaks and that additional flexibility under environmental laws is necessary for agencies to pursue these timber harvest projects [36–41].

Likewise, the U.S. Forest Service and other U.S. federal land management agencies have prescribed timber harvests as a necessary component of beetle control. For example, the Forest Service's Western Bark Beetle Strategy calls for the agency to "reduce the number of trees per acre and create more diverse stand structures to minimize extensive epidemic bark beetle areas" by using thinning and other harvest treatments [42]. While the Forest Service has applauded HFRA as "very helpful" in addressing beetle outbreaks (U.S. Forest Service, Review of the Forest Service Response: The Bark Beetle Outbreak in Northern Colorado and Southern Wyoming, September 2011), available at [43], agency leaders do not look favorably upon all legislative proposals to weaken environmental laws to facilitate timber harvest for beetle control. For example, Tom Tidwell, Chief of the Forest Service, criticized recent bipartisan legislation [25] because it would "shortchange the environmental review process, cut out public engagement and collaboration…and override roadless protections." (Testimony from House Subcommittee on Public Lands and Environmental Regulation Legislative Hearing on H.R. __, H.R. 1294, H.R. 818, H.R. 1345, H.R. __, and H.R. 1442 available at [44].

Given the geographic concentration of federal public lands in the West, most of the bills have a specific focus on western states, and were introduced or supported by westerners (Figure 2). But that is not universally the case. Two of the proposals to expand the scope of HFRA were sponsored by Representative Markey, a Democrat from Massachusetts [19,23]. Moreover, support for these bills is bipartisan, showing that the belief that timber harvest can address beetle infestations crosses the political spectrum. Of the 55 total bills, 17 were sponsored by Democrats alone, 21 sponsored by Republicans alone, and 17 had bipartisan sponsors. Markey himself has received very high ratings from the League of Conservation Voters, with a 94% lifetime score from the group.

Figure 2. Bill sponsorship, co-sponsorship, and applicability by region. (Pacific = CA, OR, W, AK, HI; mountain states = MT, ID, NV, WY, UT, CO, AZ, NM; Midwest = ND, SD, NE, KS, MN, IA, MO, WI, IL, IN, MI, OH; SOUTH = TX, OK, AR, LA, KY, TN, MS, AL, GA, FL, SC, NC, VA, WV; east = ME, NH, VT, MA, NY, RI, CT, NJ, DE, MD, PA).



The 55 bills introduced since 2001 show that many legislators, particularly those from western states, believe that timber harvests are a necessary tool to address beetle infestations. This belief has led to the enactment of laws that reduce compliance burdens under NEPA and other federal environmental laws. There are many more proposals for additional significant changes to federal environmental laws to encourage more timber harvests for beetle control. While "there is certainly a tremendous amount of social and political pressure to 'do something' about beetles," there is also growing concern by many that timber harvests for beetle control are expensive and ineffective and that long-term impacts on forests are unknown [42 citing Ann Merwin, director of policy and government affairs for the Wilderness Society]. The policy debate demonstrates the need to critically examine how well these treatments work and place policy in the context of the best available science.

3. A Mountain Pine Beetle Primer

The mountain pine beetle is native to pine forests in western North America [45]. During outbreaks, it can kill millions of trees across extensive areas. The ability to cause such widespread mortality has led it to be described as the most destructive forest pest on the continent [46]. Indeed, economic and aesthetic impacts of outbreaks can be severe. From a manager's perspective, outbreaks are often perceived as a symptom of poor "forest health", while ecologists more often view outbreaks as natural ecological processes integral to the maintenance and resilience of the forest. These differing human perceptions have led to conflicting and ambiguous management goals as well as scientific, social, and political conflict.

The mountain pine beetle is polyphagous on pines (*Pinus*) [45]. It attacks not only native pines but also exotic pines used in ornamental landscaping. Within the natural range of the beetle, only *P. jeffreyi* appears to be avoided, likely due to its unusual chemistry [45]. Pines are well defended and are not easy targets for the beetle. They produce constitutive defenses consisting of resin that can flush the tiny beetles from trees, often drowning them [47–49]. Pines also produce induced defenses in the phloem comprised of resin containing elevated concentrations of toxic monoterpenes [49,50]. Induced defenses develop in response to attack, and thus, involve a lag time of one or more days to develop and can last for a month or more even when trees are killed [51].

To contend with a defensive host, the mountain pine beetle has evolved a complex chemical communication system it uses to coordinate a mass attack on a tree [52]. A female beetle will land, begin to tunnel, and release an aggregation pheromone that attracts conspecifics of both sexes to the tree. Subsequent arrivals release additional pheromone increasing attraction to the tree [53]. If enough beetles respond, the tree can be overwhelmed in just a few days. As defenses are depleted, the beetles release an anti-aggregation pheromone which repels late arriving beetles and acts to reduce intra-specific competition among brood [53]. At this point, the tree has reached "a point of no return" [54]. It will not recover and will slowly die, although it may remain green for nine months or more due to translocation of water to needles by capillary action in the xylem.

The number of beetles needed to kill a tree varies and depends, in part, on the strength of its defenses [55]. In general, as the strength of defenses increase so does the number of beetles needed. Several factors influence the strength of tree defenses. Trees weakened by drought, disease or damage can be overwhelmed by only a few hundred beetles while very vigorous trees may require many hundreds or even thousands [56]. Genetics of the host tree also play an important role. Within a tree species, different genotypes result in differing levels of resistance and susceptibility [57,58]. Genetic differences are even more pronounced when considering differences in defenses among *Pinus* species [59,60].

The ability of tree defenses to affect mountain pine beetle success varies by whether the beetle is in endemic (non-outbreak), incipient (building) and eruptive (outbreak) phases. During the endemic phase, when beetle populations are low, host tree defenses are the major constraint in the ability of beetles to kill trees. However, tree defenses become inconsequential once the threshold to the incipient stage has been surpassed [61]. When numbers are low, beetles attack smaller diameter trees with low defenses. However, once populations rise to the incipient stage, beetles choose larger, healthier, resource-rich trees, despite their superior defenses [61]. Because larger trees have thicker phloem resources to support larval development, they support greater beetle productivity which results in positive feedback that helps fuel the expansion of the outbreak. Thus, host tree traits (primarily host defenses and diameter class) that determine which trees are killed when populations are low, may be unimportant or even have an opposing effect on beetle success when populations are high [61].

It is often reported in the press that mountain pine beetle populations are cyclical. This is not the case. The population dynamics of insects that develop cyclical outbreaks are typically dominated by *delayed* negative density dependent feedback involving regulation by natural enemies and induced resistance mechanisms [62]. This type of feedback results in predictable intervals (cycles) between outbreaks although the amplitude of population peaks can vary due to spatiotemporal variation in abiotic conditions. Bark beetle dynamics, instead, are driven by alternations of negative density dependent and positive density dependent feedbacks resulting in sporadic unpredictable population eruptions primarily driven by threshold effects and typically triggered by abiotic factors, particularly climate [61–63]. It is critical to distinguish between cyclical and eruptive population dynamics as insects exhibiting these two types of dynamics demand different management and monitoring approaches. In particular, eruptive dynamics are triggered by abiotic factors typically outside the realm of human manipulation.

Mountain pine beetle can remain in non-outbreak phase for very long periods of time, even when forests are composed of suitable age classes of host trees and in a condition often considered to be highly susceptible and "unhealthy". Outbreaks occur *only* when multiple thresholds involving temperature, tree defenses, and brood productivity are surpassed that allow positive feedbacks to amplify across several scales [2,64]. While outbreak development is complex, the primary elements that must exist are an abundance of suitable hosts *and* a trigger [63]. Triggers for mountain pine beetle that allow population amplification and subsequent widespread outbreak initiation are warm temperatures and drought, conditions that often co-occur [65]. There can also be a substantial lag period, even several years, from the initiation of the abiotic factors that trigger an outbreak to when populations actually amplify [65,66]. However, once a threshold number of beetles is surpassed, the outbreak becomes self-perpetuating.

While forest conditions alone do not cause outbreaks, certain forest conditions can support larger and more severe outbreaks once they are initiated. Mountain pine beetle attacks only pines (except in rare instances where it "bleeds over" into spruce) [67], and typically only those larger than ca. 15 cm in diameter [68]. Therefore, forests comprised mainly of large diameter pine can be at higher risk of widespread mortality when a trigger occurs than are forests comprised of young, small diameter pine or composed of a mix of tree species including non-pines [68]. Processes that homogenize forest structure and composition such as abnormally widespread stand replacement events (e.g., fires of 1910, Yellowstone 1988) or particular types of forest management (e.g., some timber harvest practices, fire suppression) that alter forest composition and structure over large areas, can contribute substantially to the extent and severity of an outbreak once it is initiated. Processes that result in heterogeneity, such as "normative" wildfires and bark beetle outbreaks, and some land management practices (e.g., restoration treatments focused on restoring a mosaic structure of forest stands of different age classes) tend to reduce outbreak severity and extent by reducing the amount of contiguous susceptible hosts [68].

Climate acts as a trigger for mountain pine beetle outbreaks for a very good reason. Like all insects, mountain pine beetle is poikilothermic-it cannot regulate its body temperature, and thus, all its metabolic rates and vital functions are dependent upon the temperature of its environment [69]. As temperatures rise, feeding, activity, development and reproductive rates increase. Importantly, this also means that the length of the mountain pine beetle life cycle is determined by temperature [69]. Under optimal thermal conditions, development is univoltine (one year). A univoltine cycle allows synchronized emergence of brood adults in mid-late summer, supporting not only mass attacks, but also attacks at a time that allows subsequent offspring to enter winter as cold-hardened larvae [70,71]. Cold hardening is a gradual process that occurs as temperatures fall in autumn. Once larvae are cold hardy it can take temperatures as low as −40 °C to kill significant numbers [72]. However, cold air incursions in fall when beetles are not yet cold hardened or in spring when larvae have lost cold hardening in preparation for transitioning to the adult stage can result in widespread mortality. This can halt an outbreak if subsequent conditions are no longer favorable for the beetle. However, if favorable conditions return, beetle populations rebuild. Importantly, outbreaks require a univoltine life cycle combined with moderate winter temperatures [73].

In areas where temperatures are too cool to support a univoltine life cycle, a semivoltine (longer than one year) life cycle occurs [73]. A semivoltine life cycle is maladaptive for the beetle in several ways. First, adaptive seasonality is disrupted, increasing the percentage of brood that enter winter in stages vulnerable to freezing (eggs, pupae and adults). Additionally, mortality increases when beetles must pass through two winters and feed on a food source increasingly depleted in moisture, nutrients, and symbiotic fungi [74]. Warm periods support not only greater brood production and survival in areas typically suitable for the beetle, but also allow a transition from a semivoltine to a univoltine life cycle in areas otherwise too cool. This increases the spatial extent of suitable habitat and tree mortality. Thus, abnormally warm periods can vastly increase the total area suitable for the beetle and play a major contribution to the synchronicity and coalescence of outbreaks across regions [2,65].

Drought can also play an important role in outbreak initiation. Host tree defense mechanisms are compromised during drought allowing beetles to more easily attack trees [2,75]. Tree defenses are major constraints when beetles are in non-outbreak phase. However, drought-weakened trees can support population amplification until a point where stand level densities surpass a critical threshold. Once this threshold is passed, tree defenses lose their importance in regulating beetle populations [61]. Very importantly, drought stresses large numbers of trees at a regional scale. This results in large numbers of trees that are easier for the beetles to kill, further supporting outbreak intensification [65,76].

Recent studies have found that drought occurring years or even decades before the outbreak can influence outbreak initiation. Furthermore, prolonged drought stress appears to pre-condition trees to be more susceptible, an effect that can continue for years after normal precipitation has returned [58,65,77]. There also appears to be a genetic component to tree sensitivity to drought, and subsequently, susceptibility to beetles. In two studies, one conducted in whitebark pine and the other in ponderosa pine, differences in growth of surviving trees and trees killed by beetles over the last century suggest that adaptive differences to changes in climate exist. In the whitebark pine study, the trees studied were co-dominants and not significantly different in diameter age or mean growth over their lifetimes [58]. However, trees that were killed exhibited faster rates of growth in the first half of the century suggesting they were better adapted to the cooler wetter conditions of that period. The surviving trees had greater growth in the latter half of the century when conditions were warmer and drier. Millar *et al.* [58]) suggested that the beetle-caused tree mortality in the stands they studied resulted in a strong natural selection event that removed trees less fit under our current climate while leaving those more well-suited.

Likewise, Knapp *et al.* [77] found genotypes of ponderosa pine that were slow-growing in the two to three decades prior to the outbreak were much more vulnerable to beetle infestation than those that were fast-growing, again suggesting the beetle may act as a selective agent shifting genetic structures in stands over time to those most suited to prevailing climatic conditions. In lodgepole pine, trees of similar age and diameter growing intermixed in the same stand and under the same conditions exhibited different levels of sapwood moisture that were highly correlated with susceptibility to beetle attack [74] hinting at genetic differences in water efficiency. Those with lower sapwood moisture were attacked and killed by the beetle while those with higher sapwood moisture were not [74].

While mountain pine beetle has developed outbreaks for millennia, the current outbreak is far outside the historic norm [2,78]. The unprecedented size and severity of this outbreak is due to a combination of increasingly favorable climate for the beetle and forest conditions. Warming trends have supported the development of a univoltine cycle in many areas that previously were too cool and have resulted in greater beetle productivity and survival [79]. This has led to massive tree mortality, not only in areas previously favorable for the beetle, but also in areas previously suboptimal or unusable. Warmer temperatures and high population levels have also supported expansions of the beetle's range hundreds of kilometers further north in British Columbia and eastward across Alberta [80–82]. In these new locations, the beetle is infesting naïve hosts including (in the eastern expansion) a novel species, jack pine [80,82]. These naïve hosts exhibit lower defenses to beetle attack [83] as well as similar chemical compositions to natural hosts [84] promoting establishment. Predictions are that the beetle will continue to move across the continent through the boreal forest and finally into eastern pine forests [78].

Warming has also allowed the beetle to move higher in elevation where it is devastating whitebark pine, a tree that is foundational to the western North American subalpine ecosystem and that was previously protected from the beetle by cold [73,85]. Movement into the subalpine has been supported by overall warmer temperatures and milder winters allowing the beetle to switch from a semivoltine to a univoltine life cycle while simultaneously reducing winter mortality [85–87]. The resulting mortality to whitebark pine in many areas, particularly the greater Yellowstone Ecosystem, has been so severe the tree is now proposed for listing as an endangered species [88]. The tree is already listed as an endangered species in Canada due to the combined effects of mountain pine beetle and white pine blister rust [89].

4. Mountain Pine Beetle Outbreak Suppression

Treatments used to mitigate the effects of mountain pine beetle are grouped into three broad categories. Treatments that strive to reduce or eliminate beetle populations are termed direct controls [90]. Treatments aimed at increasing tree vigor and altering stand conditions to be less favorable for beetles are called indirect controls [90,91]. Prophylactic treatments aim to protect high value individual trees or stands of trees from infestation. Salvage, while often included in beetle management programs does not actually reduce or impact beetle populations-it is the removal of dead trees for economic or other reasons and often involves removal of trees that are already ‘empty’ of beetles and thus has no impact on beetle population size. Because our focus is on how well science supports the use of timber harvests (including tree felling and destruction of trees in place) to reduce or suppress bark beetle outbreaks, we will focus primarily on direct and indirect controls concentrating on these treatments.

Direct control includes sanitation treatments such as removing single trees or small patches of trees that are infested with the insect, clearcutting (also called block harvesting) and prescribed burning of infested trees, as well as fell and burn, trap trees, debarking, and application of insecticides or toxins such as MSMA (monosodium methanearsonate). Sanitation cuts attempt to remove most or all beetles in an area by removing infested trees before the beetles developing within them can emerge and disperse [90,92]. Prescribed burns, fell and burn, debarking, and toxin applications attempt to destroy beetles in infested trees on-site. Trap trees are trees that are baited with attractant pheromone baits in an attempt to draw beetles into specific areas where they are concentrated into the baited trees which are subsequently taken to the mill or destroyed. Each of these methods relies on killing as many beetles as possible in order to lower beetle population thresholds below which they can maintain outbreak dynamics.

Indirect controls are primarily silvicultural in nature. The main treatment used for mountain pine beetle is thinning. Thinning is thought to act by reducing inter-tree competition for water, nutrients, and light, enhancing greater tree vigor, and thus defenses against the beetle [93]. Thinning treatments are also thought to reduce successful beetle attacks by altering microsite conditions by increasing temperatures on bark surfaces on bark in summer and decreasing them in winter, as well as disrupting beetle communication by increasing wind flow [94,95]. A new treatment recommended for reducing bark beetle infestation is “daylighting” which involves removing trees and shrubs from around trees that are to be protected to increase light on the tree’s stems to disrupt beetle colonization. Other silvicultural treatments include removal of beetle-suitable hosts (mature trees and old growth) and conversion of stands from species preferred by beetles (pines) to species that are not hosts or converting stands that are primarily pine to a mixed species composition [91,92]. Most of these approaches involve, completely or partially, the use of timber harvests.

4.1. Efficacy of Direct Controls

Direct control treatments are extremely expensive in time, effort and resources. They address only one aspect of an outbreak which is the amount of beetles present in a stand or area. Because they do not address the underlying conditions that support an outbreak (climate, tree condition/stress) their effects are considered a holding action until conditions shift to being less favorable for the beetle [92].

Direct control efforts must be maintained at a high level on an annual basis until the outbreak ceases [3,90,96]. It is highly controversial whether direct controls are effective in reducing tree mortality in the short-term, and if they can be effective in halting or suppressing outbreaks in the long-term.

One of the biggest problems in assessing the utility of direct controls is a general lack of monitoring or *post hoc* assessments of the outcomes of implementing these practices. Despite decades of direct control and large-scale implementation of these practices, few rigorous studies on its efficacy have been done and there remains no agreement among scientists or foresters regarding its ability to reduce beetle populations or losses of trees. Studies conducted prior to the current outbreak have variously concluded that direct treatments may merely act to delay infestation of susceptible stands [97], or that if used correctly, can be effective [98,99]. Many studies found that while some treatments slowed the rate of infestation, overall, they had little to no impact on mountain pine beetle populations [97,100–104].

The US and Canadian governments have spent hundreds of millions of dollars in direct control efforts to address the current outbreak. However, assessments of the efficacy of these efforts are nearly non-existent and only a few studies on assessments have been published. The few that have been published are reviewed here. Although much of our review addresses how well science supports US policy, we use primarily studies conducted in Canada as few studies have been published on direct control measures during the current outbreak in the US.

Nelson *et al.* [3] evaluated the efficacy of five direct control treatments in British Columbia roughly midpoint in the portion of the current outbreak as it progressed in that province. The assessment was extremely short-term and looked only at the response of beetles in the year immediately post-treatment. However, it provides one of the very few broadscale assessments ever conducted of the efficacy of direct controls during an outbreak. The treatments assessed were applications of MSMA, trap trees, fell and burn, and clearcutting. The study was split into three geographic regions to account for potential sources of variability due to location and different background levels of beetles. The northern-most region was at the margin of the beetles range (expansion zone) and possessed relatively low beetle populations, while the central and southern regions had higher beetle populations and were known to have supported high beetle populations historically. The study found that, overall, sites receiving MSMA treatments exhibited higher infestation intensities (a metric based on kernel density estimators) than randomly selected untreated sites with similar characteristics. This was particularly pronounced in the southern region. Results for trap tree treatments showed substantial variability within and among regions. A reduced infestation rate in response to treatment was observed more often than not in the northern area where beetle pressure was low. However, in the central and southern regions where beetle pressure was higher, the range of infestation intensities was similar for treated and untreated sites although a larger number of comparisons found higher infestation intensities in the treated sites. The overall conclusion was that MSMA and trap tree treatments may be effective, but not reliably, and only when beetle pressure is low and environmental conditions are not highly favorable for the beetle.

Results for fell and burn were also variable. In the northern region, intensities were lower overall in treated *vs.* untreated sites. However, in the central area, treated areas tended to have greater infestation intensities. In the southern area, no discernible effect of treatment was seen. Therefore, like with trap trees, fell and burn appeared to sometimes be effective, but only when populations of beetles were low, and became increasingly unreliable as beetle pressure increased and the infestation moved into outbreak phase.

Removal of trees in patches was studied only in the central region. No significant effect of treatment was detected. Clearcuts were assessed in the central and southern areas and were found to lead to a significant reduction in infestation intensity. In almost all cases, infestation intensities were lower in treated *vs.* untreated areas. However, this was likely due to the removal of all living trees (potential subsequent hosts) that survived the beetle as well as the infested trees. The overall conclusion of the study was that mitigation treatments are effective when populations are low to moderate and if infested trees can be kept to 2.5 or fewer per hectare. Efficacy was also recognized to be contingent upon a high level of accuracy in detecting infested trees and wide-scale and continuous implementation of treatments. However, with only one year of data, the authors could not predict how long treatments would need to be sustained to remain effective, nor what effect beetle pressure from surrounding areas might have on the subsequent fate of treated stands. No follow up study has been published to report how these treatments fared as the outbreak progressed.

Fell and burn has been a stalwart component of the direct control efforts against mountain pine beetle in Canada during the current outbreak, particularly on the advancing front as the beetle expands its range eastward. Coggins *et al.* [105] examined the efficacy of fell and burn treatments to "stabilize" such infestations (*i.e.*, prevent expansion) using field plot data from sites at the expanding edge of the mountain pine beetle infestation in 2008 in eastern British Columbia and western Alberta. The authors used multiple modeling scenarios along with ground data to demonstrate how infestations may develop with and without mitigation, and to predict how long mitigation may need to be maintained to be effective given different levels of infestation and detection accuracy. They found non-mitigated plots experienced more tree mortality due to the beetle and that infestations in these plots expanded more rapidly. The higher the expansion factor (means rate of increase, e.g., 2 would indicate a doubling of the population each year) the greater the detection accuracy that was required to maintain a static population. When a beetle population had an expansion factor of 5.1 (high), an 80% detection rate was required, whereas with a population with an expansion factor of 1.1 (very low), the minimum detection rate could be as low as 10% and still be effective. The authors also modeled how long it would take to achieve population stability given different levels of infestation. On average, across their stands, with a 70% detection accuracy rate, mitigation would take 11 years, at 80% 6 years, and at 90% 3 years. The actual mean mitigation efficiency at their sites was found to be 43%, a level at which no control could occur. They concluded that the stabilization of mountain pine beetle populations is possible, but only with a much higher detection accuracy than commonly occurs coupled with an intense level of mitigation maintained potentially over a very long timeframe.

Wulder *et al.* [96] looked at the effectiveness of sustained mitigation on slowing the beetle's expansion in western Canada. The results were difficult to assess because of the unevenness of application of mitigation treatments (for example, in one year only 68% of sites slated for mitigation were treated) and differences in background beetle populations. However, such a situation is typical and thus may represent the reality of many on-the-ground direct control efforts. One site where little mitigation was conducted early on, did exhibit a strong increase in tree mortality due to the beetle that declined once extensive mitigation efforts were implemented. However, overall, the conclusion was that mitigation must be extensive and continuous to work and may only be effective when populations are low to moderate.

Trzcinski and Reid [104] studied the trajectory of beetle populations in treated and untreated zones in Banff National Park from 1997–2004. The Park used a combination of pheromone-baited trees and fell and burn to remove as many beetles as possible from treatment zones—they also conducted prescribed burns to reduce beetle numbers and lodgepole pine hosts. The area colonized by the beetle increased rapidly over this time period in both the untreated and treated zones. After four years of treatment, control measures did not reduce the area affected by beetles and infestations continued to expand at a similar rate in both zones. The authors estimated that between 45% and 79% of infested trees had failed to be detected in the treated areas. This equated to *only* 0.7–3.7 infested trees remaining per thousand ha yet still was sufficient to support subsequent rapid beetle population growth.

A general consensus of these studies is that suppression of a beetle outbreak would require massive sustained efforts with extremely high detection rates to succeed. It has been estimated that 97.5% of beetles in an area must be killed to merely stabilize a mountain pine beetle population [90]. Even a small increase in survival above this value can allow a substantial increase in population size. For example, if mortality drops to 95%, this would allow a population to *double* in size annually. If the goal is not just to stabilize a population, but to reduce it, mortality of beetles would need to be higher than 97.5%, a goal that is highly unlikely given the vast areas that would need to be treated on a continual basis when conditions are favorable for outbreak development. Even if 100% removal of infested trees from an area was feasible, the migration of beetles into treated stands from surrounding areas allows reestablishment and subsequent tree mortality further decreasing the potential for effective direct control.

The on-the-ground reality is that direct control efforts typically fall far below the levels needed to stabilize, let alone control, mountain pine beetle populations. In the above cited studies, rates of detection in mitigated stands ranged from 45%–79%. These situations are not unusual. Direct control treatments are laborious, extremely costly and time consuming, and require high levels of training. Logistical difficulties, including proper seasonal timing, access, inclement weather, and lack of trained personnel, increase the odds that they will not be effective. The high financial cost of such efforts coupled with a volatile market for sawtimber, pulp and pellets further complicates the use of direct controls. Importantly, outbreak development is extremely swift and the amount of mitigation required can rapidly outstrip the ability of managers to respond.

During an outbreak the number of trees killed annually is often in the millions and infestations may cover hundreds of thousands of hectares [90]. Carroll *et al.* [90] presents an example of the degree of mitigation that would be required for an outbreak that covers 300,000 hectares with a rate of increase of 2 (the population doubles in one year-a conservative rate for an outbreak). In this case, 150,000 ha of infested trees would need to be removed each year just to maintain a *static* beetle population–this would still allow tree mortality to occur for many years, potentially until most or all mature trees were killed. In reality, such a high level of detection and mitigation is impossible. Given that the goal of direct management is to reduce populations and protect trees, the effort that would be needed to actually reduce such a high beetle population would require an even more unlikely effort.

Studies in other bark beetle systems also have found that a high degree of detection accuracy and intensity of mitigation is required to reduce beetle numbers. Fahse and Heurich [106] found that control of *Ips typographus*, a less aggressive European bark beetle, requires a detection and removal level of around 80% to be effective. They concluded that direct control efforts are useless and should be dropped if survival probabilities of the beetle after treatment are above 20%–30%. This estimate is in line with those developed in studies on mountain pine beetle in North America and highlights the challenge the high reproductive capacity of bark beetles poses when conditions are favorable for outbreak development.

It is not just the difficulty of dealing with the extreme spatial extent of outbreaks and the challenge of detection and treatment that makes the efficacy of direct control measures unlikely, but also the time frame over which direct controls must be maintained. Carroll *et al.* [90] estimated that to control a population involving 10,000 infested trees with expansion factor of 2 (conservative) and with a detection and removal rate of 80% (difficult), it would take at least 10 years of annual treatment to reduce the population to a single tree. If the population was tripling or quadrupling, a more likely scenario during an outbreak, it would take 18 or 41 years, respectively. A costly, intensive detection and treatment program lasting that long, assuming sufficient trees even remained to be infested, would be unlikely [90].

Carroll *et al.* [90] emphasized three requirements for direct controls to be effective in treating *individual* infestations: infestations must be detected early, efforts must be applied quickly and intensively, and control programs must be maintained continuously until the desired population level is achieved. Because of the cost and intensity of treating individual infestations, the US Forest Service recommends that direct control measures only be applied to higher value stands [92]. However, treating individual infestations or stands during outbreaks can fail because of the regional nature of outbreaks. Outbreaks are driven by abiotic factors that affect entire regions (warm temperatures and drought). Thus, they consist of many infestations that occur synchronously across a very large area. These infestations often coalesce to form vast expanses where beetle populations are extremely high. These characteristics mean that many stand level efforts are prone to failure due to high beetle pressure and migration into treated areas by beetles from surrounding areas. Given that treating entire regions is impossible, and that many treatments are not in line with other land use objectives, direct control efforts may in some cases, not be worth their costs. The consensus of studies and retrospectives over the course of several outbreaks is that even after millions of dollars and massive efforts, suppression using direct controls has never been effectively achieved, and at best, the rate of mortality to trees was reduced only marginally [90,101,102,105]

4.2. Efficacy of Indirect Controls

Thinning is the primary indirect control measure used to manage the mountain pine beetle. It is generally considered a preemptive measure to be implemented prior to the initiation of a mountain pine beetle outbreak, although it is increasingly employed to reduce damage by the insect during outbreaks. It is often touted as a global panacea for problems with pest bark beetles. One type of thinning is even termed “beetle-proofing” [107], further reinforcing the view among managers, the public, and policy makers, that this approach is failsafe. While overall, evidence suggests that thinning can reduce mortality of trees due to mountain pine beetle, the outcome is frequently more variable than is often recognized or reported. This is particularly true when outbreak populations are involved.

So how exactly does thinning work, and how well does thinning hold up under outbreak conditions? Surprisingly, the mechanism(s) by which thinning affects beetle activity in forest stands is still not well understood. Two, non-mutually exclusive, lines of thought exist. One hypothesis is that thinning increases tree vigor, and thus tree defenses, by reducing competition among trees for light, nutrients and water [93,108]. Intuitively, this makes sense, and indeed, immediate impacts of thinning on reducing water stress have been seen [109]. Likewise, increases in growth and photosynthetic rates also have been observed post-thinning, albeit after a lag period of one or more years [107,109,110]. Increases in growth and vigor are predicted to increase the amount of energy that trees allocate to defense, leading to greater resistance to beetle attack through increased resin and monoterpene production. In fact, the initial impetus for the use of thinning to manage mountain pine beetle came from an early study that found that ponderosa pines in thinned stands produced more defensive resin [93]. However, subsequent studies have reported a variety of responses in resin production as well as growth in response to thinning. For example, Zausen *et al.* [111] found that ponderosa pines in the thinned stands exhibited lower water stress but also produced less resin. This, along with the thicker phloem (greater food resources) found in trees in thinned stands, indicates they might be not only more susceptible to attack but also a more productive resource for beetles. In contrast, McDowell *et al.* [112] found greater resin flow in thinned stands. Both studies were conducted in southwestern US ponderosa pine forests indicating that the variable responses observed were not due to major regional differences in hosts. Six and Skov [113], in a study conducted in ponderosa pine in the northern Rocky Mountains looking at effects of thinning and burning treatments, found that resin flow was highest in trees in burn treatments, intermediate in controls, and lowest in thinned treatments. Raffa and Berryman [114] tracked the fate of trees over time during an outbreak and found no significant difference between resin flow for lodgepole pines that survived attack vs those killed by the beetle.

A number of studies have noted a reduction in beetle caused-mortality of trees immediately after thinning treatments were applied and before trees had time to respond physiologically to lower stocking densities. This timing suggests that the effects of thinning may have more to do with microsite conditions than to changes in tree vigor or defense. These observations led to the second line of reasoning that thinning affects beetle activity through changes in microsite conditions.

Thinning alters temperature, light intensity and wind speed within a forest stand; factors that can have major effects on insect behavior and success. A number of studies have tried to describe how shifts in microsite conditions due to thinning may influence mountain pine beetle activity. Bartos and Amman [94] investigated how incident solar radiation, wind speed, wind direction and temperature were altered by thinning and whether changes affected beetle responses to stands. They did not conduct statistical analyses on their data; however, there was a trend for south sides of trees in thinned stands to be warmer, and ambient temperatures in thinned stands to be overall warmer during parts of the day. Incident solar radiation was higher in the thinned stand. It is not known if bark temperature affects beetle attack behavior, although higher temperatures on south sides of trees in thinned stands have been suggested to be deleterious to beetle development [94]. However, this speculation does not account for differences in local environmental conditions. For example, at cool sites, increased temperatures and insolation could ostensibly support better beetle development by increasing thermal units sufficiently to support a univoltine life cycle.

Light intensity affects the flight behavior of mountain pine beetles [115]. However, if and how different levels of light in treated and untreated stands affect beetle attack behavior is unclear. It has been hypothesized that a reduced propensity for flight in darker stands might concentrate beetles for mass attack, while beetles may be more likely to disperse in open stands [116].

The hypothesis that light has a strong effect on mountain pine beetle behavior, particularly in reducing attacks, has led to a new treatment called daylighting. This approach is currently being implemented on a broad scale by federal and western state agencies. Daylighting involves removing trees and vegetation from around trees that are targeted for retention and is believed to work by repelling beetles from the boles of trees by increasing light and solar radiation [117]. While widely recommended, the efficacy of this treatment is unknown; there are no published studies on its effects on bark beetles.

Changes in wind speed and direction due to thinning have also been suggested to alter beetle behavior by disrupting beetle communication via disruption of pheromone communication. Schmid *et al.* [118] found no statistically significant differences in horizontal and vertical wind patterns in thinned and unthinned stands. However, disruption of pheromone plumes by greater wind speeds may affect communication and thus the potential for successful attacks [95]. Ultimately, we need to look at actual population dynamics of beetles in treated and untreated stands to understand if microsite effects hold under epidemic conditions. MacQuarrie and Cooke [119] found that, under outbreak conditions, mountain pine beetle populations exhibited density-dependent dynamics and that thinning did not change the epidemic equilibrium. In this study, population growth curves did not exhibit responses that would be expected if microsite conditions played a role in beetle behavior. It is evident that more research is needed to understand how these effects ultimately influence tree mortality due to beetle attack.

While we may not have a complete understanding of how thinning works, it is clear that this practice can have a significant effect on mountain pine beetle infestations. Several studies have reported striking differences in mortality to trees caused by beetles in thinned *vs.* un-thinned forests (reviewed in [120,121]). In contrast, only a small number of studies have reported failures. However, the disparity in numbers of successes and failures must be placed within a broader context. Many studies assessing the efficacy of thinning have been conducted under non-outbreak conditions. Their results do not reflect how stands perform during an outbreak. Additionally, failures are often not reported, dismissed as a result of poor management 'next door' or targeted for management without evaluation. This is unfortunate because thinned stands that fail may have particular characteristics that could inform a better understanding and application of this approach.

Studies conducted during outbreaks indicate that thinning can fail to protect stands. In Colorado, thinning treatments in lodgepole pine implemented in response to the outbreak that began in the 90s often only slowed the spread. Klenner and Arsenault [122] reported high levels of mortality due to the mountain pine beetle across a wide range of stands densities in lodgepole pine in British Columbia during the same outbreak. They noted that silvicultural treatments were largely ineffective in reducing damage to the beetle. Preisler and Mitchell [123] found that once beetles invaded a thinned stand the probability of trees being killed there can be greater than in unthinned stands and that larger spacings between trees in thinned stands did not reduce the likelihood of more trees being attacked. Whitehead and Russo [107] reported on the performance of 'beetle-proofed' (stands thinned to an even spacing of about 4–5 m between mature trees) and un-thinned stands in five areas in western Canada during approximately the same time period. These treatments were successful in protecting stands when they were combined with intensive direct control measures (removal of infested trees) in the areas surrounding the thinned units, but failed if units were exposed to beetle pressure from the neighboring area—a situation most thinned stands experience during an outbreak.

Unfortunately, long-term replicated studies monitoring beetle responses to thinned forests from non-outbreak to outbreak to post-outbreak phase are virtually non-existent. One large fully-replicated long-term study was initiated in 1999 under non-outbreak conditions and continues to track beetle activity [113]. In this study, mountain pine beetle was low in all treatments in the period leading up to the outbreak, but increased in some controls and burn treatment replicates as the outbreak developed. Although more trees were killed overall in control units during the outbreak, all controls still retained a greater number of residual mature trees than did thinned stands as they entered the post-outbreak phase [124].

Two factors contribute substantially to our inability to assess how well thinning performs under outbreak conditions. One, very few thinning treatments are monitored after implementation over either the short- or the long-term. Thus, for the vast majority of stands that have been treated, we have no data on how well they perform once an outbreak of the insect initiates (or for that matter, even under non-outbreak conditions). Second, stands that become infested, thinned or otherwise, are often targeted for intensive suppressive management and are cut without assessment or data collection. This even includes studies and sites that are intended to inform management. For example, at the sites studied by Whitehead and Russo [107], infested trees were being removed from the study sites even before data collection for their study could be completed. The long-term study discussed previously [113,124] is under continual pressure to be logged to remove beetle kill even though the site lies within an experimental forest designated specifically for studies assessing the outcomes of forest management.

5. What are the Goals?

When we manage forests, we do so in an attempt to achieve one or more outcomes, preferably with minimal negative effects on non-target resources. To be effective, management must have explicit and appropriate goals as well as clear metrics for success. Ideally, management is monitored to assess how well it meets its goals, where it falls short, and whether and how it can be improved. This approach is called adaptive management and implies an iterative process through time whereby we learn from the outcomes of our actions and base future actions on improving performance [125].

Not only outcomes, but the costs of management must be factored into decision making. These include direct financial costs as well as the less tangible (at least in dollar values) effects on ecosystem services and functions. By considering the full cost of management along with benefits as verified through monitoring and evaluation, we lessen the risk of failure, financial waste, and unnecessary negative environmental impacts.

In assessing how well we meet goals when managing for mountain pine beetle, we must ask several questions. Do our management practices actually control the beetle during outbreaks? Do the outcomes justify the financial and ecological costs? And, what long-term impacts do these treatments have on forests and their ability to adapt to climate change? These questions are difficult to answer. Only limited data are available on the short-term efficacy of direct and indirect controls, and information on long-term effects is virtually nonexistent. The results of short-term assessments can be difficult to interpret. For example, often only the proportion or numbers of trees killed by beetles post-treatment are reported. This does not allow a complete evaluation of outcomes. A study may report that 75% of trees in controls are killed by the beetle, whereas only 10% are killed in thinned stands. At first glance, this appears to be a resounding success in saving trees. However, if we approach this situation from a pretreatment perspective, our interpretation of success may change. In this example, 400 mature trees existed in each plot prior to treatment. After treatment, 100 mature trees remain in the thinned plots (300 trees have been removed by thinning). Doing the math, we find that once the beetles have run their course, more residual living trees (100) actually remain in the control plot than in the thinned plot (90) and, in fact, humans have contributed more to tree mortality than have the beetles. In the case of silvicultural intervention, humans typically must expend considerable effort and expense. They also choose the trees that remain, and thus the structure and composition of the remaining forest. This may result in very different trajectories for residual forests as discussed below.

When we include pre-treatment conditions as well as post-treatment responses we can assess the management efficacy from a more informed position. For instance, in a retrospective study investigating the effects of management on spruce beetle, researchers found that post-infestation, untreated stands had more live spruce trees and greater basal areas. When comparing only residual large spruce, final densities in both stand types were similar [126]. Six [124] found higher numbers of mature living trees remained in control stands of ponderosa pine than in thinned stands post-mountain pine beetle outbreak. In a study in Canada focusing on stocking density of living lodgepole pine post-outbreak, the authors found that, even in hard hit stands, stocking density in post-outbreak unmanaged stands was sufficient to maintain desired levels of productivity [127]. Klutsch *et al.* [128] in a study conducted in lodgepole pine forests in Colorado, found greater mortality of trees due to the beetle in more densely stocked stands. However, while the density and basal area of lodgepole pine in infested plots declined 62% and 71%, respectively, the number of trees that remained and their size distribution post-outbreak indicated that lodgepole pine would remain the dominant overstory tree. In another study in Colorado, the beetle killed 60%–92% of overstory lodgepole pine. However, these stands retained residual overstory trees as well as advance regeneration. Furthermore, untreated stands were predicted to return to pre-outbreak stocking levels approximately 25 years sooner than treated stands [129]. Other studies have found similar results for both lodgepole and ponderosa pine [130–134]. These studies highlight a seldom considered impact of mountain pine beetle- that it can act as a natural thinning agent and seldom removes all mature trees during outbreaks. These effects are an important part of the ecological role that the beetle plays in western pine forests [135].

It is also important to recognize there can be significant differences in long-term forest trajectories for stands thinned by beetles *vs.* those thinned by humans. When humans thin, they select for particular size classes, often favoring the retention of larger, older trees, selecting toward one desired tree species, and often ‘thinning from below’ which removes advanced regeneration (small trees) [123,136]. Thinning prescriptions also typically call for relatively even spacing between residual trees [92,107,121]. Mountain pine beetle, on the other hand, often selects the largest trees during outbreaks (with exceptions; [121,123,131]) which can lower the mean diameter of the stand [128]. However, beetles often leave sufficient numbers of large diameter trees to maintain a dominant overstory of pine. Beetles also leave substantial amounts of advanced regeneration to replace the mature trees that arekilled [121,129]. Spacing among trees after an outbreak is uneven, resulting in a clumpy network of living trees [129]. Patches where all trees are killed are seldom extensive and add to a mosaic structure as forests recover post-outbreak. Heterogeneous stand and mosaic forest structures are more typical of natural conditions and can support greater biodiversity and resilience against fire and subsequent beetle outbreaks [137–139]. In contrast, intensive thinning treatments by humans typically favors the retention of mature pines. Over time, these pine-dominated stands grow, they are predicted to have increased susceptibility and potential for tree mortality from future mountain pine beetle outbreaks [123,136].

Very importantly, the beetle exercises selectivity in the trees it kills. While extremely high numbers may override this selectivity, evidence is accumulating that, even under outbreak conditions, beetles choose trees that have particular qualities. Beetles commonly select trees for attack that exhibit lower growth rates, defenses, and higher water stress [58,74,77]. While these factors can be influenced both locally and regionally by site conditions and climate, much of the variation in these properties within individual stands that affect bark beetle choice likely has a genetic basis. Outbreaks can result in strong natural selection against trees with phenotypes (and likely genotypes) favorable for the beetle and for those that possess unfavorable qualities [58,77]. However, when humans thin forests, trees are removed according to size, species, and density, without consideration of genetics. Thus, trees best adapted to surviving beetle outbreaks are as likely to be removed as those that are not.

When humans thin forests, they typically manage for resistance and resilience, rather than adaptation which involves genetic change. It is very important to distinguish between resistance, resilience, and adaptation, as each have different goals and operate on different temporal scales [140]. Resistance is a short-term holding action where we try to maintain an existing state. Approaches focusing on resistance often require massive interventions and increasing physical and financial investments over time. Such approaches may set forests up for future outbreaks [136] and even catastrophic failure as they surpass thresholds in a warming climate [140]. In contrast, practices that promote resilience attempt to allow forests the ability to adjust to gradual changes related to climate change and to recover after disturbance. However, like resistance, resilience is not a long-term solution. In the long term, forests must be able to adapt to change. Adaptation involves genetic change driven by natural selection. Currently, much of forest management, including bark beetle management, focuses on resistance and resilience, mainly through direct and indirect management, respectively. However, neither approach allows for true adaptation. For long term continuity of our forests, it will be imperative to begin to incorporate this aspect of management into our approaches.

We also need to reassess the ecological role of bark beetles, including the mountain pine beetle, in our forest ecosystems. As has been well demonstrated by a century of fire suppression, the dampening or suppression of natural disturbance can alter forest trajectories in undesirable ways, many of which can be irreversible. Although beetle outbreaks, like fire, can have negative impacts on timber values and aesthetics, their natural role in many forest ecosystems is seldom considered and beetle suppression is often perceived as something that must be conducted at all costs. However, as with fire, suppression of beetles over the long term may alter forests in ways that are not desirable or sustainable. While intensive management for bark beetle suppression is called for in some situations such as in the wildland urban interface, it may not be appropriate in many other areas where natural processes including natural selection are needed to maintain a dynamic and functional forest.

6. What are the Needs in Research and Monitoring?

There is clearly a need to better understand how well management programs aimed at reducing mountain pine beetle work, particularly under outbreak conditions, and what impacts these treatments have on forests in both the short and long term.

Perhaps the biggest area of need is in monitoring. Monitoring is essential to understanding whether mountain pine beetle treatments work, and in which contexts, but as noted above there has been all too little long-term monitoring of the effectiveness of various treatment efforts. This is a failing among both agencies and researchers. Agencies often do not have strong incentives to conduct long-term monitoring: Monitoring is costly; external and internal political pressures focus on short time frames; and monitoring may produce information that conflicts with agency goals or missions. It is also difficult to get strong public pressure to force agencies to conduct the necessary monitoring, particularly when the public has been led to believe that outbreaks are strictly the result of a lack of management. Even for scientists, long-term monitoring projects are not encouraged by short-term funding time frames and professional incentives or norms; monitoring is often not viewed as "real" science, and the long-time frames required for monitoring to result in significant gains in information are often longer than the time frames used for professional advancement (e.g., completion of a dissertation, tenure review) [141].

Addressing the shortage of monitoring for beetle treatments may, therefore, require far more than simply trying to provide additional funds (even assuming additional funding is politically feasible). Scientists can help by encouraging and rewarding projects that involve long-term monitoring. Agencies might try to establish units that are focused specifically on monitoring forest health, insulating monitoring projects from adverse political or bureaucratic pressure [141]. Finally, tools that might reduce the cost of monitoring significantly, such as retrospective studies and remote sensing, should be used to complement traditional monitoring and decrease its costs.

Monitoring is all the more essential if forest health management in general, and beetle treatments in particular, are truly to be guided by adaptive management. The high levels of uncertainty and dynamism associated with beetle infestations and the effectiveness of beetle treatments make adaptive management a very appealing tool to reduce uncertainty and allow us to respond to changes in global climate and forest ecosystems. But adaptive management requires monitoring to be successful [141], monitoring that is currently not occurring even as agencies conduct massive beetle treatments and propose to pursue even more.

There is also a real need to increase research on management efficacy and, in particular, how our approaches affect forest adaptation including genetic responses of trees to climate and the role in bark beetle selectivity and fitness. With a changing climate we will need to develop new approaches rather than trying to force old methods of questionable efficacy onto new conditions.

Unfortunately, most funding for research on bark beetles is very short-term, sometimes even as short as on an annual cycle, and thus cannot hope to address the complexities of beetle responses to treatments. Funding cuts to research personnel, particularly in agencies like the US Forest Service, have exacerbated this problem exactly at the time when the need for rigorous research is increasing at a rapid pace. The US Forest Service has recognized that long-term planning must include explicit goals to increase forest resilience and adaptation to disturbance, including outbreaks of the mountain pine beetle. However, with extreme cuts to budgets and personnel, they are highly constrained to meet these needs at this time. Likewise, cuts in federal funding to agencies such as United States Department of Agriculture and the National Science Foundation concurrently reduce the ability of academic researchers to address these problems.

7. Aligning Policy to Science

Our survey of the relevant literature finds that there is significant uncertainty about whether the most commonly used beetle timber harvest treatments are, indeed, effective. Yet there has been little discussion of this uncertainty in the relevant policy debates. Politicians have instead latched on to beetle timber treatments as a cure-all for beetle infestations and have pushed to weaken or eliminate environmental laws that are perceived to be obstructing these treatments. Agencies such as the US Forest Service, to their credit, have been more nuanced in their support for bills that package beetle timber harvest treatments with weakened environmental laws; they have opposed several proposals to alter environmental laws to allow more treatments, but on the other hand, the agencies have at times also aggressively pushed for the implementation of treatments.

It seems clear that the policy debates–both in the agencies and in Congress–need to be better informed by science. Researchers should be more proactive in communicating their understandings of the current science to policymakers. This does not mean that researchers need to take a position pro or con vis-à-vis beetle treatments, or even vis-à-vis specific legal proposals. In the face of uncertainty, aggressive beetle timber harvest treatments may be warranted in some instances. However, policymakers should be aware of uncertainty when they are making the relevant decisions and should also be more willing to include the voices of scientists in the development of policy.

Given the uncertainty about the effectiveness of many beetle timber harvest treatments, the high financial costs of those treatments, the impacts on other environmental resources and values, and the possibility that in the long-run those treatments may interfere with the ability of North American forests to adapt to climate change, our position is that weakening or eliminating environmental laws to allow more beetle timber harvest treatments is the wrong choice for advancing forest health in the United States. Indeed, given the uncertainty, the costs, and the possibilities of both short-term harm to other resources and long-term ineffectiveness, we believe that the current structure of thoughtful, detailed environmental review for these projects is, in general, appropriate. If agencies believe that they need to be able to react quickly to specific infestations with treatments, and that this quick reaction is incompatible with existing legal procedures, we encourage the agencies to adopt overall programmatic environmental reviews based on the principles of adaptive management. Agencies should be able to build (or tier) on these programmatic reviews to respond quickly to individual events as needed. However, the programmatic reviews should allow the agency to build in the monitoring, replication, and variance of treatments that are essential for successful adaptive management [142].

8. Conclusions

The manner in which policy makers have accepted beetle timber harvest treatments as a panacea for responding to bark beetle outbreaks in North American forests raises a number of red flags. As ecosystems and places that have economic, social, and cultural value to human communities are altered by climate change, there is a risk that people will overreact because of a need to "do something" to respond to change, and to give themselves some sense of control over broader forces that appear to be out of control. That pressure, to "do something", might also interact with the uncertainty about which choices are effective and appropriate (as with beetle timber harvest treatments) to create an opportunity for political pressures to force the adoption of particular choices that benefit specific interest groups [143]. It is perhaps no accident that the beetle treatments that have been most aggressively pushed for in the political landscape allow for logging activities that might provide revenue and jobs for the commercial timber industry. The result is that the push to "do something," uncertainty, and political pressures might lead us to act to respond to climate change before we understand the consequences of what we are doing, in the end producing more harm than good.

Our argument here is not to forgo management, but rather that management should be led by science and informed by monitoring. Both direct and indirect management for bark beetles have their place. However, to manage our forests in a way that best ensures their long-term function while wisely using limited financial resources, policy makers and the public need a clearer understanding of current science and gaps.

s0010 10.1 MIXED-SEVERITY FIRES: A DIVERSITY OF FUELS, ENVIRONMENTS, AND FIRE BEHAVIORS

p0010 Recent increases in global temperatures are projected by some research to increase the frequency and severity of wildfires in certain regions, particularly those experiencing warmer, drier summers (McKenzie et al., 2004; Flannigan et al., 2006). While the annual area burned in most forests of western North America remains well below historical levels (see Chapter 9), many areas have experienced significant increases in annual burning, particularly from 1970 to 1986 (Westerling et al., 2006), prompting concerns about the additional release of carbon, primarily in the form of carbon dioxide. However, concerns over a positive feedback between wildfire-caused carbon emissions and temperature increase must be considered in the context of the physical magnitudes of pyrogenic carbon emissions and the respective constituents of forest carbon storage from which they are derived. Here I discuss the factors influencing the combustion of different constituents of forest carbon storage and how rates of fuel combustion vary among fires of low, medium, and high severity. This chapter also addresses the relationship of fuel reduction treatments with regard to reducing fire severity and carbon emissions at the potential expense of forest carbon storage. Finally, I discuss postfire carbon emissions from the decomposition of fire-killed biomass, postfire forest succession, and the eventual recovery of forest carbon storage.

p0015 Rates of pyrogenic carbon emission from wildfires can be highly variable among mixed-severity wildfires. The consumption of each respective component of forest fuel is strongly determined by individual particle geometry, often expressed as the surface area-to-volume ratio for the purposes of quantifying the amount of fuel that is likely to be consumed. Combustion generally occurs at the surface of the fuel particle, and the size of each particle and its surface area-to-volume ratio control the amount of heat required for ignition and consumption. Fuels with large surface area-to-volume ratios, such as grasses and pine needles, require less heat for ignition and combustion. Conversely, large fuels with low surface area-to-volume ratios, such as standing trees, as well as snags, downed logs, and other forms of coarse woody debris, require considerably more energy for ignition and combustion. Fuel particle size also influences the rates of moisture absorption and release, as smaller fuel particles release moisture more rapidly than larger particles in response to increasing atmospheric vapor pressure deficits, as well as in response to the thermal energy brought about by an approaching flaming front. Consequently, large fuels are much more likely to burn during the smoldering stage, in which the emissions of combustible gases and vapors are too low to support flaming combustion (Lobert and Warnatz, 1993).

p0020 Fuel consumption also is influenced by the compactness of the fuel bed, in part because of the two-stage process of consumption through pyrolysis and combustion. While these processes are nearly simultaneous, pyrolysis occurs first and is the heat-absorbing reaction that converts fuel elements such as cellulose into char, carbon dioxide, carbon monoxide, water vapor, highly combustible vapors and gases, and particulate matter (DeBano et al., 1998; Ward, 2001; Ottmar, 2014). Pyrolysis is followed by combustion, in which escaping hydrocarbon vapors are released from the surface of the fuels and are oxidized. Thus fuel compaction presents a tradeoff between heat transfer and oxygen diffusion. Highly compacted fuels facilitate a more efficient transfer of heat between fuel particles while limiting the diffusion of oxygen and, by extension, limiting consumption. Conversely, low fuel compaction allows for high diffusion of oxygen, albeit with a low diffusion of heat between fuel particles (Hardy et al., 2001). Fuel consumption also is influenced by the spacing, or continuity, of fuels across the forest floor (Finney et al., 2010) (Figure 10.1).

p0025 While the amount of consumption that is to be expected can be strongly determined by the fuel's physical and chemical characteristics, it is also a function of climate and topography. Regional climate exerts a top-down influence on fire frequency through seasonal patterns of temperature and precipitation (Littell et al., 2010), whereas local factors such as topography, vegetative composition, and fuel loads exert a bottom-up influence on fire behavior (Perry et al., 2011; Miller et al., 2012). Topography can influence the species composition of a forest, the composition and accumulation of fuels from a forest, and the topographically mediated content of fuel moisture. Among landscapes at elevations dominated by ponderosa pine (*Pinus ponderosa*) in eastern Oregon and Washington, white fir (*Abies concolor*) and grand fir (*Abies grandis*) are more common on north-facing slopes

f0010 **FIGURE 10.1** Aerial view of a smoke plume. *(Photo courtesy of M. Welling, Max Planck Institute for Chemistry.)*

because of the cooler and moist conditions that result from less incoming solar radiation (Cowlin et al., 1942). Stand composition and structure interact with the edaphic (pertaining to soils) moisture gradients to determine patterns of fire severity (Hessburg et al., 2000; Miller, 2003; Hessburg et al., 2004). In areas north of the Klamath Mountains in northwestern California, north-facing slopes may burn with mixed severity, whereas south-facing slopes can burn with mixed or low fire severity. However, the opposite occurs in the more xeric (dry) forests of the Klamath Mountains, wherein mixed-severity fires have historically dominated on south- and west-facing aspects, whereas low-severity fires were dominant on north- and east-facing aspects (Taylor and Skinner, 1998). Extreme weather conditions can override these effects, however, as was the case in the Biscuit Fire of 2002 in southwest Oregon; hot, dry winds from the northeast drove the fire, thereby eclipsing much of the influence of topographic positions (Thompson and Spies, 2010). Other fires with severe conditions have shown a stronger response to topographic controls, such as the Megram Fire in northern California (Jimerson and Jones, 2000).

p0030 The expected fuel consumption for a given level of fire severity is often expressed as a combustion factor (CF). A CF is the proportion of a biomass constituent that is expected to be consumed in a wildfire. CFs vary with respect to different biomass components such as live foliage, litter, stem, branches, shrubs, and soil. CFs can also vary as a function of fire severity: Lower levels of fire severity typically result in lower levels of combustion for each respective constituent of forest carbon storage. Note, however, that the use here of the term "fire severity," expressed as the proportion of mortality observed in overstory trees, can be misleading when used as a determinant of fuel combustion. Fuel combustion often ~~is~~ determined by fire intensity, a measure of energy output

B978-0-12-802749-3.00010-4, 00010

from a fire (Keeley, 2009). A fire of relatively low intensity could conceivably result in a fire of medium or even high severity if it occurred among trees with relatively low tolerance to fire. Because this is a book concerned about forest ecosystems with mixed- and high-severity fire regimes, however, we are largely dealing with ecosystems that have evolved at least some adaptations to moderate- or high-severity fire.

p0035 An improper use of a CF in estimating the carbon emissions of a given fire can produce vastly different estimates of pyrogenic carbon emissions. Worldwide, forests store about 45% of terrestrial carbon (861 ± 66 pg carbon) in soils, ~42% in above- and belowground live biomass, ~8% in dead wood, and ~5% in litter (Bonan, 2008). Given the magnitude of carbon stored in, say, dead wood, a poorly derived CF for dead wood can have a considerable impact on the resulting estimates of carbon dioxide emissions. Estimates of average pyrogenic carbon emissions for a given time period can produce a considerable range of values, some of which can be over four times higher than those of others (Wiedinmyer and Neff, 2007; Ghimire et al., 2012), in part because of methodological differences in the approaches used to estimate biomass accumulation and area burned, as well as different approaches used by different studies to obtain CFs.

p0040 Here I discuss factors controlling the combustion of different constituents of carbon storage in forest ecosystems and how these constituents can influence, and can be influenced by, different levels of fire severity in forested landscapes with mixed- and high-severity fire regimes. I also discuss the indirect impacts of wildfire through the long-term carbon emissions of fire-killed biomass and how emissions after wildfire can influence the source-sink dynamics throughout a postfire landscape.

s0015 10.2 DUFF, LITTER, AND WOODY DEBRIS COMBUSTION

p0045 Duff carbon comprises the dead organic matter found in the O_a (almost complete decomposition) through the O_e (moderate composition) horizons, whereas litter comprises the dead materials found in the O_i horizon (undecomposed plant parts) and includes small, woody fragments <0.51 cm in diameter, also known as 1 h fuels. Small, woody debris consists of particles 0.51-2.54 cm in diameter, also known as 10-h fuels. While only a small fraction of total forest carbon storage, these components of carbon storage on the forest floor often constitute the majority of combusted fuel for fires of all severities. Campbell et al. (2007) estimated that duff, litter, and small, downed, woody debris consumption constituted about 60% of direct carbon emissions in the Biscuit Fire of 2002. High rates of combustion among these components are consistent with the principle that fuels with large surface area-to-volume ratios have higher CFs than fuels with lower surface area-to-volume ratios, much of which can be attributed to the short time periods required for woody materials (1- to 10 h fuels) to dry out. Seasonal variation in fuel moisture can thus have a considerable impact on carbon emissions. Knapp et al. (2005) found that early season burns, in which fuel

B978-0-12-802749-3.00010-4, 00010

moisture was higher, left approximately five times more litter and duff unconsumed in areas where fire passed over the forest floor than late season burns.

p0050 Noting that this pool of carbon storage is destined for biogenic emission to the atmosphere in the absence of wildfires is important. Pools of litter, foliage, and small, downed wood are thought to have a mean residence time of 10-20 years (Law et al., 2001), and while a portion of this eventually transitions into more stable forms of soil carbon storage, much of it is lost through decay. Furthermore, much of the carbon stored in a pool with such high turnover should equate to a subsequent reduction in heterotrophic (requiring organic matter for food) respiration until these pools become recharged by the addition of leaf litter and small, woody debris (Campbell et al., 2007).

p0055 Because additional energy is necessary to remove water before combustion is possible, more energy is required to propagate flaming combustion in moist fuels than dry fuels (Nelson, 2001). In theory (Finney et al., 2013), as well as in some modeling studies (Hargrove et al., 2000; Miller and Urban, 2000), the probability that fire will propagate to neighboring fuels is reduced at higher fuel moisture levels. Knapp et al. (2005) found that the amount of area within the fire perimeter burned, and greater patchiness of early season burns conducted under higher fuel moisture conditions, are consistent with these model predictions. Thus the combustion of large, woody debris (1000-h fuels) can be particularly sensitive to fuel moisture. Estimates of combustion of downed, coarse, woody debris suggest that the majority of carbon contained therein will remain after the fire, with CFs of 0.04 for low- and very-low-severity fires and up to 0.08 and 0.24 for medium- and high-severity fires (Table 10.1). CFs are even lower f standing coarse, woody debris, ranging from 0.02 for low- and very-lo severity fires to 0.04 and 0.12 for medium- and high-severity fires (Table 10.1).

p0060 Interestingly, levels of fuel consumption for woody debris, duff, and litter exhibit a surprisingly high level of similarity at different levels of fire severity, even among different forest types (Table 10.2). CFs for woody debris (including all diameter classes) averaged 0.56, 0.63, and 0.79 for low-, medium-, and high-severity fires, respectively (Table 10.2). Average duff combustion (0.46) was lower than average woody debris combustion among stands burned by low-severity fires, but it was higher in stands burned by medium- and high-severity fires, with average CFs of 0.70 and 0.90, respectively (Table 10.2). The highest rates of combustion were observed in litter biomass, which had CFs of 0.68, 0.7 0.95 for low-, medium-, and high-severity fires, respectively (Table 10.2).

s0020 10.3 LIVE FOLIAGE COMBUSTION

p0065 Estimates of live, crown foliage combustion are difficult because few studies have attempted to distinguish between crown consumption and noncombustive mortality (Wyant et al., 1986; McHugh et al., 2003; Hull Sieg et al., 2006; Campbell et al., 2007; Keyser et al., 2008). While live foliage can be consumed

Soil to 10 cm	45,500	0.08	0.04	0.04	0.02

Litter consists of materials in the O_i horizon, and duff is in the O_e and O_a horizon. Soil is all mineral soil to a depth of 10 cm, including fine roots. For live trees, small is a <7.62 cm diameter at breast height (DBH); large is a >7.62 cm DBH. For dead wood, small is 0.51-2.54 cm, medium is 2.54-7.62 cm, and large is a >7.62 cm diameter.

np0010 [a]*Data from Campbell et al. (2007).*

by wildfires, foliage can also be scorched and damaged by direct contact with or indirect convective heating from flames, leading a yellowing or browning of foliage. Once scorched, the foliage is usually killed and subsequently falls to the ground.

p0070 Understory and shrub-layer vegetation can have a significant impact on foliage consumption, but these effects depend on species composition. In the 2002 Biscuit Fire, open conifer forests with a predominantly sclerophyllous (trees and shrubs with hard, thick leaves) shrub understory experienced the most crown mortality (Thompson and Spies, 2009). Conversely, an assessment of the foliar moisture content of several grass and nonsclerophyllous shrub species suggested the possibility that the presence of a grass and/or shrub in the understory could reduce flame height throughout most of the fire season (Agee et al., 2002). If true under field conditions of fire ignition and development, such a finding would suggest a possible caveat to the common assumption that fuels with high surface area-to-volume ratios are among the most combustible and efficiently burning fuel types. The abundance of foliage fuel found throughout densely stocked, uniform forests, however, clearly has a high probability of combustion capable of propagating fires with high subsequent mortality. In a mixed conifer system in the Sierra Nevada range, North and Hurteau (2011) examined the effects of "thin from below" treatments, in which trees of a given diameter are removed to minimize the presence of ladder fuels that could t0015 **TABLE 10.2** ~~Mortality Factors (MFs) and~~ Combustion Factors (CFs) for Woody Debris (WD), Litter, and Duff Fuels for Different Forest Species Groups and Levels of Fire Severity[a]

np0015 [a] *Data from Ghimire et al. (2012).*

propagate a crown fire. Following wildfire, differences in fire mortality between treated (53%) and untreated (97%) forest suggest that fuel reduction treatments can allow for a considerable reduction in the presence of foliage and ladder fuels throughout the stand, though this did not include the effects of direct mortality from the mechanical thinning itself, which would substantially increase overall mortality in the thinned areas.

p0075 The potential for fire to spread vertically to the forest canopy is highly dependent upon the successional stage of the forest stand. As densely stocked stands of shade-intolerant species mature, self-thinning raises the crown height, and the resulting shading discourages the development of ladder fuels, thereby reducing the probability of fire propagation from the ground fuels into the canopy (Odion et al., 2004; Perry et al., 2011). Collins and Stephens (2010) found that stands were most susceptible to high-severity reburn when they were between 17 and 30 years old (also see Chapter 1). Consequently, mature, closed conifer stands can be more resistant to foliage combustion and tree morality than their younger counterparts (Thompson and Spies, 2009, 2010). These findings bear relevance to the commonly held assumption that the probability of high severity fires tends to increase with stand age. Such assumption is often made on the premise that forests accumulate more biomass through time, and thus have more total fuel that could be burned, thereby resulting in fires of higher severity. However, the infrequent occurrence of high-severity wildfires is not necessarily the result of infrequently high amounts of forest fuel availability. For many ecosystems, it is the infrequent occurrence of extreme weather conditions that may lead to a high-severity, foliage-consuming crown fire (Perry et al., 2011).

p0080 Foliage combustion rates may thus be best thought of as a function of fire severity and the vertical strata of the foliage. CFs for grass and forbs range from 0.70 to 0.75 in very-low-/low-severity fires to 1.00 in high-severity fires, whereas the combustion of fuels of small (<7.62 cm diameter at breast height [dbh]) trees and shrubs at a slightly higher vertical strata is slightly less: CFs for low-, medium-, and high-severity fires are 0.44, 0.76, and 0.89 for conifers and 0.50, 0.80, and 1.00 for hardwoods, respectively. Estimated CFs for the foliage of large trees are, as expected, lower than the others because of the vertical distance between foliage and surface fuels, where the majority of combustion takes place. CFs for large (>7.62 cm dbh) foliage in low-, moderate- and high-severity fires are 0.09, 0.27, and 0.69 for conifers and 0.12, 0.29, and 0.58 for hardwoods, respectively (Table 10.1).

s0025 10.4 SOIL COMBUSTION

p0085 Soil represents a considerable fraction of forest carbon, comprising approximately 44% of total forest carbon storage worldwide (Bonan, 2008). Soil carbon storage is usually low among ecosystems with frequent, low-severity fire regimes, such as those found in semiarid ponderosa pine forests. Conversely, soil carbon storage can be very high in ecosystems with infrequent (i.e., a mean fire return interval of >200 years) fires. Fires of high intensity and severity typify many forests with infrequent fire regimes. Because of the high magnitude of soil carbon storage in stands with infrequent, high-severity fires, estimates of carbon emissions from wildland fires are highly sensitive to the CF used to estimate the proportion of soil carbon that is consumed. However, estimates of soil carbon combustion are difficult to obtain, particularly in high-severity wildland fires, because of the lack of prefire estimates of soil carbon content.

p0090 The process of soil carbon consumption is dominated by smoldering, as opposed to flaming, combustion. Smoldering combustion is a result of insufficient amounts of oxygen required to support flaming combustion and is most prevalent in organic soils and rotting logs. The combustion of forest soils is highly dependent on the magnitude of the temperatures they are exposed to and the duration of exposure. Agee (1993) suggested that soils can be combusted at temperatures as low as 100 °C, but laboratory-based experiments suggest that significant amounts of soil carbon volatilization require temperatures between 200 °C and 315 °C (Lide, 2004), with peak smoldering temperatures ranging from 300 °C to 600 °C (Rein et al., 2008). Work by Fernández et al. (1997) heated the top 10 cm of soil taken from a *Pinus sylvestris* stand to 150° at a gradually increasing rate (+3 °C min^{-1}), at which point the soil was heated for 30 min thereafter, yet no significant amount of soil carbon combustion was observed. Upon applying the same heating regime at temperatures of 220°, 350°, and 490°C, however, there were significant changes in the content of soil organic matter (i.e., soil carbon). Temperatures of 220°, 350°, and 490°C resulted in losses of 37%, 90%, and nearly 100%, respectively. Others have noted that shorter heating times at 350 °C resulted in a 50% weight loss after only 180 s (Almendros et al., 2003), compared with 90% at 350 °C observed by Fernández et al. (1997). Consequently, exposure to increased temperatures is highly dependent on combustion times and rates of fire spread; the relatively high rates at which fire moves across western North American landscapes, combined with the relatively limited diffusion of oxygen into the relatively nonporous soil profile, limit soil carbon emissions. CFs for soils described by Campbell et al. (2007) were 0.04 for low- and medium-severity fires and 0.08 for high-severity fires (Table 10.1).

p0095 The combustion of soils in boreal forests represents an important exception to the relatively low rates of soil carbon emissions observed in most western US forests. Turetsky et al. (2011) and Kasischke and Hoy (2012) found that the combustion of soil carbon in Alaskan boreal forests can actually constitute the majority of carbon emissions during fires, representing 54-70% of total carbon emissions. Turetsky et al. found that three factors explained most of the variation in the depth of burning/carbon consumption in the surface organic layers of black spruce forests. First, topography was a significant control: Higher fractions of consumption were observed in upland sites compared with lowland sites. Second, season of the fire was also a factor: Seasonal thawing of permafrost resulted in drier ground layers as the growing season progressed. Finally, in upland sites, fires that exhibited higher consumption occurred in the early season in years where fires had a large spatial extent compared to those in years where fires had a smaller spatial extent because of drier conditions and more extreme fire behavior.

p0100 Large amounts of biomass with long-term smoldering potential also are found in pocosin shrublands (a type of wetland with deep, sandy, and acidic soils) in the southeastern United States. While pocosin systems can have substantial amounts of combustible fuel contained in deep peat layers, they differ most notably from boreal forests in their lack of both a freeze-thaw cycle and a strong, seasonally sensitive decline in moisture as the growing season progresses. Consumption of fuel beds in these systems is poorly understood, and additional research on moisture dynamics, biogeochemical processes, and combustion is needed (Reardon et al., 2007, 2009).

s0030 10.5 BOLE BIOMASS CONSUMPTION

p0105 While many studies report tree mortality rates, relatively little on the fraction of fire-killed trees that were combusted during wildfire has been reported. In estimates of pyrogenic carbon emissions taken from the Biscuit Fire in 2002, Campbell et al. (2007) found no combustion of bole biomass among large (>7.62 cm dbh) trees, regardless of fire severity (Table 10.1). The lack of combustion for the boles of large trees seems to have been effectively mediated by the combustion of bark, which had CFs of 0.03, 0.06, and 0.20 for conifers and 0.03, 0.11, and 0.22 for hardwoods in low-, medium-, and high-severity fires, respectively. Such a finding is consistent with what is expected of fuels with low surface area-to-volume ratios (Table 10.1).

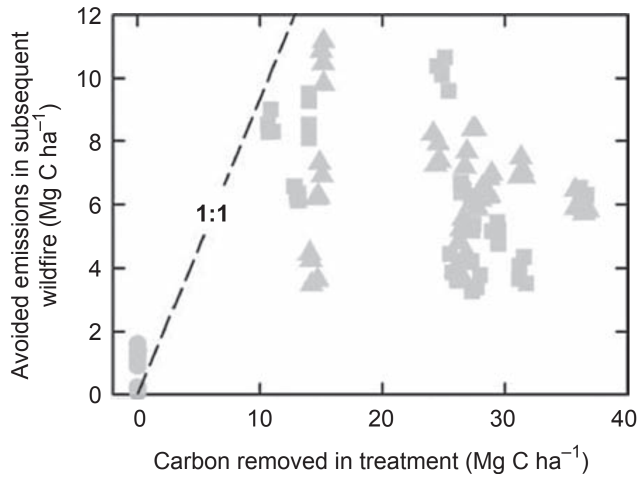
p0110 Bark CFs were much higher for small trees; for low-, medium-, and high-severity fires there were CFs of 0.42, 0.70, and 0.70 for conifers and 0.40, 0.63, and 0.79 for hardwoods, respectively (Table 10.1). As expected, the thinner bark of smaller trees, much of which was combusted, was not effective in protecting the bole biomass from combustion. Estimates of the combustion of the boles of small trees for low-, medium-, and high-severity fires were 0.40, 0.68, and 0.61 for conifers and from 0.40, 0.63, and 0.79 for hardwoods, respectively (Table 10.1). Weighted CFs for all trees, adjusted for the abundance of small tree biomass versus large tree biomass, would be approximately 0.03, 0.07, and 0.08 for low-, medium-, and high-severity fires, respectively (Campbell et al., 2007). Others have used far higher CFs for high-severity fires in modeling studies. An estimated high-severity CF of 0.30 has been used for Siberian forests (Soja et al., 2004), which may be realistic, given the small diameters prevalent in boreal forest stands. Estimates of bole CFs, however, some of which are as high as 0.30 for North American forests (Wiedinmyer et al., 2006), seem to be at odds with those estimated by Campbell et al.

(2007), given the majority of biomass is stored in boles of large trees, none of which is combusted by high-severity fires. Such estimates, if inaccurate, can result in substantial overestimates of pyrogenic carbon emissions because of the considerable stocks of carbon in bole biomass of large trees. Overall, the CFs for total forest biomass (i.e., trees, snags, shrubs, woody fuels, litter, duff, and soil), weighted according to their respective prefire biomass, were 0.13, 0.15, and 0.21 for low-, medium-, and high-severity fires, respectively, in the Biscuit Fire (Campbell et al., 2007) (Table 10.1).

s0035 10.6 FUEL REDUCTION TREATMENTS, CARBON EMISSIONS, AND LONG-TERM CARBON STORAGE

p0115 The application of fuel reduction treatments have become common in many fire-adapted forests throughout the western North America. Such treatments are intended to reduce the severity of fires, primarily out of concern over public safety in fire-prone regions, as well as ~~because of land management agencies that want~~ to minimize ~~widespread mortality in the forests within their jurisdiction~~. ~~Common fuel~~ reduction treatments ~~include~~ understory removal, whereby midstory and understory vegetation ~~is~~ removed through pruning or harvesting. ~~Anothe~~[illegible] ~~reduction treatment is~~ prescribed fire, which reduces surface fuels in orde[illegible]mit the flame height of a wildfire that might enter the stand. ~~In the field, this~~ is done by removing fuel through prescribed fire or pile burning, both of which reduce the potential magnitude of a wildfire by making it more difficult for a surface fire to ignite the canopy. The timing of prescribed fire can be central to its effectiveness. If performed *after* an understory removal treatment, it may burn any additional residue created by the treatment. ~~Performing~~ prescribed fire under cooler and moisture conditions than those experienced during the fire season is also ideal to avoid the propagation of an unplanned fire. Other fuel reduction treatments involve a partial harvest of overstory trees to limit the potential of fire to spread from crown to crown.

p0120 While such treatments can sometimes be effective in reducing fire severity, if and when fires occur in thinned areas (Rhodes and Baker, 2008), they can come at the expense of carbon storage. The majority of carbon stored in leaves, leaf litter, and duff is typically consumed by high-severity wildfire and often constitutes the majority of the carbon emissions during the a given fire, yet most of the carbon stored in forest biomass (stem wood, branches, and coarse, woody debris) remains unconsumed even by high-severity wildfires. Consequently, fuel removal via forest thinning almost always reduces carbon storage more than the additional carbon that a stand is able to store when made more resistant to wildfire. For this reason, removing large amounts of biomass to reduce the fraction by which other biomass components are consumed via combustion is inefficient (Mitchell et al., 2009). Fuel reduction treatments that involve the removal of overstory biomass (i.e., intermediate-sized and large trees) are, perhaps unsurprisingly, the most inefficient methods of reducing wildfire-related



f0015 **FIGURE 10.2** Simulated effectiveness of various fuel-reduction treatments in reducing future wildfire combustion in a ponderosa pine ~~(*P. ponderosa*)~~ forest. In general, protecting one unit of carbon (C) from wildfire combustion came at the cost of removing approximately three units of carbon in treatment. At the very lowest (least biomass removed) treatment levels, more carbon was protected from combustion than removed during treatment; however, the absolute gains were extremely low. Circles show understory removal, squares show prescribed fire, and triangles show understory removal and prescribed fire. Simulations were run for 800 years with a treatment-return interval of 10 years and a mean fire-return interval of 16 years. Forest structure and growth were modeled to represent mature, semiarid ponderosa pine forest growing in Deschutes, Oregon. Further descriptions of these simulations are given by Mitchell et al. (2009).

carbon losses because they remove large amounts of carbon for only a marginal reduction in expected fire severity (Figure 10.2).

s0040 10.7 INDIRECT SOURCES OF CARBON EMISSIONS

p0125 Our discussion thus far has focused on the *direct* effects of wildfire on carbon emissions as a result of the combustion of live vegetation, dead biomass, and soil organic matter. *Indirect* effects, by contrast, are not the result of the active combustion of biomass or soil organic matter; instead, they result from the long-term decomposition of vegetation killed in wildfire. The magnitude of indirect emissions, and the temporal scales at which they affect the net ecosystem carbon balance, vary with different fire behaviors. Most of the mortality resulting from low-severity fires is limited to understory plants, shrubs, and small trees, which do not typically constitute a significant portion of total stand carbon storage and, by extension, do not represent a significant source of carbon emissions upon decomposition. High-severity fires, by contrast, result in the near-total death of all trees within a stand, including overstory dominants. While the addition of any unburned leaf litter and fine, woody debris from fire-killed trees represent pools with relatively high turnover (10-20 years), a large pool of coarse woody debris (e.g., logs, snags) can be a significant source of carbon

B978-0-12-802749-3.00010-4, 00010

emissions (Bond-Lamberty et al., 2003), one that can ~~continue to release carbon~~ for periods of up to, and even exceeding, 100 years (Kashian et al., 2006).

p0130 Fire severity has a significant impact on postdisturbance rates of net primary production and net ecosystem production (NEP). Net primary production is the difference between photosynthesis and autotrophic (i.e., plant) respiration, whereas NEP is a measure of net ecosystem carbon uptake, defined as the difference between photosynthesis and autotrophic respiration plus heterotrophic (i.e., decomposition) respiration. Following a high-severity disturbance, rates of heterotrophic respiration are, for a period of time, far higher than rates of photosynthesis, resulting in negative NEP (Harmon et al., 2011). While indirect sources of carbon emissions following fire can be substantial, particularly following high-severity fire, the postdisturbance regrowth of a new cohort of trees is also a significant contributor to total ecosystem carbon storage and the net ecosystem carbon balance (Figure 10.3).

p0135 The amount of time required for a recently disturbed forest to shift from a source to a sink depends on fire severity, forest type, and local climate. Following high-severity wildfires, forests with low rates of productivity, such as the ponderosa pine forests of the southwestern United States, take relatively longer to make the postfire transition from carbon source to carbon sink (Ghimire et al., 2012). Dore et al. (2008) examined a ponderosa pine forest in northern Arizona 10 years after a stand-replacing fire and found it to be a moderate source of carbon (109 g carbon m^{-2} $year^{-1}$), but they observed a moderate carbon sink (164 g carbon m^{-2} $year^{-1}$) in an unburned stand nearby. The burned stand remained a source of carbon during all months of the year that were measured, even during the growing season in the summer months. Annual ecosystem respiration was 33% lower in the burned stand. The slow recovery of such stands is largely attributed to the climate, whereby cold winters combine with low springtime precipitation to limit gross primary production (GPP), whereas warm summers with periodic precipitation are conducive to respiration-driven losses of soil carbon (Dore et al., 2008). However, this analysis was based on only five plots with a 25 m radius; therefore, some caution regarding broader inferences is appropriate.

p0140 Differences in the postfire carbon balance of uptake were observed in semiarid, mixed-conifer forests of eastern Oregon. Meigs et al. (2009) found that 4-5 years after a mixed-severity fire, areas that burned at low severity were modest net carbon sinks. By contrast, ponderosa pine forests that also were affected by a low-severity fire were carbon neutral in low-severity fire areas. Differences in the recovery time to being a source of carbon once again may be because of differences in productivity; ponderosa pine forests are typically less productive than mixed-conifer forests (Franklin and Dyrness, 1973). Among areas affected by high severity fires, both ponderosa pine and mixed-conifer stands were sources of carbon emissions 4-5 years following fire. Modeled estimates of the postfire transition from carbon source to carbon sink suggest that ~40 years may necessary for low-productivity ponderosa pine forests to shift

f0020 **FIGURE 10.3** The classic pattern of net primary production (NPP), heterotrophic respiration (RH), and net ecosystem production (NEP) (A) and associated carbon stores (B) following a high-severity disturbance. *(From Harmon et al. (2011).)*

from being a carbon source to a carbon sink (Ghimire et al., 2012), though this analysis did not control for the potentially confounding effect of postfire logging, which is common after high-severity fire in ponderosa pine and mixed-conifer forests (see Chapter 11). Forests with higher rates of productivity, such as coastal range Sitka spruce (*Picea sitchensis*)/western hemlock (*Tsuga* *heterophylla*) forests in the Pacific Northwest, seem to make the postfire transition from carbon source to carbon sink in a shorter amount of time than any other coniferous western forest, potentially in <30 years. Harmon et al. (2011) reviewed the scientific literature on this question for various forest types and concluded that the transition from source to sink following fire sufficiently severe to reset the successional "clock" varied from 14-50 years in forests types characteristic of the Pacific northwestern United States and 5-15 years in boreal forests. High-severity fire rotation intervals are currently several hundred years to more than 1000 years in most mixed-conifer and ponderosa pine forest regions of the western United States, however, and these rates are generally substantially lower than historical rates (see Chapter 1). Thus a long-term spatiotemporal perspective is important to understand more fully the natural disturbance dynamics in these systems (see Chapter 9).

s0045 10.8 CONCLUSIONS

p0145 The majority of carbon stored in montane forest ecosystems of western North America remains unconsumed, even in high-severity wildfires. Large carbon stores in the bole biomass of large forest trees are not consumed, and the substantial proportion of carbon stored in forest soils is only slightly consumed. Most of the carbon emissions in a wildfire are from combustion of litter, duff, and woody debris. In the 2002 Biscuit Fire, CFs for total forest biomass (i.e., trees, snags, shrubs, woody fuels, litter, duff, and soil), weighted according to their respective prefire biomass, were 0.13, 0.15, and 0.21 for low-, medium-, and high-severity fires, respectively. Such factors can be even lower among stands with a higher proportion of carbon storage in bole biomass that likewise remains unconsumed in high-severity wildfires, such as Sitka spruce (*P. sitchensis*)/Western Hemlock (*T. heterophylla*) forests in the coast range of the Pacific Northwest (Smithwick et al., 2002; Mitchell et al., 2009). The application of fuel treatments can be effective in reducing fire severity and carbon emissions, but such treatments come at the cost of a net reduction in carbon storage relative to fire alone (Mitchell et al., 2009).

p0150 Postfire carbon emissions from fire-killed biomass can be substantial for decades following wildfires. Low- or even moderate-severity fires, however, do not necessarily result in a postfire source of carbon released to the atmosphere. High-severity fire temporarily creates a source of postfire carbon emissions as a result of the decomposition of fire-killed biomass, which lessens each year with natural postfire succession of vegetation, transitioning from a carbon source to a carbon sink within 5-50 years, depending on the ecosystem. Rates of postfire recovery are highest among systems with high productivity, whereas high-severity wildfires in forests with low productivity transition from source to sink over a relatively longer timeline, though there are important limitations in the amount and scope of existing studies of these systems. ~~Future~~ research on the relationship between climatic change, disturbance regimes, and postdisturbance successional trajectories may prove to be a crucial step toward projecting the future of pyrogenic carbon emissions in mixed-severity fire regimes.

Abstract

Among the concerns raised by climatic change is the potential for the additional release of carbon dioxide as a result of biomass combustion. Most of the carbon emissions from wildfires are from the combustion of litter, duff, and small woody debris, whereas most, if not all, of the biomass stored in the boles of large trees is not combusted. Consequently, most of the carbon stored in forests remains unconsumed, even by high-severity wildfires. Thus the application of fuel reduction treatments, while sometimes effective in reducing fire severity and carbon emissions, nearly always result in a net reduction in carbon storage. Postfire carbon emissions from the decomposition of fire-killed biomass can continue for decades, but effects of forest regrowth can exceed the losses of carbon from biomass combustion and the decomposition of fire-killed biomass within 5-50 years, depending on the ecosystem.

Forest fuel reduction alters fire severity and long-term carbon storage in three Pacific Northwest ecosystems

Stephen R. Mitchell,[1] Mark E. Harmon, and Kari E. B. O'Connell

Department of Forest Science, Oregon State University, Corvallis, Oregon 97331 USA

Abstract. Two forest management objectives being debated in the context of federally managed landscapes in the U.S. Pacific Northwest involve a perceived trade-off between fire restoration and carbon sequestration. The former strategy would reduce fuel (and therefore C) that has accumulated through a century of fire suppression and exclusion which has led to extreme fire risk in some areas. The latter strategy would manage forests for enhanced C sequestration as a method of reducing atmospheric CO_2 and associated threats from global climate change. We explored the trade-off between these two strategies by employing a forest ecosystem simulation model, STANDCARB, to examine the effects of fuel reduction on fire severity and the resulting long-term C dynamics among three Pacific Northwest ecosystems: the east Cascades ponderosa pine forests, the west Cascades western hemlock–Douglas-fir forests, and the Coast Range western hemlock–Sitka spruce forests. Our simulations indicate that fuel reduction treatments in these ecosystems consistently reduced fire severity. However, reducing the fraction by which C is lost in a wildfire requires the removal of a much greater amount of C, since most of the C stored in forest biomass (stem wood, branches, coarse woody debris) remains unconsumed even by high-severity wildfires. For this reason, all of the fuel reduction treatments simulated for the west Cascades and Coast Range ecosystems as well as most of the treatments simulated for the east Cascades resulted in a reduced mean stand C storage. One suggested method of compensating for such losses in C storage is to utilize C harvested in fuel reduction treatments as biofuels. Our analysis indicates that this will not be an effective strategy in the west Cascades and Coast Range over the next 100 years. We suggest that forest management plans aimed solely at ameliorating increases in atmospheric CO_2 should forgo fuel reduction treatments in these ecosystems, with the possible exception of some east Cascades ponderosa pine stands with uncharacteristic levels of understory fuel accumulation. Balancing a demand for maximal landscape C storage with the demand for reduced wildfire severity will likely require treatments to be applied strategically throughout the landscape rather than indiscriminately treating all stands.

Key words: biofuels; carbon sequestration; fire ecology; fuel reduction treatment; Pacific Northwest, USA; Picea sitchensis; Pinus ponderosa; Pseudotsuga menziesii.

Introduction

Forests of the U.S. Pacific Northwest capture and store large amounts of atmospheric CO_2, and thus help mitigate the continuing climatic changes that result from extensive combustion of fossil fuels. However, wildfire is an integral component to these ecosystems and releases a substantial amount of CO_2 back to the atmosphere via biomass combustion. Some ecosystems have experienced an increase in the amount of CO_2 released due to a century-long policy of fire suppression that has led to increased levels of fuel buildup, resulting in wildfires of uncharacteristic severity. Fuel reduction treatments have been proposed to reduce wildfire severity, but like wildfire, these treatments also reduce the C stored in forests. Our work examines the effects of fuel reduction on wildfire severity and long-term C storage to gauge the strength of the potential trade-off between managing forests for increased C storage and reduced wildfire severity.

Forests have long been referenced as a potential sink for atmospheric CO_2 (Vitousek 1991, Turner et al. 1995, Harmon et al. 1996, Harmon 2001, Smithwick et al. 2002, Pacala and Socolow 2004), and are credited with contributing to much of the current C sink in the coterminous United States (Pacala et al. 2001, Hurtt et al. 2002). This U.S. carbon sink has been estimated to be between 0.30 and 0.58 Pg C/yr for the 1980s, of which between 0.17 Pg C/yr and 0.37 Pg C/yr has been attributed to accumulation by forest ecosystems (Pacala et al. 2001). While the presence of such a large sink has been valuable in mitigating global climate change, a substantial portion of it is due to the development of understory vegetation as a result of a national policy of fire suppression (Pacala et al. 2001, Donovan and Brown 2007). Fire suppression, while capable of incurring

Manuscript received 13 March 2008; revised 12 June 2008; accepted 16 June 2008. Corresponding Editor: D. R. Zak.

short-term climate change mitigation benefits by promoting the capture and storage of atmospheric CO_2 by understory vegetation and dead fuels (Houghton et al. 2000, Tilman et al. 2000), has, in part, led to increased and often extreme fire risk in some forests, notably *Pinus ponderosa* forests (Moeur et al. 2005, Donovan and Brown 2007).

Increased C storage usually results in an increased amount of C lost in a wildfire (Fahnestock and Agee 1983, Agee 1993). Many ecosystems show the effects of fire suppression (Schimel et al. 2001, Goodale et al. 2002, Taylor and Skinner 2003), and the potential effects of additional C storage on the severity of future wildfires is substantial. In the *Pinus ponderosa* forests of the east Cascades, for example, understory fuel development is thought to have propagated crown fires that have killed old-growth stands not normally subject to fires of high intensity (Moeur et al. 2005). Various fuel reduction treatments have been recommended for risk-prone forests, particularly a reduction in understory vegetation density, which can reduce the ladder fuels that promote such severe fires (Agee 2002, Brown et al. 2004, Agee and Skinner 2005). While a properly executed reduction in fuels could be successful in reducing forest fire severity and extent, such a treatment may be counterproductive to attempts at utilizing forests for the purpose of long-term C sequestration.

Pacific Northwest forests, particularly those that are on the west side of the Cascade mountain range, are adept at storing large amounts of C. Native long-lived conifers are able to maintain production during the rainy fall and winter months, thereby out-competing shorter-lived deciduous angiosperms with a lower biomass storage capacity (Waring and Franklin 1979). Total C storage potential, or upper bounds, of these ecosystems is estimated to be as high as 829.4 Mg C/ha and 1127.0 Mg C/ha for the western Cascades and Coast Range of Oregon, respectively (Smithwick et al. 2002). Of this high storage capacity for west Cascades and Coast Range forests, 432.8 Mg C/ha and 466.3 Mg C/ha, respectively, are stored in aboveground biomass (Smithwick et al. 2002), a substantial amount of fuel for wildfires.

High amounts of wildfire-caused C loss often reflect high amounts of forest fuel availability prior to the onset of fire. Given the magnitude of such losses, it is clear that the effect of wildfire severity on long-term C dynamics is central to our understanding of the global C cycle. What is not clear is the extent to which repeated fuel removals that are intended to reduce wildfire severity will likewise reduce long-term total ecosystem C storage (TECμ). Fuel reduction treatments require the removal of woody and detrital materials to reduce future wildfire severity. Such treatments can be effective in reducing future wildfire severity, but they likewise involve a reduction in stand-level C storage. If repeated fuel reduction treatments decrease the mean total ecosystem C storage by a quantity that is greater than the difference between the wildfire-caused C loss in an untreated stand and the wildfire-caused C loss in a treated stand, the ecosystem will not have been effectively managed for maximal long-term C storage.

Our goal was to test the extent to which a reduction in forest fuels will affect fire severity and long-term C storage by employing a test of such dynamics at multi-century time scales. Our questions were as follows: (1) To what degree will reductions in fuel load result in decreases in C stores at the stand level? (2) How much C must be removed to make a significant reduction in the amount of C lost in a wildfire? (3) Can forests be managed for both a reduction in fire severity and increased C sequestration, or are these goals mutually exclusive?

Methods

Model description

We conducted our study using an ecosystem simulation model, STANDCARB (Appendix A), that allows for the integration of many forest management practices as well as the ensuing gap dynamics that may result from such practices. STANDCARB is a forest ecosystem simulation model that acts as a hybrid between traditional single-life-form ecosystem models and multi-life-form gap models (Harmon and Marks 2002). The model integrates climate-driven growth and decomposition processes with species-specific rates of senescence and stochastic mortality while incorporating the dynamics of inter- and intraspecific competition that characterize forest gap dynamics. Inter- and intraspecific competition dynamics are accounted for by modeling species-specific responses to solar radiation as a function of each species' light compensation point as well as the amount of solar radiation delineated through the forest canopy to each individual. By incorporating these processes the model can simulate successional changes in population structure and community composition without neglecting the associated changes in ecosystem processes that result from species-specific rates of growth, senescence, mortality, and decomposition.

STANDCARB performs calculations on a monthly time step and can operate at a range of spatial scales by allowing a multi-cell grid to capture multiple spatial extents, as both the size of an individual cell and the number of cells in a given grid can be designated by the user. We used a 20×20 cell matrix for all simulations (400 cells total), with 15×15 m cells for forests of the west Cascades and Coast Range and 12×12 m cells for forests of the east Cascades. Each cell allows for interactions of four distinct vegetation layers, represented as upper canopy trees, lower canopy trees, a species-nonspecific shrub layer, and a species-nonspecific herb layer. Each respective vegetation layer can have up to seven live pools, eight detrital pools, and three stable C pools. For example, the upper and lower tree layers comprise seven live pools: foliage, fine roots, branches, sapwood, heartwood, coarse roots, and heart-rot, all of which are transferred to a detrital pool following mortality. Dead wood is separated into snags and logs to capture the effects of spatial position on microclimate. After detrital materials have undergone significant decomposition, they can contribute material to three increasingly decay-resistant, stable C pools: stable foliage, stable wood, and stable soil. Charcoal is created in both prescribed fires and wildfires and is thereafter placed in a separate pool with high decay resistance. Additional details on the STANDCARB model can be found in Appendix A.

Fire processes

We generated exponential random variables to assign the years of fire occurrence (sensu Van Wagner 1978) based on the literature estimates (see experimental design for citations) of mean fire return intervals (MFRI) for different regions in the U.S. Pacific Northwest. The cumulative distribution for our negative exponential function is given in Eq. 1 where X is a continuous random variable defined for all possible numbers x in the probability function P, and λ represents the inverse of the expected time $E[X]$ for a fire return interval given in Eq. 2:

$$P\{X \leq x\} = \int_0^x \lambda e^{-\lambda x} dx \qquad (1)$$

where

$$E[X] = \frac{1}{\lambda}. \qquad (2)$$

Fire severities in each year generated by this function are cell specific, as each cell is assigned a weighted fuel index calculated from fuel accumulation within that cell and the respective flammability of each fuel component, the latter of which is derived from estimates of wildfire-caused biomass consumption (see Fahnestock and Agee 1983, Covington and Sackett 1984, Agee 1993). Fires can increase (or decrease) in severity depending on how much the weighted fuel index of a given cell exceeds (or falls short of) the fuel level thresholds for each fire severity class (T_{light}, T_{medium}, T_{high}, and T_{max}), and the probability values for the increase or decrease in fire severity (P_{i} and P_{d}). For example, while the natural fire severity of many stands of the west Cascades can be described as high severity, other stands of the west Cascades have a natural fire severity that can be best described as being of medium severity (~60–80% overstory tree mortality) (Cissel et al. 1999). For these stands, medium-severity fires are scheduled to occur throughout the simulated stand and can increase to a high-severity fire depending on the extent to which the weighted fuel index in a cell exceeds the threshold for a high-severity fire, as greater differences between the fuel index and the fire severity threshold will increase the chance of a change in fire severity. Conversely, medium-severity fires may decrease to a low-severity fire if the fuel index is sufficiently below the threshold for a medium-severity fire. High-severity fires are likely to become medium-severity fires if the weighted fuel index within a given cell falls sufficiently short of the threshold for a high-severity fire, and low-severity fires are likely to become medium severity if the weighted fuel index in a given cell is sufficiently greater than the threshold for a medium-severity fire. Fuel level thresholds were set by monitoring fuel levels in a large series of simulation runs where fires were set at very short intervals to see how low fuel levels needed to be to create a significant decrease in expected fire severity. We note that, like fuel accumulation, the role of regional climate exerts significant influence on fire frequency and severity, and that our model does not attempt to directly model these effects. We suspect that an attempt to model the highly complex role of regional climate data on fine-scale fuel moisture, lightning-based fuel ignition, and wind-driven fire spread adds uncertainties into our model that might undermine the precision and applicability of our modeling exercise. For that reason we incorporated data from extensive fire history studies to approximate the dynamics of fire frequency and severity.

Final calculations for the expected stand fire severity $E[F_{\mathrm{s}}]$ at each fire are performed as follows:

$$E[F_{\mathrm{s}}] = \frac{100}{C} \sum_{i=1}^{n} c_{i(\mathrm{L})} m_{i(\mathrm{L})} + c_{i(\mathrm{M})} m_{i(\mathrm{M})} + c_{i(\mathrm{H})} m_{i(\mathrm{H})} \qquad (3)$$

where C is the number of cells in the stand matrix and $c_{i(\mathrm{L})}$, $c_{i(\mathrm{M})}$, and $c_{i(\mathrm{H})}$ are the number of cells with light, medium, and high-severity fires, and $m_{i(\mathrm{L})}$, $m_{i(\mathrm{M})}$, and $m_{i(\mathrm{H})}$represent fixed mortality percentages for canopy tree species for light, medium, and high-severity fires, respectively. This calculation provides an approximation of the number of upper-canopy trees killed in the fire. The resulting expected fire severity calculation $E[F_{\mathrm{s}}]$ is represented on a scale from 0 to 100, where a severity index of 100 indicates that all trees in the simulated stand were killed.

Our approach at modeling the effectiveness of fuel reduction treatments underscores an important trade-off between fuel reduction and long-term ecosystem C storage by incorporating the dynamics of snag creation and decomposition. Repeated fuel reduction treatments may result in a reduction in long-term C storage, but it is possible that if such treatments are effective in reducing tree mortality, they may also offset some of the C losses that would be incurred from the decomposition of snags that would be created in a wildfire of higher severity. STANDCARB accounts for these dynamics by directly linking expected fire severity with a fuel accumulation index that can be altered by fuel reduction treatments while also incorporating the decomposition of snags as well as the time required for each snag to fall following mortality.

Total ecosystem C storage (TEC) is calculated by summing all components of C (live, dead, and stable). For each replicate (i = 1, 2, ... 5) and for each period

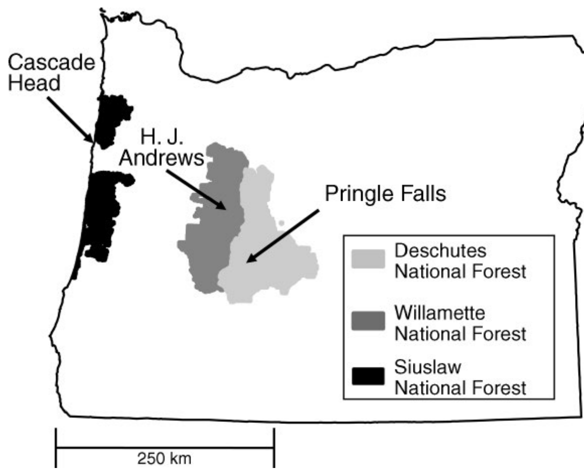

FIG. 1. Site locations in Oregon. Pringle Falls is our representative site for the east Cascades, H. J. Andrews is our representative site for the west Cascades, and Cascade Head is our representative site for the Coast Range.

between fires ($x = 1, 2, \ldots P_i$), the mean total ecosystem C storage (TEC_μ) is calculated by averaging the yearly TEC values ($k = 1, 2, \ldots R_x$).

$$\mathrm{TEC}_{\mu(i,x)} = \frac{1}{R}\sum_{k=1}^{R}\mathrm{TEC}_{(i,x,k)}.$$

Aggregating TEC_μ values in this manner permits the number of TEC_μ values to be the same as the number of $E[F_s]$ values, permitting a PerMANOVA analysis to be performed on $E[F_s]$ and TEC_μ.

Fuel reduction processes

STANDCARB's fire module allows for scheduled prescribed fires of a given severity (light, medium, high) to be simulated in addition to the nonscheduled wildfires generated from the aforementioned exponential random variable function. In addition to simulating the prescribed fire method of fuel reduction, STANDCARB has a harvest module that permits cell-by-cell harvest of trees in either the upper or lower canopy. This module allows the user to simulate understory removal or overstory thinning treatments on a cell-by-cell basis. Harvested materials can be left in the cell as detritus following cutting or can be removed from the forest, allowing the user to incorporate the residual biomass that results from harvesting practices. STANDCARB can also simulate the harvest of dead salvageable materials such as logs or snags that have not decomposed beyond the point of being salvageable.

Site descriptions

We chose the *Pinus ponderosa* stands of the Pringle Falls Experimental Forest as our representative for east Cascades forests (Youngblood et al. 2004). Topography in the east Cascades consists of gentle slopes, with soils derived from aerially deposited dacite pumice. The *Tsuga heterophylla–Pseudotsuga menziesii* stands of the H. J. Andrews Experimental Forest were chosen as our representative of west Cascades forests (Greenland 1994). Topography in the west Cascades consists of slope gradients that range from 20% to 60% with soils that are deep, well-drained dystrochrepts. The *Tsuga heterophylla–Picea sitchensis* stands of the Cascade Head Experimental Forest were chosen as our representative of Coast Range forests. We note that most of the Oregon Coast Range is actually composed of *Tsuga heterophylla–Pseudotsuga menziesii* community types, similar to much of the west Cascades. *Tsuga heterophylla–Picea sitchensis* communities occupy a narrow strip near the coast, due to their higher tolerance for salt spray, higher soil moisture optimum, and lower tolerance for drought compared to forests dominated by *Pseudotsuga menziesii* (Minore 1979), and we incorporate this region in order to gain insight into this highly productive ecosystem. Topography in the Cascade Head Experimental Forest consists of slope gradients of ~10% with soils that are silt loams to silt clay loams derived from marine siltstones. Site locations are shown in Fig. 1 and are located within three of the physiographic regions of Oregon and Washington as designated by Franklin and Dyrness (1988). Additional site data are shown in Table 1.

Experimental design

The effectiveness of forest fuel reduction treatments is often, if not always, inversely related to the time since their implementation. For this reason, our experiment incorporated a factorial blocking design where each ecosystem was subjected to four different frequencies of each fuel reduction treatment. We also recognize the fact that fire return intervals can exhibit substantial variation within a single watershed, particularly those with a high degree of topographic complexity (Agee 1993, Cissel et al. 1999), so we examined two likely fire regimes for each ecosystem. Historic fire return intervals may become unreliable predictors of future fire intervals (Westerling et al. 2006); thus ascertaining the differences in TEC_μ that result from two fire regimes might be a useful metric in gauging C dynamics resulting from fire regimes that may be further altered as a result of continued global climate change.

We based the expected fire return time in Eqs. 1 and 2 on historical fire data for our forests based on the following studies. Bork (1985) estimated a mean fire return interval of 16 years for the east Cascades *Pinus ponderosa* forests, and we also considered a mean fire return interval of 8 years for this system. Cissel et al. (1999) reported mean fire return intervals of 143 and 231 years for forests of medium- and high-severity (stand-replacing) fire regimes, respectively, among the *Tsuga heterophylla–Pseudotsuga menziesii* forests of the west Cascades. Less is known about the fire history of the Coast Range, which consists of *Tsuga heterophylla–Pseudotsuga menziesii* communities in the interior and *Tsuga heterophylla–Picea sitchensis* communities occu-

TABLE 1. Site characteristics (from Smithwick et al. 2002).

Site characteristic	Pringle Falls	H. J. Andrews	Cascade Head
Vegetation	PIPO	TSHE–PSME	TSHE–PISI
Elevation (m)	1359	785	287
Mean annual temperature (°C)	5.5	8.4	8.6
Mean annual precipitation (mm)	544	2001	2536
Soil porosity	sandy loam	loam	loam
Mean C storage potential (Mg C/ha)	183	829	1127

pying a narrow edge of land along the Oregon Coast. Work by Impara (1997) in the interior region of the Coast Range suggested a natural fire return interval (expected fire return time) of 271 years in the *Tsuga heterophylla–Pseudotsuga menziesii* zone, and Long et al. (1998) reported lake-derived charcoal sediment-based estimates of mean fire return interval for the Coast Range forests to be fairly similar, at 230 years. However, the *Tsuga heterophylla–Picea sitchensis* community type dominant in our study area of the Cascade Head Experimental Forest has little resistance to fire, and thus rarely provides a dendrochronological record. We estimated a mean fire return interval of 250 years as one fire return interval for a high-severity fire, derived from interior Coast Range natural fire return interval estimates, and also included another high-severity fire regime with a 500-year mean fire return interval in our analysis.

It is important to note that while the forests of the east Cascades exhibit a significant and visible legacy of effects from a policy of fire suppression, many of the mean fire return intervals for the forests of the west Cascades and Coast Range exceed the period of fire suppression (~100 years), and these forests in the west Cascades and Coast Range will not necessarily exhibit uncharacteristic levels of fuel accumulation (Brown et al. 2004). However, the potential lack of an uncharacteristic amount of fuel accumulation does not necessarily preclude these forests from future fuel reduction treatments or harvesting; thus we have included these possibilities in our analysis. The frequencies at which fuel reduction treatments are applied were designed to be reflective of literature-derived estimates of each ecosystem's mean fire return intervals, since forest management agencies are urged to perform fuel reduction treatments at a frequency reflective of the fire regimes and ecosystem-specific fuel levels (Franklin and Agee 2003, Dellasala et al. 2004). Treatment frequencies for the Coast Range and west Cascades were 100, 50, 25 years, plus an untreated control group, while treatment frequencies in the east Cascades were 25, 10, and 5 years, and an untreated control group.

We incorporated six different types of fuel reduction treatments largely based on those outlined in Agee (2002), Hessburg and Agee (2003), and Agee and Skinner (2005). Treatments 2–5 were taken directly from the authors' recommendations in these publications, treatment 1 was derived from the same principles used to formulate those recommendations, and treatment 6, clear-cutting, was not recommended in these publications but was incorporated into our analysis because it is a common practice in many Pacific Northwest forests. Treatments 1–4 were applied to all ecosystems, while treatments 5 and 6 were applied only to the west Cascades and Coast Range forests, as such treatments would be unrealistic at the treatment intervals necessary to reduce fire severity in the high-frequency fire regimes of the east Cascades *Pinus ponderosa* forests. Note that these treatments and combinations thereof are not necessarily utilized in each and every ecosystem. Managers of forests on the Oregon Coast, for example, would be unlikely to use prescribed fire as a fuel reduction technique. Our experimental design simply represents the range of all possible treatments that can be utilized for fuel reduction and is applied to all ecosystems purely for the sake of consistency.

1. *Salvage logging (SL)*.—The removal of large woody surface fuels limits the flame length of a wildfire that might enter the stand. Our method of ground fuel reduction entailed a removal of 75% of salvageable large woody materials in the stand. Our definition of salvage logging includes both standing and downed salvageable materials (sensu Lindenmayer and Noss 2006).

2. *Understory removal (UR)*.—Increasing the distance from surface fuels to flammable crown fuels will reduce the probability of canopy ignition. This objective can be accomplished through pruning, prescribed fire, or the removal of small trees. We simulated this treatment in STANDCARB by removing lower canopy trees in all cells.

3. *Prescribed fire (PF)*.—The reduction of surface fuels limits the flame length of a wildfire that might enter the stand. In the field, this is done by removing fuel through prescribed fire or pile burning, both of which reduce the potential magnitude of a wildfire by making it more difficult for a surface fire to ignite the canopy (Scott and Reinhardt 2001). We implemented this treatment in STANDCARB by simulating a prescribed fire at low severity for all cells.

4. *Understory removal and prescribed fire (UR + PF)*.—This treatment is a combination of treatments 2 and 3, where lower canopy trees were removed (treatment 2) before a prescribed fire (treatment 3) the following year for all cells.

5. *Understory removal, overstory thinning, and prescribed fire (UR + OT + PF)*.—A reduction in crown density by thinning overstory trees can make crown fire spread less probable (Agee and Skinner 2005) and can reduce potential fuels by decreasing the amount of biomass available for accumulation on the forest floor. Some have suggested that such a treatment will be effective only if used in conjunction with UR and PF (Perry et al. 2004). We simulated this treatment in STANDCARB by removing all lower canopy trees (treatment 2), removing upper canopy trees in 50% of the cells, and then setting a prescribed fire (treatment 3) the following year. This treatment was excluded from the east Cascades forests because it would be unrealistic to apply it at intervals commensurate with the high-frequency fires endemic to that ecosystem.

6. *Understory removal, overstory removal, and prescribed fire (clear-cutting) (UR + OR + PF)*.—Clear-cutting is a common silvicultural practice in the forests of the Pacific Northwest, notably on private lands in the Oregon Coast Range (Hobbs et al. 2002), and we included it in our analysis for two ecosystems (west Cascades and Coast Range) simply to gain insight into the effects of this practice on long-term C storage and wildfire severity. We simulated clear-cutting in STANDCARB by removing all upper and lower canopy trees, followed by a prescribed burn the following year. This treatment was excluded from the east Cascades forests because it would be unrealistic to apply it at intervals commensurate with the high-frequency fires endemic to that ecosystem.

7. *Control group*.—Control groups had no treatments performed on them. The only disturbances in these simulations were the same wildfires that occurred in every other simulation with the same MFRI.

In sum, our east Cascades analysis tested the effects of four fuel reduction treatment types, four treatment frequencies, including one control group, and two site mean fire return intervals (MFRI = 8 years, MFRI = 16 years). Our analysis of west Cascades and Coast Range forests tested the effects of six fuel reduction treatment types, four treatment frequencies, including one control group, and two site mean fire return intervals (MFRI = 143 years, MFRI = 230 years for the west Cascades, MFRI = 250 years, MFRI = 500 years for the Coast Range) on expected fire severity and long-term C dynamics. This design resulted in 32 combinations of treatment types for the east Cascades and 48 combinations of treatment types and frequencies for each fire regime in the west Cascades and Coast Range, with each treatment combination in each ecosystem replicated five times.

Biofuel considerations

Future increases in the efficiency of producing biofuels from woody materials may reduce potential trade-offs between managing forests for increased C storage and reduced wildfire severity. Much research is currently underway in the area of lignocellulase-based (as opposed to sugar- or corn-based) biofuels (Schubert 2006). If this area of research yields efficient methods of utilizing woody materials directly as an energy source or indirectly by converting them into biofuels such as ethanol, fuels removed from the forest could be utilized as an energy source and thus act as a substitute for fossil fuels by adding only atmosphere-derived CO_2 back to the atmosphere. However, the conversion of removed forest biomass into biofuels will only be a useful method of offsetting fossil fuel emissions if the amount of C stored in an unmanaged forest is less than the sum of managed stand TEC_{μ}, and the amount of fossil fuel emissions averted by converting removed forest biomass from a stand of identical size into biofuels over the time period considered. We performed an analysis on the extent to which fossil fuel CO_2 emissions can be avoided if we were to use harvested biomass directly for fuel or indirectly for ethanol production. We recognize that many variables need to be considered when calculating the conversion efficiencies of biomass to biofuels, such as the amount of energy required to harvest the materials, inefficiencies in the industrial conversion process, and the differences in efficiencies of various energy sources that exist even after differences in potential energy are accounted for. Rather than attempt to predict the energy expended to harvest the materials, the future of the efficiency of the industrial conversion process, and differences in energy efficiencies, we simply estimated the maximum possible conversion efficiency that can be achieved, given the energy content of these materials. The following procedure was used to estimate the extent to which fossil fuel CO_2 emissions can be avoided by substituting harvested biofuels as an energy source:

1) Estimate the mean annual biomass removal that results from intensive fuel reduction treatments.

2) Calculate the ratio of the amount of potential energy per unit C emissions for biofuels (both woody and ethanol) to the amount of energy per unit C emissions for fossil fuels.

3) Multiply the potential energy ratios by the mean annual quantity of biomass harvested to calculate the mean annual C offset by each biofuel type for each forest.

4) Calculate the number of years necessary for biofuels production to result in an offset of fossil fuel C emissions. This procedure was performed for two land-use histories: managed second-growth forests, and old-growth forests converted to managed second-growth forests.

Calculations for each ecosystem are shown in Appendix B.

Simulation spin-up

STANDCARB was calibrated to standardized silvicultural volume tables for Pacific Northwest stands. We then calibrated it to permanent study plot data from three experimental forests in the region (Fig. 1) to

TABLE 2. Treatment abbreviations.

Treatment abbreviation	Treatment
SL	salvage logging
UR	understory tree removal
PF	prescribed fire
UR + PF	understory tree removal + prescribed fire
UR + PF + OT	understory removal + prescribed fire + overstory thinning
UR + PF + OR	understory removal + prescribed fire + overstory removal

incorporate fuel legacies, which were taken from a 600-year spin-up simulation with fire occurrences generated from the exponential distribution in Eq. 1, where λ was based on each ecosystem's mean fire return interval. Spin-up simulations were run prior to the initiation of each series of fuel reduction treatments, and simulations were run for a total of 800 years for forests of the east Cascades, and a total of 1500 years for simulations of the west Cascades and Coast Range.

Data analysis

We employed a nonparametric multivariate analysis of variance, PerMANOVA (Anderson 2001), to test group-level differences in the effects of fuel reduction frequency and type on mean total ecosystem C storage and expected fire severity. PerMANOVA employs a test statistic for the F ratio that is similar to that of an ANOVA calculated using sum of squares, but unlike an ANOVA, PerMANOVA calculates sums of squares from distances among data points rather than from differences from the mean. PerMANOVA was used instead of a standard MANOVA because it was highly unlikely that our data would meet the assumptions of a parametric MANOVA. PerMANOVA analysis treated fuel reduction treatment type and treatment frequency as fixed factors within each respective fire regime for each ecosystem simulated. The null hypothesis of no treatment effect for different combinations of these factors on TEC_{μ} and $E[F_s]$ was tested by permuting the data into randomly assigned sample units for each combination of factors so that the number of replicates within each factor combination were fixed. Each of our 12 PerMANOVA tests incorporated 10 000 permutations using a Euclidian distance metric, and multiple pairwise comparison testing for differences among treatment types and treatment frequencies was performed when significant differences were detected (i.e., $P < 0.05$).

RESULTS

Results of the PerMANOVA tests indicate that mean expected fire severity ($E[F_s]$) and mean total ecosystem C storage (TEC_{μ}) were significantly affected by fuel reduction type ($P < 0.0001$), frequency ($P < 0.0001$), and interactions between type and frequency ($P < 0.0001$) in all three ecosystems. These results were significant for type, frequency, and interaction effects even when clear-cutting was excluded from the analysis for the west Cascades and Coast Range simulations, just as it was a priori for simulations of the east Cascades. When the PerMANOVA was performed on only one of our response variables ($E[F_s]$ or TEC_{μ}), groupwise comparisons of effects of treatment type showed that the most significant effects of treatment and frequency were related to TEC_{μ}. TEC_{μ} was strongly affected by treatment frequency for each fire regime in each ecosystem ($P < 0.0001$) and consistently showed an inverse relationship to the quantity of C removed in a given fuel reduction treatment, and was thus highly related to treatment type. $E[F_s]$, similar to TEC_{μ}, showed significant relationships with treatment frequency for all three ecosystems ($P < 0.0001$), with statistically significant differences among most treatment types. Boxplots of TEC_{μ} and $E[F_s]$ for each treatment type in each fire regime for each ecosystem are shown in Appendix C.

Fuel reduction treatments in east Cascades simulations reduced TEC_{μ} with the exception of one treatment type; UR treatments (see Table 2 for acronym descriptions) in these systems occasionally resulted in additional C storage compared to the control group. These differences were very small (0.6–1.2% increase in TEC_{μ}) but statistically significant (Student's paired t test, $P < 0.05$) for the treatment return interval of 10 years in the light fire severity regime No. 1 (MFRI = 8 years) and for all treatment return intervals in light fire severity regime No. 2 (MFRI = 16 years). The fuel reduction treatment that reduced TEC_{μ} the least was SL, which, depending on treatment frequency and fire regime, stored between 93% and 98% of the control group, indicating that there was little salvageable material. UR + PF, depending on treatment frequency and fire regime, resulted in the largest reduction of TEC_{μ} in east Cascades forests, storing between 69% and 93% of the control group.

Simulations of west Cascades and Coast Range forests showed a decrease in C storage for all treatment types and frequencies. Fuel reduction treatments with the smallest effect on TEC_{μ} were either SL or UR, which were nearly the same in effect. The treatment that most reduced TEC_{μ} was UR + OT + PF. Depending on treatment frequency and fire regime, this treatment resulted in C storage of between 50% and 82% of the control group for the west Cascades, and between 65% and 88% of the control group for the Coast Range. Simulations with clear-cutting (UR + OR + PF), depending on application frequency and fire regime, resulted in C storage that was between 22% and 58% of

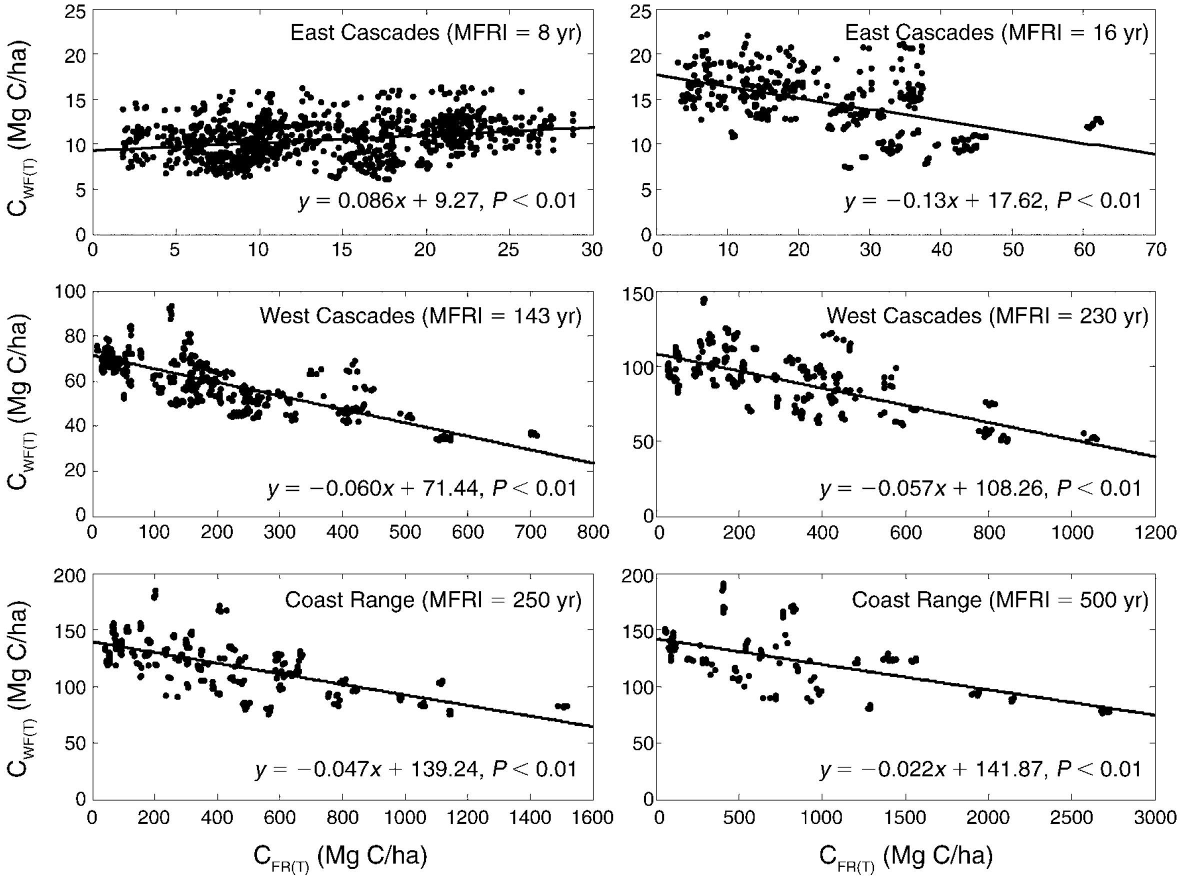

FIG. 2. Scatterplots of C removed in fuel reduction treatments between wildfires $C_{FR(T)}$ (representing fuel reduction [treatment]) and C lost in wildfires $C_{WF(T)}$ for the east Cascades, west Cascades, and Coast Range. Notice the differences in the axes scales. Also note the downward sloping trend for all ecosystems except for the east Cascades where MFRI = 8 years.

the control group for the west Cascades and between 44% and 87% of the control group for the Coast Range.

Similar to TEC_{μ}, $E[F_s]$ was significantly affected by fuel reduction treatments. Fuel reduction treatments were effective in reducing $E[F_s]$ for all simulations. UR treatments had the smallest effect on $E[F_s]$ in the east Cascades simulations and $E[F_s]$ in the east Cascades simulations was most affected by combined UR + PF treatments applied every five years, which reduced $E[F_s]$ by an average of 6.01 units (units range from 0 to 100, see Eq. 3) for stands with an MFRI = 8 years and by 11.08 units for stands with an MFRI = 16 years. In the west Cascades and Coast Range, $E[F_s]$ was least affected by UR treatments, similar to the east Cascades simulations. The most substantial reductions in $E[F_s]$ were exhibited by treatments that removed overstory as well as understory trees, as in treatments UR + OT + PF and UR + OR + PF. In the west Cascades simulations, depending on treatment frequency, $E[F_s]$ was reduced by an average of 11.72–15.68 units where the MFRI = 143 years and by an average of 3.92–26.42 units where the MFRI = 230 years when UR + OT + PF was applied. When UR + OT + PF was applied to the Coast Range, $E[F_s]$ was reduced by an average of 7.06–23.72 units where the MFRI = 250 years and by an average of 1.95–20.62 units where the MFRI = 500 years, depending on treatment frequency. Some UR + OR + PF treatments, when applied at a frequency of 25 years, resulted in $E[F_s]$ that was higher than that seen in UR + OT + PF in spite of lower TEC_{μ} in UR + OT + PF. A result such as this is most likely due to an increased presence of lower canopy tree fuels as a consequence of the increased lower stratum light availability that follows a clear-cut, as lower canopy tree fuels are among the highest weighted fuels in our simulated stands.

Modeled estimates of $E[F_s]$ were reflective of the mean amounts of C lost in a wildfire ($\bar{C}_{WF}$). $\bar{C}_{WF}$ was lower in the stands simulated with fuel reduction treatments compared to the control groups, with the exception of the east Cascades stands subjected to understory removal. Reductions in the amount of C lost in a wildfire, depending on treatment type and frequency, were as much as 50% in the east Cascades, 57% in the west Cascades, and 50% in the Coast Range. In the east Cascades simulations, amounts lost in wildfires were inversely related to the amounts of C removed in an average fire return interval for each ecosystem (Fig. 2), except for the Light Fire Regime No. 1 (MFRI = 8 years). Simulations in this fire regime revealed a slightly increasing amount of C lost in wildfires with increasing amounts removed, though amounts removed were nonetheless larger than the amounts lost in a typical wildfire.

Biofuels

Biofuels cannot offset the reductions in TEC_μ resulting from fuel reduction, at least not over the next 100 years. For example, our simulation results suggest that an undisturbed Coast Range *Tsuga heterophylla–Picea sitchensis* stand (where MFRI = 500 years) has a TEC_μ of 1089 Mg C/ha. By contrast, a Coast Range stand that is subjected to UR + OT + PF every 25 years has a TEC_μ of 757.30 Mg C/ha. Over a typical fire return interval of 450 years (estimated MFRI was 500 years, MFRI generated from the model was 450 years) this stand has 1107 Mg C/ha removed, a forest fuel/biomass production of 2.46 Mg C$\cdot$ha$^{-1}\cdot$yr^{-1}, which amounts to emissions of 1.92 Mg C$\cdot$ha$^{-1}\cdot$yr^{-1}and 0.96 Mg C$\cdot$ha$^{-1}\cdot$yr^{-1} that can be avoided by substituting biomass and ethanol, respectively, for fossil fuels (see calculations in Appendix B). This means that it would take 169 years for C offsets via solid woody biofuels and 339 years for C offsets via ethanol production before ecosystem processes result in net C storage offsets (see Fig. 3). Converting Coast Range old-growth forest to second-growth forest reduces the amount of time required for atmospheric C offsets to 34 years for biomass and 201 years for ethanol, and like all other biofuel calculations in our analysis, these are assuming a perfect conversion of potential energies. West Cascades *Tsuga heterophylla–Pseudotsuga menziesii* ecosystems (where MFRI = 230 years) that are subjected to UR + OT + PF every 25 years would require 228 years for C offsets using biomass as an offset of fossil-fuel-derived C and 459 years using ethanol. Converting west Cascades old-growth forest to second-growth forest reduces the amount of time required for atmospheric C offsets to 107 years for biomass fuels and 338 years for ethanol. Simulations of east Cascades *Pinus ponderosa* ecosystems had cases where stands treated with UR stored more C than control stands, implying that there is little or no trade-off in managing stands of the east Cascades for both fuel reduction and long-term C storage.

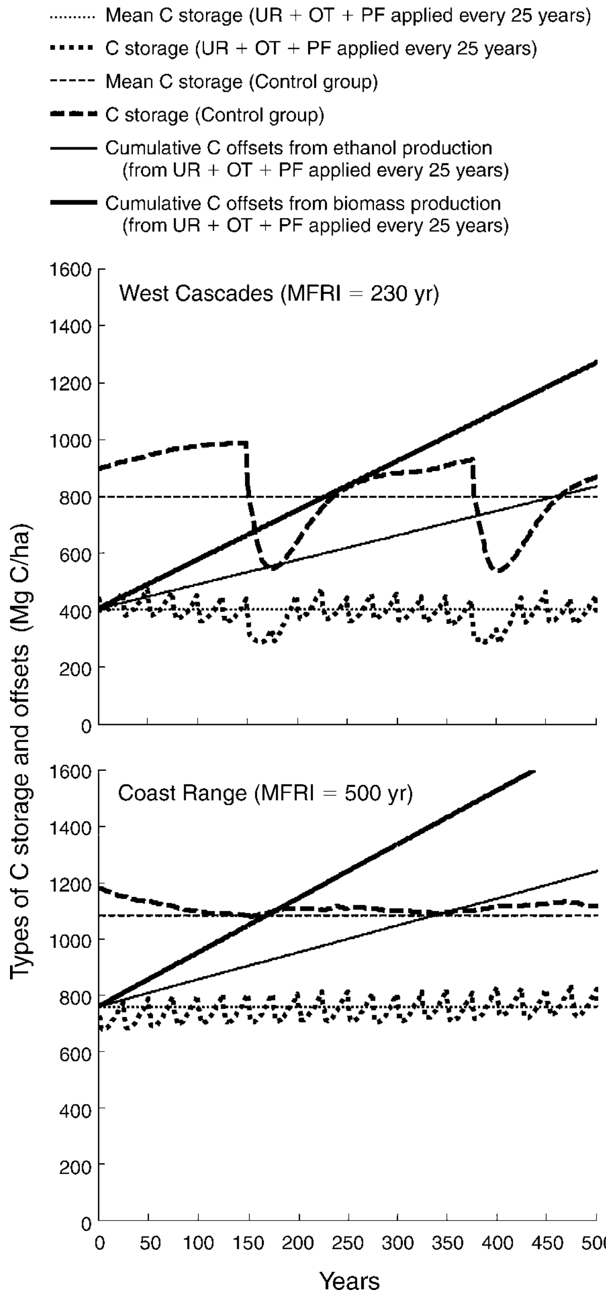

FIG. 3. Time series plots of C storage, mean C storage, and biofuels offsets for control groups and fuel reduction treatment UR + OT + PF (understory removal + overstory thinning + prescribed fire) applied to a second-growth forest every 25 years for the west Cascades and Coast Range. East Cascades simulations were excluded from this plot because there was little or no trade-off incurred in managing these forests for both fuel reduction and C sequestration.

DISCUSSION

We employed an ecosystem simulation model, STANDCARB, to examine the effects of fuel reduction on expected fire severity and long-term C dynamics in three Pacific Northwest ecosystems: the *Pinus ponderosa* forests of the east Cascades, the *Tsuga heterophylla–Pseudotsuga menziesii* forests of the west Cascades, and the *Tsuga heterophylla–Picea sitchensis* forests of the Coast Range. Our fuel reduction treatments for east Cascades forests included salvage logging, understory removal, prescribed fire, and a combination of understory removal and prescribed fire. West Cascades and Coast Range simulations included these treatments as well as a combination of understory removal, overstory thinning, and prescribed fire. We also examined the effects of clear-cutting followed by prescribed fire on expected fire severity and long-term C storage in the west Cascades and Coast Range.

Our results suggest that fuel reduction treatments can be effective in reducing fire severity, a conclusion that is shared by some field studies (Stephens 1998, Pollet and

Omi 2002, Stephens and Moghaddas 2005) and modeling studies (Fulé et al. 2001). However, fuel removal almost always reduces C storage more than the additional C that a stand is able to store when made more resistant to wildfire. Leaves and leaf litter can and do have the majority of their biomass consumed in a high-severity wildfire, but most of the C stored in forest biomass (stem wood, branches, coarse woody debris) remains unconsumed even by high-severity wildfires. For this reason, it is inefficient to remove large amounts of biomass to reduce the fraction by which other biomass components are consumed via combustion. Fuel reduction treatments that involve a removal of overstory biomass are, perhaps unsurprisingly, the most inefficient methods of reducing wildfire-related C losses because they remove large amounts of C for only a marginal reduction in expected fire severity. For example, total biomass removal from fuel reduction treatments over the course of a high-severity fire return interval (MFRI = 230 years) in the west Cascades could exceed 500 Mg C/ha while reducing wildfire-related forest biomass losses by only ~70 Mg C/ha in a given fire (Fig. 2). Coast Range forests could have as much as 2000 Mg C/ha removed over the course of an average fire return interval (MFRI = 500 years), only to reduce wildfire-related biomass combustion by ~80 Mg C/ha (Fig. 2).

East Cascades simulations also showed a trend of decreasing $E[F_s]$ with increasing biomass removal, though a higher TEC_μ was seen in some understory removal treatments compared to control groups. We believe that the removal of highly flammable understory vegetation led to a reduction in overall fire severity that consequently lowered overall biomass combustion, thereby allowing increased overall C storage. Such a result may be indicative of actual behavior under field conditions, but the very low magnitude of the differences between the treated groups and the control group (0.6%–1.2%) suggests caution in assuming that understory removal in this or any ecosystem can be effective in actually increasing long-term C storage. Furthermore, we recognize that the statistically significant differences between the treated and control groups are likely to overestimate the significance of the differences between groups that would occur in the field, as the differences we are detecting are modeled differences rather than differences in field-based estimates. Field-based estimates are more likely to exhibit higher inter- and intrasite variation than modeled estimates, even when modeled estimates incorporate stochastic processes, such as those in STANDCARB. Our general findings, however, are nonetheless consistent with many of the trends revealed by prior field-based research on the effects of fuel reduction on C storage (Tilman et al. 2000), though differences between modeled and field-based estimates are also undoubtedly apparent throughout other comparisons of treated and control stands in our study.

We note an additional difference that may exist between our modeled data and field conditions. Our study was meant to ascertain the long-term average C storage (TEC_μ) and expected fire severities ($E[F_s]$) for different fuel reduction treatment types and application frequencies, a goal not be confused with an assessment of exactly what treatments should be applied at the landscape level in the near future. Such a goal would require site-specific data on the patterns of fuel accumulation that have occurred in lieu of the policies and patterns of fire suppression that have been enacted in the forests of the Coast Range, west Cascades, and east Cascades for over a century. We did not incorporate the highly variable effects of a century-long policy of fire suppression on these ecosystems, as we know of no way to account for such effects in a way that can be usefully extrapolated for all stands in the landscape. *Pinus ponderosa* forests may exhibit the greatest amount of variability in this respect, as they are among the ecosystems that have been most significantly altered as a result of fire suppression (Veblen et al. 2000, Schoennagel et al. 2004, Moeur et al. 2005). Furthermore, additional differences may be present in our estimates of soil C storage for the east Cascades. Our estimates of soil C storage match up very closely with current estimates from the Pringle Falls Experimental Forest, but it is unclear how much our estimates would differ under different fuel reduction treatment types and frequencies. Many understory community types exist in east Cascades *Pinus ponderosa* forests (i.e., *Festuca idahoensis*, *Purshia tridentata*, *Agropyron spicatum*, *Stipa comata*, *Physocarpus malvaceus*, and *Symphoricarpos albus* communities) (Franklin and Dyrness 1988). An alteration of these communities may result from fuel reduction treatments such as understory removal or prescribed fire, leading to a change in the amount and composition of decomposing materials, which can influence long-term belowground C storage (Wardle 2002). Furthermore, there may be an increase in soil C storage resulting from the addition of charcoal to the soil C pool, whether from prescribed fire or wildfire (DeLuca and Aplet 2008).

By contrast, ecosystems with lengthy fire return intervals, such as those of the west Cascades and Coast Range, may not be strongly altered by such a policy, as many stands would not have accumulated uncharacteristic levels of fuel during a time of fire suppression that is substantially less than the mean fire return intervals for these systems. Forests such as these may actually have little or no need for fuel reduction due to their lengthy fire return intervals. Furthermore, fire severity in many forests may be more a function of severe weather events rather than fuel accumulation (Bessie and Johnson 1995, Brown et al. 2004, Schoennagel et al. 2004). Thus, the application of fuel reduction treatments such as understory removal is thought to be unnecessary in such forests and may provide only limited effectiveness (Agee and Huff 1986, Brown et al. 2004). Our results provide additional support for this notion, as they show a minimal effect of understory removal on expected fire severity in these forests, and if in fact climate has far stronger control over fire severity in these forests than fuel abundance, then the small reductions in expected fire severity that we have modeled for these fuel reduction treatments may be even smaller in reality.

We also note that the extent to which fuel reductions in these forests can result in a reduction in fire severity during the extreme climate conditions that lead to broad-scale catastrophic wildfires may be different from the effects shown by our modeling results, and are likely to be an area of significant uncertainty. Fuel reductions, especially overstory thinning treatments, can increase air temperatures near the ground and wind speeds throughout the forest canopy (van Wagtendonk 1996, Agee and Skinner 2005), potentially leading to an increase in fire severity that cannot be accounted for within our particular fire model. In addition to the microclimatic changes that may follow an overstory thinning, logging residues may be present on site following such a procedure, and may potentially nullify the effects of the fuel reduction treatment or may even lead to an increase in fire severity (Stephens 1998). Field-based increases in fire severity that occur in stands subjected to overstory thinning may in fact be an interaction between the fine fuels created by the thinning treatment and the accompanying changes in forest microclimate. These microclimate changes may lead to drier fuels and allow higher wind speeds throughout the stand (Raymond and Peterson 2005). While our model does incorporate the creation of logging residue that follows silvicultural thinning, increases in fire spread and intensity due to interactions between fine fuels and increased wind speed are neglected. However, we note that even if our model is failing to capture these dynamics, our general conclusion that fuel reduction results in a decrease in long-term C storage would then have even stronger support, since the fuel reduction would have caused C loss from the removal of biomass while also *increasing* the amount that is lost in a wildfire.

The amounts of C lost in fuel reduction treatments, whether nearly equal to or greater than our estimates, can be utilized in the production of biofuels. It is clear, however, that an attempt to substitute forest biomass for fossil fuels is not likely to be an effective forest management strategy for the next 100 years. Coast Range *Tsuga heterophylla–Picea sitchensis* ecosystems have some of the highest known amounts of biomass production and storage capacity, yet under the UR + OT + PF treatment a 169-year period is necessary to reach the point at which biomass production will offset C emitted from fossil fuels, and 338 years for ethanol production. Likewise, managed forests in the west Cascades require time scales that are too vast for biofuel alternatives to make a difference over the next 100 years. Even converting old-growth forests in these ecosystems would require at least 33 and 107 years for woody biomass utilization in the Coast Range and west Cascades, respectively, and these figures assume that all possible energy in these fuels can be utilized. Likewise, our ethanol calculations assumed that the maximum theoretical ethanol yield of biomass is realized, which has yet to be done (Schubert 2006); a 70% realization of our maximum yield is a more realistic approximation of contemporary capacities (Galbe and Zacchi 2002).

In addition to these lags, management constraints could preclude any attempt to fully utilize Pacific Northwest forests for their full biofuels production potential. Currently in the Pacific Northwest there are $\sim 3.6 \times 10^6$ ha of forests in need of fuel reduction treatments (Stephens and Ruth 2005), and in 2004 the annual treatment goal for this area was 52 000 ha (1.44%). Unless a significantly larger fuel reduction treatment workforce is employed, it would take 69 years to treat this area once, a period that approximates the effective duration of fire suppression (Stephens and Ruth 2005). The use of SPLATs (strategically placed area treatments) may be necessary to reduce the extent and effects of landscape-level fire (Finney 2001). SPLATs are a system of overlapping area fuel treatments designed to minimize the area burned by high-intensity head fires in diverse terrain. These treatments are costly, and estimates of such treatment costs may be underestimating the expense of fuel reduction in areas with high-density understory tree cohorts that are time consuming to extract and have little monetary value to aid in offsetting removal expenses (Stephens and Ruth 2005). Nevertheless, it is clear that not all of the Pacific Northwest forests that are in need of fuel reduction treatments can be reached, and the use of strategically placed fuel reduction treatments such as SPLATs may represent the best option for a cost-effective reduction in wildfire severity, particularly in areas near the wildland–urban interface. However, the application of strategically placed fuel reduction treatments is unlikely to be a sufficient means in itself toward ecosystem restoration in the forests of the east Cascades. Stand-level ecosystem restoration efforts such as understory removal and prescribed fire may need to be commenced once landscape-level reductions in fire spread risk have been implemented.

Conclusions

Managing forests for the future is a complex issue that necessitates the consideration of multiple spatial and temporal scales and multiple management goals. We explored the trade-offs for managing forests for fuel reduction vs. C storage using an ecosystem simulation model capable of simulating many types of forest management practices. With the possible exception of some xeric ecosystems in the east Cascades, our work suggests that fuel reduction treatments should be forgone if forest ecosystems are to provide maximal amelioration of atmospheric CO_2 over the next 100 years. Much remains to be learned about the effects of forest fuel reduction treatments on fire severity, but our results demonstrate that if fuel reduction treatments are effective in reducing fire severities in the western hemlock–Douglas-fir forests of the west Cascades and the western hemlock–Sitka spruce forests of the Coast Range, it will come at the cost of long-term C storage, even if harvested materials are utilized as biofuels. We agree with the policy recommendations of Stephens and Ruth (2005) that the application of fuel reduction treatments may be essential for ecosystem restoration in forests with uncharacteristic levels of fuel buildup, as is often the case in the xeric forest ecosystems of the east Cascades. However, this is often impractical and may even be counterproductive in ecosystems that do not exhibit uncharacteristic or undesirable levels of fuel accumulation. Ecosystems such as the western hemlock–Douglas-fir forests in the west Cascades and the western hemlock–Sitka spruce forests of the Coast Range may in fact have little sensitivity to forest fuel reduction treatments and may be best utilized for their high C sequestration capacities.

This work was conducted by the Fire Research Consensus expert working group supported in part by Science for Nature and People Partnership (SNAPP) — a partnership of The Nature Conservancy, the Wildlife Conservation Society, and the National Center for Ecological Analysis and Synthesis (NCEAS) at University of California, Santa Barbara — and by the Wilburforce Foundation.

The Steering Committee (Craig Allen, Paul Hessburg, Penelope Morgan, Max Moritz, Dennis Odion, Christopher Topik, and Thomas Veblen) is collectively responsible for the work summarized here, and we adhered to a Project Charter that clarified our goals, roles, and responsibilities. The contributions of Ian McCullough were valuable and substantial enough to merit coauthorship. Excellent project facilitation was provided by Julian Griggs of the Dovetail Consulting Group. The substantial suggestions of Rachel White, science writer/editor for the US Forest Service, were very helpful; additional constructive comments were provided in the USGS internal review process.

Many scientists and managers contributed to this report, either through input to a questionnaire or by providing feedback on interim drafts. Please refer to the online supplemental materials associated with the questionnaire and review process, which include a record of contributors and other documents. The project would not have been possible without the time, effort, and trust of our colleagues, and we are grateful for all contributions.

Executive Summary

For millennia, wildfires have markedly influenced forests and non-forested landscapes of the western United States (US), and they are increasingly seen as having substantial impacts on society and nature. There is growing concern over what kinds and amounts of fire will achieve desirable outcomes and limit harmful effects on people and nature. Moreover, the increasing complexity surrounding cost and management of wildfires suggests that science should play a more prominent role in informing decisions about the need for fire in nature, and the need for society to adapt to the inevitable occurrence of different kinds and amounts of fire and smoke.

Scientists widely view the natural wildfire regime as essential to western US forest ecosystem functioning. However, debates continue over how much low-, moderate-, and high-severity fire is “natural” or desirable in these forests. Ongoing disagreement centers on the characteristics and importance of historical proportions and patch size distributions of low-, moderate-, and high-severity fires of dry, moist, and cold forests, and on the ecological consequences of changing fire-patch patterns and relative abundances. Scientists also debate the relative importance of climate and extreme weather versus fuel as drivers of high-severity fire, as well as the effectiveness and value of fuel treatments for reducing risks of undesired fire effects.

Climate research shows that we should expect shifting future climates in all ecoregions. These expected changes make it difficult for scientists, land managers, and decision-makers to know the degree to which future forest management should be informed by historical conditions. There also is disagreement about how to make western forests more resilient to future disruptions in both climatic and fire regimes. To complicate matters, areas of scientific agreement -- the “common ground” shared by those in the research community -- are poorly articulated. Thus, the focus of the Fire Research Consensus (FRC) project has been to identify common ground among scientists, and provide a summary that can inform management. Land and fire managers are one audience for this report, as are stakeholders and the interested public.

Our analysis, which results from extensive scientific literature reviews and questionnaires sent to western fire scientists and land managers, is summarized in nine key topics:

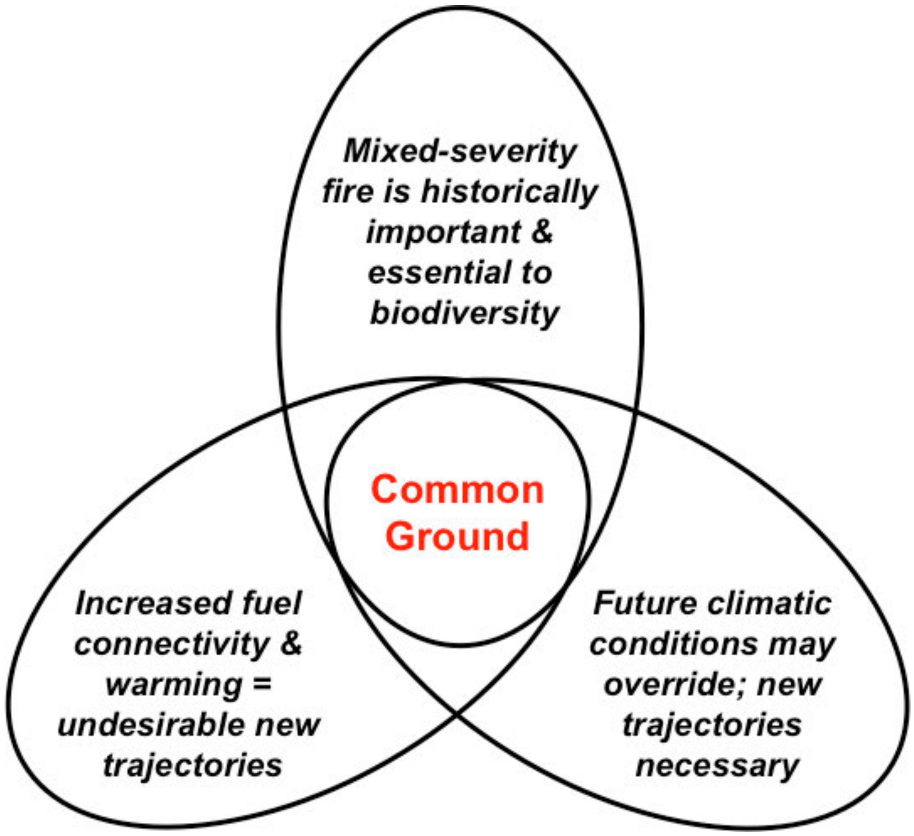
A. Fire history and fire ecology vary with geography.
B. Human impacts and management history vary with geography.
C. Fire is a keystone process, which occurs in almost all western US forest types.
D. Knowledge of historical range of variability (HRV) is useful but does not dictate land management goals.
E. Forest structure, composition, and fuels have changed, affecting burn severity and fire extent.
F. Climate and fuels both influence current fire sizes and their severities.
G. The role of changing climatic conditions is increasingly important.
H. Multiple fire ecology and fire history research approaches can be useful for characterizing fire regimes.
I. Many existing fire management tools and strategies can be useful moving forward.

We found much common ground that will be useful to scientists, managers, citizens, and policy decision-makers. For example, there is wide agreement among scientists that fire is one of the most essential influences on western forests and that more fire is needed on most landscapes, but not all wildfire behavior or extent will do. Fires can produce more positive benefits and fewer negative impacts when they burn with an ecologically appropriate mix and pattern of low, moderate, and high severity. Managers will need assistance and funding to create landscape conditions that favor more desirable fire behavior at broad spatial scales. Note that much societal impact from western wildfires occurs in non-forested landscapes that are not covered in this report, where findings would differ from those reported here for forested landscapes. We summarize additional key points below.

High-severity fire

Respondents disagreed about whether large, high-severity fires have increased to a significant and measurable degree in all forest types *in comparison to historical fire regimes* (i.e., prior to modern fire suppression). There was strong agreement that in dry pine forests at low elevations there has been either an observed increase in high-severity fires or an increase in the potential for fires of elevated severity as the result of increased abundance and connectivity of woody fuels since the late 19th century. There was similar strong agreement about dry mixed-conifer forests in the Inland Northwest, Pacific Southwest, and Inland Southwest (Arizona and New Mexico) that there has been an increase in high-severity fires and an increase in the potential for fires of elevated severity. There was less agreement about the changes in extent, and causes of changes in extent, of high-severity fires in moist mixed-conifer forests. Although there is general agreement that high-severity fires historically played an important role in moist mixed-conifer and cold subalpine forests, there is strong disagreement over the degree of changes in burn severity patch-size distributions and associated successional conditions for these forests between different regions.

Opinions also vary over the consequences of any increases in fire severity. For most dry forests, although there may be some disagreement about trends in burn severity and their causes, there is broad agreement that under current and projected climate, post-fire forest resilience is less than in the past. Some forest habitats, particularly at drier sites, but also in some moist and cold forest sites, show evidence of converting to more flammable non-forest vegetation or less dense forests following recent fires where large patches burn severely, especially if reburned. Reburn potential may depend on the interaction of vegetation, weather, rate of fire spread, time since prior fire, ignitions and fire suppression. Opinions are varied concerning the ecological consequences of departures from historical patterns of fire severity in various mixed conifer and subalpine forests. For example, one viewpoint supports the historical precedence of mixed-severity fire (including relatively large patches of high-severity fire), and the concept that pyrodiversity begets biodiversity. Another viewpoint asserts that increased woody fuel connectivity in combination with a warming climate trend is setting large areas of landscapes on fundamentally new trajectories, with significant undesirable ecological and societal consequences. Still a third viewpoint emphasizes that climatic changes increasingly are of overriding importance, and that new trajectories are unavoidable and thus may be considered desirable in many cases to incrementally foster necessary ecosystem transitions. The figure below characterizes these divergent viewpoints – typical of many areas of disagreement we addressed – and the potential common ground among them.



Uncertainties associated with relative proportions of different burn severities and patch-size distributions combine to cloud key points of consensus that have important management implications. We suggest that resolving many fire science disagreements depends on greater consideration of specific geographical context. This may imply that a narrow range of field experience can limit one's ability to accept findings that depart from that range. A logical way forward is to increase in-depth cross-regional field research experiences of the fire research community. Cross-regional comparisons of top-down and bottom-up determinants of fire activity in similar forest cover types is a fertile area of future research to examine how differences in seasonality, productivity, understory fuels, land use history, and other factors may explain some of the reported geographical differences in historical fire regimes in broadly similar forest types.

There are several reasons for the disagreements about the amount and roles of past higher-severity fire. Both scientists and managers often transfer concepts and findings from one place to another, yet we know that "no one size fits all" for historical fire regimes, even within the same forest type. Likewise, the extent of change in abundance and connectivity of woody fuels varies across forest types and ecoregions. Some of the disagreement derives from use of different scientific approaches. For instance, there is strong debate about the fire regime inferences made from historical and modern tree inventory data, simulation models, and other approaches. We believe that application of diverse research approaches will be useful going forward. Further, multiple approaches will be useful in "triangulating" interpretations for which there is some scientific consensus (see Topic H). We challenge fire scientists who do not share similar perspectives on historical fire regimes in particular ecosystems to engage in civil discourse to better understand the reasons for their disagreement, and to objectively communicate those reasons to managers and other stakeholders. We are heartened by the positive outcomes achieved by some previous attempts when small or large groups work together to find common ground.

The Wildland Urban Interface and Beyond

Respondents strongly agreed on the need for fuel treatments and fire suppression to protect human infrastructure within and adjacent to the wildland urban interface (WUI). There is a strong consensus that preventing undesired human-set fires in the WUI is essential to reducing societal vulnerability. The strategies for managing fire may be different within and adjacent to the WUI than in areas far from the WUI. However, what fire managers do beyond the WUI has implications for fire behavior approaching the WUI, forest resilience, smoke production and its human impacts, water quality, and many other ecosystem services people value.

Fuels management alone, especially if limited to public land, will be insufficient to address the vulnerability of WUI communities to fires. Fuels management will be important for influencing how wildfire behavior will approach the WUI. Thus, policies to make current WUI communities more fire adapted (e.g., implementing current WUI codes) are a critical piece of the puzzle, as are changes in land use policies that influence where and how future WUI areas develop, and the spatial extent and arrangement of managed and wildfire fuel treatments. Controlling human ignitions is important to address fire risk, especially in landscapes where ignitions have the potential to radically increase fire frequency. Communities in fire-prone areas need to learn to live with fire and increase their use of fire and other methods to reduce susceptibility to unacceptable fire damage.

Pattern and Process for Fires in Forest Landscapes

Heterogeneity of fire effects, including the patterns of patches created by fires of all severities, is important to forest resilience to future fires (see Topic E). The scale of the problem is vast, however, so it is likely that the scale of analysis and solutions (e.g., fraction of landscape treated via wildfire use) is also necessarily vast. There are potentially profound implications for forest regeneration, watershed protection, biodiversity, and carbon sequestration if the proportion and spatial pattern of area burned with high-severity fire change. Where wildfires severely burn large areas of forest, local elimination of conifer tree seed sources and reduced tree regeneration under emergent warmer-drier conditions can occur. Large areas of forest are converting to persistent grasslands or shrublands post-fire in some regions. Even relatively small changes in the proportion of large patches can alter system behavior for decades and even centuries. Thus, the patch-size distributions of both forest and non-forest patches are of concern to policy makers, scientists, and managers.

Climate, Fuels, and Implications of Landscape Change

Both fuel and climate are important drivers of fire activity. Increased woody fuel connectivity in combination with a warming climate trend are setting large areas of many landscapes on new trajectories where very large patches burn with high severity. There is agreement that all fire regimes are the product of interactions among varying degrees of top-down climate and weather forcing and bottom-up spatio-temporal controls of local topography and fuels, which reflect legacies of past fires and other agents altering vegetation. In other words, fires respond to interacting influences of climate, weather, fuels, topography, legacies of prior disturbance, and management. The relative importance of these factors varies across landscapes and through time.

While climate is of increasing importance, fuels management is also important. Indeed, fuels are the main landscape characteristic that management can change. But an ecologically and socially appropriate mix of fuel management tools and practices is needed. More flexible management of wildfires and prescribed fires will be useful, depending on local objectives and conditions, to increase the footprint of land areas showing reduced surface and canopy fuel abundance and connectivity. Increased use of prescribed burning combined with thinning will be helpful where forest conditions are not currently manageable via wildfires and prescribed fires alone, and where high certainty about fire perimeter control and fire behavior are key objectives (e.g., adjacent to WUI). Some respondents suggested that accepting a more proactive approach to fire and fuels management on public lands may initially be more expensive, but may reduce overall costs and improve climate change adaptation in the long-term. Other respondents questioned the practicality and effectiveness of fuel treatments under a changing climate. Notably, in their responses, respondents did not integrate the concomitant effects of weather, climate, topography, and fuel abundance.

Decades of research in landscape ecology show that emergent properties have central importance to ecosystems and their pattern and process regulation, whereas many recent studies of climate-driven fire and vegetation change are less focused on local-scale feedbacks and emergent patterns. This difference creates a fundamental problem in linking climate change and landscape ecology research. Climate models assume that top-down climate covariates drive temperature, precipitation, and solar radiation conditions. Landscape ecology research shows that those top-down inputs can be highly modified by meso- and fine-scale bottom-up environmental controls to produce emergent climatic conditions that are strictly speaking neither the top-down or bottom-up inputs, but are influenced by these inputs. Climatic forcing alone poorly explains the shifts in landscape patterns because lagged patterns of historical disturbances continue to influence emergent patterns, under all but the most extreme events. The path forward to more effective projection of future fire and landscape change includes better integration of feedbacks from landscape ecological models into climate-driven models of future fire and landscape change. Broad-scale studies are still needed to tease apart the roles of changing climate and changes in fuels in the observed trends in frequency of large fires.

Effective Management will Depend on Both Science and Trust

Our understanding of historical fire regimes can inform decision-making; indeed, such evidence-based decision-making can build trust. While history does not provide precise prescriptions for managing landscapes, it does offer precautionary principles. Adaptive resilience for the future will require applying what we learn from history to some future range of variability, where fires burn and ecosystems respond in both similar and different ways.

At the same time, fire science points to complex patterns that vary with local conditions. Unique ranges of vegetation and fuel patterns are the result of interactions among regional climate, topography, landforms, geology, and biotic communities of an area, along with associated meso- to fine-scale pattern heterogeneity. Thus, no single solution, such as logging or limiting all logging, will accomplish desired objectives in all forests. Further, any management, including no intervention, has consequences, so all decisions need monitoring to evaluate the assumptions of management. Effective monitoring can improve knowledge, and through collective learning can build common understanding and trust.

Fire management can become more proactive and strategic. Existing tools, such as mechanical fuel treatments, prescribed fire, prevention of accidentally-ignited human fires, and managing wildfires, will all be useful, but adaptation and mitigation responses to climate change and changing fire activity will require using these tools in strategic ways to fit area-specific goals. Some past disagreements about fire and fuel management strategies may be due to lack of clarity about specific goals, such as resident and firefighter safety, cost reduction, biodiversity issues, and ecosystem resilience under a changing climate.

The timing of fires is important, particularly in the context of a changing climate. While recognizing that wildfire seasons are long and getting longer, we must also take advantage of the milder fire weather and associated effects of fires in the “shoulder seasons.” Managers may find that both less-aggressive fire suppression and expanded use of managed wildfire under relatively moderate weather conditions can aid them where reducing the vulnerability of people and natural resources to fires is the objective. Managing wildfires may be one important way to achieve relatively widespread vegetation change at the spatial scales and in the short timeframe needed.

One of the grand challenges of fire management is balancing the reality that wildfires will occur and are needed by western forest ecosystems, yet people, property, and economies need protection from the adverse effects of fire. Another grand and fairly urgent challenge is discovering the tipping points of transformative change for various forest landscapes in their respective geographies, where large, high severity fires (regardless of whether they are considered unprecedented or not) may tip forest ecosystems into persistent non-forest states by constraining tree regeneration opportunities. Particularly as climate changes, we also need a deeper understanding of which landscapes may not be able to sustain forests in the future and how fast such transitions are likely to occur. It is clear that our western history of substantial forest fire activity will continue, one way or another -- many fires will occur in the future and some will be large. Ultimately, we must find ways to both sustainably use and live with fires that are well-adapted to both ecosystem and societal needs of local landscapes.

Introduction

Wildfires have, for millennia, markedly influenced forests and non-forested landscapes of the western United States (US), and they are increasingly seen as having substantial impacts on society and nature, even though less area burns in many forests than burned historically. Informed planning and fire management preparations and responses are thus becoming more important, with lives, property, government expenditures, biodiversity, and ecosystem services at stake. Federal and state firefighting costs now routinely exceed available funds, which are then either borrowed or permanently taken from funds that would ordinarily support resource management activities.

At the same time, climate research shows that we should expect to experience future climates in many ecoregions that will, to varying degrees, differ from those of the recent past. These expected changes make it more difficult for scientists, land managers, and decision makers to know the degree to which future forest management and wildfire policy should be informed by the past. The increasing complexity surrounding cost and management of wildfires suggests that science might play a prominent role in informing decisions about the need for fire in nature, and the need for society to adapt to fire.

Scientists widely view fire as a normal part of ecosystem functioning and one of the most essential influences on forests of the western US. They also recognize that fire directly affects the health and wellbeing of people living near fire-prone landscapes, influencing the water, wildlife, recreation, forest products, and other aesthetic and spiritual benefits these landscapes provide. However, scientific debates continue over several important fire-related topics, including: how much low-, moderate-, and high-severity fire[1] is "natural" or desirable in varied forests across the western US; the relative importance of climatic versus fuel factors as drivers of high-severity fire; and the effectiveness and value of fuel treatments for reducing risks of undesired fire effects.

There is also apparent disagreement about how to make these forests more resilient to future disruptions in both climatic and fire regimes. In many policy and management arenas—from national forest policy to state, county and Tribal-level management—debates about wildfire have sometimes slowed effective integration of research into public policy, and hindered informed planning and management. Much is clearly at stake.

[1] Low, moderate, and high burn severity are usually defined in the western USA by level of mortality of overstory trees or shrubs within individual fires. Low-severity burns are often surface fires with scattered tree torching, where most trees survive (e.g., <20% mortality), while high-severity burns are often stand-replacing fires that kill >70% of the overstory trees (derived from some mix of surface and crown fire behavior). Moderate-severity fires include areas with intermediate levels of overstory mortality (20-70% of basal area or canopy cover of a given patch) from fire. All low-, moderate- and high-severity fire regimes result in intermixed patches of burned and unburned vegetation, but the scale of patchiness differs. Note that we use moderate for intermediate effects of individual fires and mixed for fire regimes. From Agee (1993) Fire ecology of Pacific Northwest forests. Island Press.

Overview: Purpose and Scope of this Report

This report summarizes work of the Fire Research Consensus (FRC) project, which formed to provide insights for scientists, land managers, and human communities with respect to recent controversies over the role of low-, moderate-, and high-severity fires in western US forests. The goal has been to clarify agreements, disagreements, research needs, and possible management implications of scientific common ground. Our hope is that stakeholder groups will avoid the selective use of particular scientific papers to argue for their particular ends. Instead, they will be able to point to key shared assumptions, common understandings considering the entire body of fire science literature, and terminology to support decision-making in constructive ways. This should facilitate better awareness and application of existing and future scientific findings. In particular, land and fire managers are a key audience for this report, as are other stakeholders and the interested public engaged in discussions about land management. Future work is needed to more directly emphasize fire-related research needs and open scientific questions.

We acknowledge that public land management agencies are charged by society to make management decisions, and take associated actions on those lands. Actions are constrained and focused by existing laws, land use plans, policies, and pertinent Acts. We further acknowledge that management agencies are required to accomplish annually-funded land management targets, which can be at odds with some societally-held land-use values, or other landscape and resource management goals. Our focus on areas of broad scientific agreement within the fire science community is intended to make the application of fire science more useful to land management agencies and lawmakers, but it does not, and cannot, resolve diverse social, economic, philosophical, and political debates about preferred land use values across a spectrum of ideologies and management methods. These societal debates play out through broader public conversations and decision-making processes that are only partly informed by fire science. Key roles of fire science are to provide high-quality information to support high-quality societal conversations and decision-making about land (and fire) management, and to assist in monitoring outcomes. In our implications comments at the close of each major section, we provide case examples of how areas of agreement might be considered in the development of management applications.

As a prelude to more in-depth coverage in the report, our analysis can be summarized to nine key topics:

A. Fire history and fire ecology vary with geography.
B. Human impacts and management history vary with geography.
C. Fire is a keystone process, which occurs in almost all western US forest types.
D. Knowledge of historical range of variability (HRV) is useful but does not dictate land management goals.
E. Forest structure, composition, and fuels have changed, affecting burn severity and fire extent.
F. Climate and fuels both influence current fire sizes and their severities.
G. The role of changing climatic conditions is increasingly important.
H. Multiple fire ecology and fire history research approaches can be useful for characterizing fire regimes.
I. Many existing fire management tools and strategies can be useful moving forward.

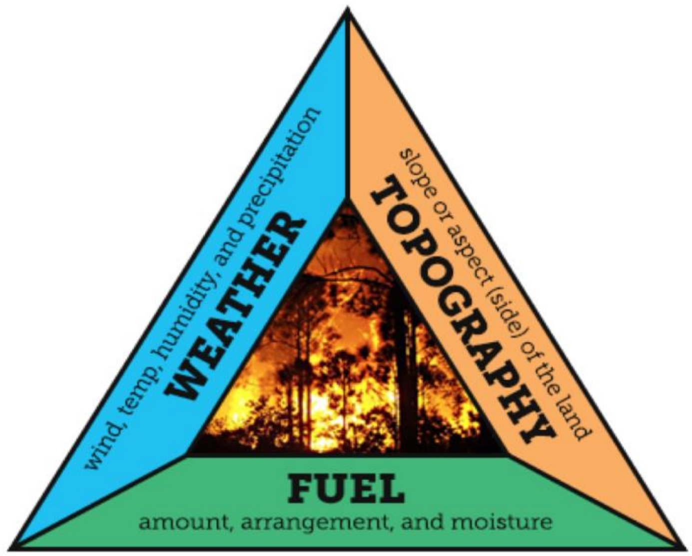
Given the intertwined nature of these topics, there is repetition of themes among some of the material presented. The FRC steering committee believes that the summaries derived from this work are representative of current fire science and can usefully inform fire and land management. It is our intent that in the future, land managers and community leaders will be able to better understand, and more accurately and precisely communicate, the need for fire in the environment and how to better prepare for its impacts. Further, the goals and priorities for fuel and climate change adaptation treatments will be better understood, such that responses to them are less polarized. Scientists will have a clearer picture of the key research questions that underpin current debates. Instead of a focus on disagreements, a deeper appreciation of the research that is agreed upon will allow us all to be more deliberate and proactive when thinking about and managing wildfire environments in the West.

Note that much societal impact from western wildfires occurs in non-forested landscapes that are not covered in this report, where findings would differ from those reported here for forested landscapes.

Fundamental Principles vs. “Common Ground”

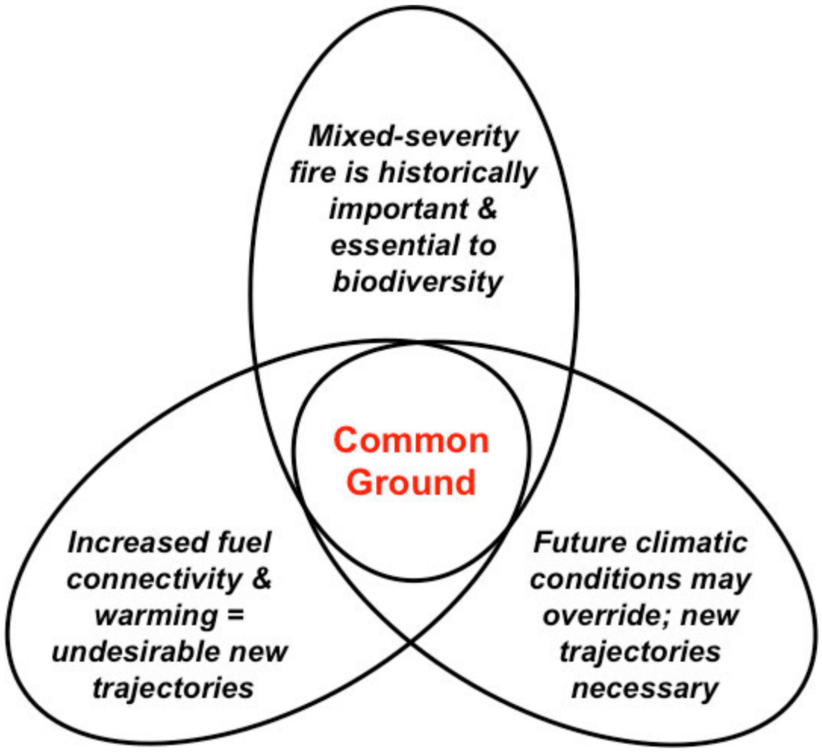
At the outset, we acknowledge some core scientific principles that are widely accepted by those engaged in all sides of these debates. One example is the idea that wildfire is inevitable, and it is a process essential to all western forest ecosystems. Wide agreement therefore exists about the extensive benefits of fire, even if this agreement may not be shared outside of the research community. The notion that fire is an essential ecological process was universally shared and was a guiding principle of most questionnaire respondents.

Another key example is the set of factors making up what is considered the “fire behavior triangle” shown below. This construct was developed by scientists to capture the physical and chemical principles that govern fire behavior, namely characteristics of 1) fuel, 2) weather, and 3) topography in affecting a given fire’s rates of spread, flame lengths, and intensities. There is also extensive agreement about there being trade-offs in the relative importance of these factors, such as the influence of fuel characteristics in some instances diminishing in more extreme topographic settings (e.g., steeper slopes) and weather conditions (e.g., higher wind speeds, lower humidities). There is natural variation in how different factors intersect in space and time, resulting in often complex dynamics and only semi-predictable outcomes. Even so, certain relationships are predictable enough at finer scales to be useful for models of fire spread and crown fire initiation; broad-scale simulation of fire behavior patterns is also possible, although with known limitations.



Fire Behavior Triangle

In the context of our project, the fundamental science that underpins the study of fire is not what we mean by “common ground” shared among disagreeing groups. Here instead we are referring to areas of agreement, or the overlap in perspectives, that emerge when debates over a given issue are deconstructed. As a hypothetical but realistic example, consider the Venn diagram below, which represents three partly overlapping views about possible causes and consequences of increases in high-severity fires. There is evidence that some forest habitats, particularly at drier sites, are converting to non-forest vegetation or less-dense forests following recent fires, where large and severely burned patches are created. Conversely, afforestation has occurred in some forest types as a result of fire suppression, which can reduce fire intensity and spread, compared to some non-forest vegetation. Opinions are varied concerning departures from historical patterns of fire severity in various mixed-conifer and subalpine forests, as well as their ecological consequences. One viewpoint supports the historical precedence of mixed-severity fire (including relatively large patches of high-severity fire), and the concept that pyrodiversity begets biodiversity. Another viewpoint asserts that increased woody fuel connectivity in combination with a warming climate trend is setting large areas of landscapes on fundamentally new trajectories, with significant undesirable ecological and societal consequences. Still a third viewpoint emphasizes that climatic changes increasingly are of overriding importance, and that new trajectories are unavoidable and thus may be considered desirable in many cases to incrementally foster necessary ecosystem transitions.



In the realm of public discourse, these three perspectives might be reduced to simplistic and utterly contrasting sound bites, spanning the following extremes:

- Fuel treatments are urgently needed across nearly all forests.
- Fuel treatments should be focused around communities and plantations; hazard reduction elsewhere is futile.
- There is high uncertainty about where and when fuel treatments are beneficial.

Regardless of public perception, there is still a solid scientific basis for each of the three perspectives shown in the example above, and much can be learned by examining the common ground of their intersection. We explore the common ground of these and other such areas of overlap in divergent scientific perspectives in this document.

Philosophical and Contextual Issues

At times, differences in perspective may be linked to whether one's research emphasizes fire effects on tree survival, residual vegetation structure, or fire effects on overall ecosystem function and biodiversity. Frustrations and value judgements about management activities and their impacts on public lands have also contributed to differing scientific perspectives about possible paths forward. Scientist and public mistrust of past and current management on some public lands is one of the largest impediments to forward progress, and yet most discussions focus on improving fire science rather than improving trust. Fire scientists, ecologists, and land managers need to better understand how science has been used in the past to justify various management actions, and how various breaches of trust have affected adoption of modern scientific findings. Such trust can be rebuilt with monitoring and stakeholder engagement in land management decision making.

There was wide agreement among questionnaire respondents that fire science often gets overly simplified in the media, even when more nuanced views may be held among scientists doing the research. Sometimes simplification links back to early narratives and research findings, which may then be inappropriately applied by others beyond their original context. An example of this is the notion that climate change will universally increase fire frequencies and severities, despite growing evidence of more complex outcomes. In other cases, scientists, journalists, policy makers, land managers, NGOs, or politicians may simplify stories to increase their clarity or impact, or to deliver specific messages to the public, and these stories are then carried forth as "debates."

Many respondents also recognize the need for better terminology and conceptualizations of fire regimes[2], both for communicating with the public, and for use among scientists. To some extent, imprecision or ambiguity of terms and concepts may be partly responsible for certain debates in the fire literature. For example, numerous respondents commented on how fire regimes have been oversimplified as fitting into one of the three broad classes of low-, mixed-, or high-severity. Imprecision or lack of agreement on objective classification of fire regimes conflates with actual disagreements over the interpretation of fire history evidence. Although disagreements are not simply based on semantics, poor semantics contribute to confusion. In addition, scientific interpretations of fire regimes made at specific spatial and temporal scales are sometimes fraught with unspecified assumptions, imprecision, or error in the scope of the inferences made.

Additionally, respondents often had differing priorities for, and definitions of, "restoration" and "resilience," generally reflecting the plurality of these definitions and priorities in modern society. For example, how important is the past to understanding and planning for the future? What exactly is being restored, to what benchmark, and for what purposes? What ecological and social values support any intended restoration? Underpinning each of these questions are differing perspectives about the importance of historical ecology based on differences in human social values, even on the part of scientists.

Restoration[3] and resilience[4] are often identified as goals of forest management, and yet the enabling legislation and funding sources of different land management agencies actually

---

[2] A fire regime is the pattern, frequency, fire size, spatial complexity, and severity of fires over space and time. Fire regimes are characterized based on fire frequency (how often fires occur), intensity (amount of heat released at the flaming front), severity (both soil and tree mortality effects), type (ground, surface, crown), size, spatial pattern (including patch size distribution) and seasonality. Ground fires burn organic matter in the soil. Surface fires burn leaf litter, fallen branches, and plants on and near the soil surface. Crown fires burn through to the top layer of trees and shrubs. From Morgan et al. (2001) Mapping fire regimes across time and space: understanding coarse and fine-scale fire patterns. International Journal of Wildland Fire, 10(4): 329-342.

[3] Restoration is "the process of assisting the recovery of an ecosystem that has been degraded, damaged, or destroyed" (Society for Ecological Restoration International Science & Policy Working Group [2004] Primer on Ecological Restoration. www.ser.org). Also see Hessburg et al. (2015) Restoring fire-prone forest landscapes: Seven core principles. Landscape Ecology 30(10): 1805-1835.

[4] Resilience: The capacity of a system to absorb disturbance and reorganize while undergoing change so as to still retain essentially the same function, structure, identity, and feedbacks (Society for Ecological Restoration www.ser.org). See also Schoennagel et al. (2017) Adapt to more wildfire in western North American forests as climate changes. Proceedings of the National Academy of Sciences. 114(18): 4582-4590.

dictate how restoration and resilience are defined and implemented. Therefore, even if common ground might exist on the need for fire to play a more natural or culturally central role, there can be widely varying opinions about what to do, and varying options as to how to make that happen, legislatively and administratively.

Not surprisingly, there were differing opinions about tradeoffs between human social values and the ecological benefits of fire. For example, smoke from wildfires or prescribed fires is a great concern that can have important influences on how various fire treatments are applied. Reconciling these varied opinions and the associated trade-offs was not in the purview of this effort. Views on forest restoration and ecosystem resilience are thus embedded in this larger context of other human social values, which greatly adds to the complexity of consensus-building and informed decision-making.

Looking forward, assessments of the effectiveness of fire management under climate warming will provide important results, ideally through science-based monitoring and management actions that are intentionally adapted by lessons learned. Most fire scientists and managers agree that fuel treatments can affect fire behavior, though effectiveness can vary with weather, treatment type, location, and time since treatment. Clearly, wildfire researchers recognize the importance of both extreme weather and fuel conditions on fire behavior. However, some respondents suggested that policy makers are unaware of uncertainties associated with attaining fire mitigation goals in the face of more frequent extreme-fire weather, but the management requirement to address such goals persists. Fire managers look to fire science for clear answers about methods, and their reasonable application, because planning and implementing actions in response to climate change, forest restoration, and other needs are essential to their mission.

A number of respondents lamented the time and energy devoted to disagreements over the interpretation of fire history in forest management debates. They suggested that the real challenge is to face the reality of a changing climate and changing fuels by considering the effectiveness of fire mitigation strategies (both old and new). There was also wide agreement on the need for land-use strategies that reduce societal and resource vulnerability to negative consequences of wildfire and climate change, while providing for the essential role and many benefits of fire in forests. We acknowledge that this is an example of fire scientists pointing to a need for stronger engagement with social scientists.

Numerous western fire scientists, when asked, chose not to participate in this survey, and others reluctantly participated. Several cited previous unproductive and unprofessional interactions in the context of debating fire science and related land management issues. Some questioned the motives of researchers not sharing compatible viewpoints on fire issues. Quite a few, including individuals from all sides of the debate, expressed frustrations with the peer review process of some mainstream ecology and forest science publications, and the resulting contradictory messages conveyed to land managers. The FRC Project Steering Committee is well aware of deep division within a portion of the fire research community that is impeding healthy, productive scientific debate. It is beyond the scope of the FRC to examine the non-scientific bases of these conflicts. Instead, our focus has been to identify the common ground shared among a majority of fire scientists on key issues, and to provide a summary that can support informed management decision-making going forward.

Methods and Data

We considered the entire extent of the scientific literature and views of scientists relating to fire research in western US forests. The Steering Committee is committed to inclusion of the full range of scientific perspectives reflected in the questionnaire responses and in the peer-reviewed literature. To facilitate a broad scope of input, we invited responses to a multi-part questionnaire from scientists from many different geographic areas and scientific perspectives. Invited respondents were those who had "*published significant primary research on fire occurrence and fire effects on ecosystem attributes in forests of the western US prior to intensive management, or in areas with limited active management such as large wilderness areas*."

This invitation criterion filtered out potentially important scientific contributions (e.g., those focusing on Native American use of fire, wildlife, post-European settlement periods, ecosystem resilience, and climate change adaptation) from the initial questionnaire. However, a broader range of scientific perspectives was included when the draft common ground statement was distributed for external review. After several rounds of invitation, 77 researchers were contacted, which yielded 36 respondents, including steering committee members. We believe that the depth and geographical breadth of responses were sufficient to identify key areas of agreement and disagreement among fire scientists.

Individual questions in the questionnaire were often intentionally structured as false dichotomies. Using this mechanism, we intended to generate thoughtful responses that would include details as to why a respondent might agree or disagree with the framing of a given issue. While this approach worked overall, it was clearly frustrating to some, and even appeared to a few as evidence of inherent bias in the process.

Between November 1st and 4th, 2016, our steering committee convened a workshop to summarize and organize responses to the questionnaire. Due to great variation in the nature of the questions and how much respondents tended to use literature citations in their responses, we opted not to incorporate citations throughout this report; doing so in a consistent manner was simply seen as intractable. In addition, our common ground document draws upon our own experience and critical reading of the literature, also without the use of citations. As an archived supplement to this report, however, we list citations that were used by respondents in supplemental online materials; any future refereed publications derived from this work will incorporate citations. Note that an exception to this approach is our inclusion of citations in a relatively small number of definitional footnotes throughout the report.

An external evaluation of the completeness and tone of our common ground statement was undertaken in June of 2017. For scientific perspectives, we invited 100 researchers for feedback on our draft statement; this group was larger than the original 77 invitees, to include a broader range of expertise. We received feedback from 36 individuals, not including the FRC steering committee. We also invited review and comments on the draft and its usefulness from 60 land managers and other stakeholders, 22 of whom provided feedback. To the best of our ability, we then integrated the feedback we received into this final document.

Forest Type Classifications

We based our discussion on three broad forest types in the western US, which we refer to as 1) dry pine and/or dry mixed-conifer (*aka*, dry forests), 2) moist mixed-conifer (moist forests), and 3) cold subalpine (cold forests). These are broad terms that are used colloquially to generalize forest types across the western US. Within particular regions, these terms can be crosswalked to classifications that are commonly used by land managers and in peer-reviewed literature.

To the extent that it may be helpful for cross-regional communication and possible generalizations we provided some examples of forest types covered in the questionnaire based on the US National Vegetation Classification (US NVC).

Dry forests, including for example:

- Central Rocky Mountain Dry Forest Macrogroup M501 (1.B.2.Nb.2 *Pinus ponderosa var. ponderosa - Pseudotsuga menziesii - Pinus flexilis*)
- Southern Rocky Mountain Forest & Woodland Group G228 (1.B.2.Nb.1.b *Pinus ponderosa*)

Moist forests, including for example:

- Central Rocky Mountain Mesic Lower Montane Forest Macrogroup M500 (1.B.2.Nb.3 *Tsuga heterophylla - Abies grandis - Larix occidentalis*)
- Central Rocky Mountain Forest Group (1.B.2.Nb.3.c *Abies grandis - Pseudotsuga menziesii* East Cascades Forest Group)
- Mesic Southern Rocky Mountain Forest Group G225 (*Abies concolor - Picea pungens - Pseudotsuga menziesii)*
- Vancouverian Lowland & Montane Forest Macrogroup M023 (*Calocedrus decurrens – Pinus jeffreyi – Abies concolor* var*. lowiana* Forest Macrogroup (exclude *Pseudotsuga macrocarpa –Quercus chrysolepis*)

Cold subalpine forests, including for example:

- Rocky Mountain Subalpine-High Montane Conifer Forest (1.B.2.Nb.5 *Abies lasiocarpa - Picea engelmannii - Pinus albicaulis)*
- California Red Fir - Mountain Hemlock - Sierra Lodgepole Pine Forest (1.B.2.Nd.4 *Abies magnifica - Tsuga mertensiana - Pinus contorta* var. *murrayana)*

Topic A. Fire history and fire ecology vary across geography

Common Ground

Key points of common ground among respondents to the questionnaire include:

- Generalized models of historical fire regimes vary by ecoregion and forest type.
- Even within the same ecoregion and forest type, there is variation in historical fire regimes among differing environmental gradients.
- There are many different historical fire regimes throughout the western US, and a single model cannot represent this variation (i.e., one size does not fit all).
- Historically, some degree of low-, moderate-, and high-severity fire has occurred in all forest types, but in substantially different proportions and patch size distributions at different locations.
- Classification of historical fire regimes according to forest types can be coarse; thus, failure to recognize variation of historical fire regimes *within* forest types can lead to overgeneralization and oversimplification of landscape conditions.

Respondents strongly emphasized how geographical context is critical in understanding and characterizing past, present, and future fire regimes. Many respondents commented that their responses were dependent on geographical context, or they simply noted that the geography under consideration is important. Respondents described numerous examples of how fire regimes vary at a broad scale across large gradients from warm-dry to cool-wet habitats.[5] Within the fire research community, there is essentially unanimous agreement that historical fire regimes differed fundamentally among strongly contrasting forest types such as low-elevation dry pine forests (mainly involving relatively frequent surface fires) versus cool to cold subalpine forests (mainly involving relatively infrequent high-severity fires), so that a one-size-fits-all approach clearly should not apply to management discussions. The spatial and temporal scales at which generalizations about natural or cultural fire regimes are valid vary, and can be uncertain or as yet poorly researched, which may be an important explanation for some disagreements about fire history among researchers, and appropriate management goals among practitioners. In these latter cases, managers with a need to make progress toward agency goals may inappropriately apply knowledge gained from different but related systems, or from expert panels.

A majority of respondents agreed that any singular characterization of fire regimes and how they have been altered by modern land-use practices—at the scale of the western US—is clearly inappropriate. For example, only at the scale of an ecoregion can we estimate patch size distributions of low-, moderate-, and high-severity fires of any particular forest type. However, individual landscapes within ecoregions do not show the full variability extant within an ecoregion. Neither is it always appropriate to simply assign fire regimes by forest type. Within an ecoregion, gradients of climate and vegetation attributes are well understood as determinants of fire regimes and their variation. Most significantly, broad-scale spatial variability of fire regimes results from broad spatial variability in long-term climate, annual weather,

[5] The existence of major differences in fire regimes in strongly contrasting ecosystems such as low-elevation, dry pine forests and high-elevation cold forests is relatively non-controversial and well documented in the literature (e.g., Schoennagel et al. 2004; Hessburg et al. 2007, Perry et al. 2011).

environmental and topographic conditions suitable for burning, *and* variability in amounts and spatial continuity of fuels, the nature of fuels, (e.g., forest vs. shrub vs. grass vegetation), and in the history of prior fires.

Many respondents emphasized that the commonly applied classification of fire regimes as "low-, mixed- , or high-severity" adequately describes dominance but inadequately describes variation in fire regimes across the western US (see Topic C). Whereas low- and high-severity fires are at least theoretically well understood endpoints of a continuum, a broad, poorly defined "mixed" category is the source of much confusion and misunderstanding. For example, "mixed-severity" is used to describe both the temporal variability in fire effects over multiple fire events at one site, and the spatial variation in burn severity within a single fire. Even in the case of the two extremes of low-and high-severity, respondents noted that there is often some degree of variability, with under-appreciated ecological impacts. However, there is agreement among respondents that all fire regimes are the product of interactions between varying degrees of top-down climate and weather-forcing and of bottom-up spatio-temporal controls of topography and local fuel, that reflect legacies of past fires and other agents altering vegetation, and hence fuel properties (see also Topic E).

Some respondents questioned whether commonly used vegetation classification schemes are a suitable basis for generalizing about fire regimes, and expressed that known geographic variation in fire regimes within forest types argues for improved forest and fire regime classifications. Many noted that broad classifications such as "dry forest" encompass substantial amounts of variability in historical, current, and future fire regimes, making generalizations at the level of an entire forest type suspect. Numerous respondents emphasized that variability in historical fire regimes within a broad forest type often reflects dominant influences of neighboring forest types and their associated fire regimes.

Areas of Divergence

Key areas of divergent opinion among respondents included:

- The relative proportions of different historical fire severities in particular geographical areas.
- The relative importance of extreme weather events to historical burn severity.
- Desirable proportions of low-, moderate-, and high-severity fire in the future.

Respondents disagreed about the relative proportions of different severities of historical fires for some of the *same geographical areas of study*. While this is a key source of debate, it is noteworthy that most studies conducted in the same study areas find qualitative similarities in historical fire regimes. Some studies stress the quantitative differences in the proportions of a study area interpreted as fitting into various classes of burn severity. Most commonly, such disagreement involves potential inferences from different types and scales of evidence of past fire, or past vegetation attributes. For example, tree-ring evidence sometimes supports conclusions that contrast with those derived from landscape-scale inventory and monitoring data using different sampling frames (see Topic H). Yet these different types of evidence of past fire sometimes also yield overlapping or even similar estimates of past fire activity.

In other cases, disagreements about proportions of low-, moderate-, and high-severity fire are based on findings from studies conducted in one area that were applied to another. In other words, some respondents assumed transferability of research findings across ecoregions, based on similarity of forest type. In certain instances, this may be true, but in others it may be inaccurate. Respondents expressed a fairly high degree of consensus about historical fire regimes within particular forest types and ecoregions. Few fire history researchers have significant field experience in more than one ecoregion, but a few of those with cross-regional experiences articulated support for the occurrence of contrasting fire regimes in similar dry, moist, and cold forest types among differing ecoregions. Certainly a narrow range of field experience can limit the ability to interpret and accept findings that differ from one's own experience.

Respondents exhibited a wide range of opinions, explicit or implied, about the potential importance of extreme weather events in overriding historical fire behavior and burn severities (see Topic F). Respondents noted that historical fires in some areas were mostly low-severity, but some high-severity events were also evident in tree-ring records incorporating stand ages, tree growth changes, and tree mortality dates, consistent with other evidence. Most others emphasized the greater frequency and extent of low-severity events and their role in reducing fuel quantities, creating fuel-limited systems or open canopy forests. Some respondents stressed the importance of long-lasting ecological effects from infrequent, moderate- or high-severity fires in the same study areas. Respondents who emphasized the longer time scales of charcoal records noted that most areas of predominantly low-severity fires also showed some incidence of moderate- or high-severity fire over longer time frames. However, the spatial imprecision of those longer charcoal records relative to particular forest types and their location makes these insights difficult to interpret. Some respondents related the occurrence of high-severity fires to extreme climate/weather conditions (both past and present), whereas other literature stresses fuel accumulation or both climate and fuel as the main explanations for high-severity fire.

Determining what proportions and patterns of various burn severities[6] may be desirable in the future is a question that goes far beyond the information available from either fire history research or elicited in our questionnaire. What is desirable will be based on fire's expected influence on ecosystem goods and services that are valued by people, and the social acceptability of those influences. Thus, the predominant viewpoint among land managers and policy makers is that wherever feasible, fire and fuels management should promote the fuel and successional conditions that will support the natural fire regime going forward. In areas such as wilderness, where commodity production is not a management objective, the goals are much the same. Regardless of the management allocation, heterogeneity of fire effects, including the pattern of patches created by fires and other disturbances, is important to forest resilience to future fires (see Topic E).

Respondents exhibited a wide range of opinions about desirable future proportions of burn severity. Some stressed that fire and forest managers often propose treatments designed to reduce future potential for large areas burned with high severity. In contrast, others explicitly stated the benefits of high-severity fire, generally stressing its role in providing habitats for certain wildlife species, forest successional heterogeneity, and biodiversity. Proponents of this latter viewpoint stressed recognition and agreement that allowing high-severity fires in the Wildland-Urban Interface (WUI)[7] was not socially acceptable. Some respondents noted a

---

[6] Burn severity is ecological change due to fire, often characterized within the first year or more after fire. In contrast, fire severity refers to effects during the fire. From 1) Morgan et al. (2014). Challenges of assessing fire and burn severity using field measures, remote sensing and modelling. *International Journal of Wildland Fire 23*(8):1045-1060, and 2) Keeley (2009) Fire intensity, fire severity and burn severity: a brief review and suggested usage. *International Journal of Wildland Fire 18*(1): 116-126.

[7] Wildland Urban Interface (WUI): The area where structures and other human development meet or intermingle with undeveloped wildland or vegetative fuels. From NWCG glossary of wildland fire terms (https://www.nwcg.gov/glossary-of-wildland-fire-terminology, accessed 8 May 2017).

paradigm shift from a prevalent view in the 1990s that the only acceptable or “good fire” is a low-severity fire, to a growing viewpoint stressing the benefits of some level of moderate- and high-severity fires, as well as the need for societal adaptation to “managing wildfire” and “living with fire.” Many respondents stressed the importance of different management objectives in different settings (e.g., remote areas versus the WUI, general forest versus wilderness management), and of the clearly different historical fire regimes in low-elevation dry mixed-conifer forests versus cold subalpine forests.

Implications

Managers and scientists alike are challenged with overcoming the tendency to simplify historical fire regimes across and within ecoregions and forest types. While managing for the inherent complexity of fire regimes can be daunting and painstaking work, the resulting patterns and effects on processes provide important and compensating benefits. There is no single model of historical fire regimes applicable to all forest types and ecoregions. Managers should exercise care when applying scientific understanding developed in different landscapes, and recognize that this may result in erroneous scientific underpinnings and failure to meet objectives. Thus, management decisions are generally best-informed by area-specific understanding of fire ecology, which in some cases may require new partnerships between managers and researchers, both in implementation and monitoring. Scientists must clarify the importance of place when characterizing and presenting knowledge about historical fire regimes, and would benefit by sharing methodological approaches and collaborating across ecoregions. Stakeholders—from the general public to land managers to society at large—must wrestle with and decide what future proportion and pattern of burn severity might be desirable in each locality, both for the ecosystem, and for the people who live nearby and depend upon their services. Bearing this in mind, stakeholders will need to discuss the ability of various management prescriptions to achieve their desired changes, the social cost and acceptability of the changes, and alternative approaches to accomplishing them (see Topic I).

A logical way forward is to increase cross-regional and in-depth field research experiences within the fire research community. Improved collaboration across research groups, defined geographically or by previous narratives, can overcome some of the current atmosphere of deep distrust and interpersonal acrimony. Cross-regional comparisons of top-down and bottom-up determinants of fire activity is a fertile area of future research, which can examine how differences in seasonality, productivity, surface and canopy fuels, climatic differences, and other factors may explain some of the reported geographical differences in historical fire regimes in broadly-similar forest types. Likewise, inter-regional comparisons of various land-use practices by Native Americans and EuroAmerican settlers would improve our understanding of how these practices have contributed to past and present geographic differences in fire regimes.

Agencies like the US Forest Service and Bureau of Land Management, by virtue of their enabling legislation and Congressionally appropriated annual budgets, are legally required to manage for improved fuel and fire behavior conditions. Actions that can effectively treat large areas over a short period of time often suffer from an oversimplified understanding of the desired conditions. Because there are strong relationships among spatial patterns of surface and canopy fuels, seral stages, expected burn severity patterns, and onsite climate and fire weather conditions, care must be taken to avoid oversimplifying those patterns for the sake of simply reducing expected wildfire severity. Such oversimplifications can have profound effects on habitat patterns resulting from all burn severities, and their spatial complexity and connectivity. Thus, in each geographic area, managers must seek to obtain a clear understanding of the historical spatial patterns of surface and canopy fuels, and of seral stages through focused study and reconstruction of those conditions. Further, they should use modern climate change evaluation tools to assess how these historical patterns would be altered under the 21st century climate anticipated for that area. This larger understanding would enable managers to then consider conditions in this larger context, and develop landscape prescriptions to make the needed adjustments. Tools to be applied would be those that matched the land allocation and the specific needs for change.

Topic B. Human impacts and management history vary with geography

Common Ground

Key points of common ground among respondents to the questionnaire included:

- The influence of humans directly on fire ignitions and suppressions as well as on landscape drivers of fire activity is ubiquitous and important.
- Impacts of humans vary through time, and are not uniform geographically.
- Human influences are pronounced in dry, moist, and cold forests, but impacts vary.
- The role of human ignitions on wildfire prevalence and severity varies markedly in western forests.
- Climate change is a human impact and a strong driver of fire occurrence and effects.

Respondents to the questionnaire strongly emphasized that fire suppression[8], despite its widespread effects, was not the only human activity profoundly affecting fire regimes and fire-prone ecosystems. Most respondents mentioned other activities as influential in altering fire regimes, such as domestic livestock grazing, logging (selective, post-fire, and clearcut), diverse types of anthropogenic ignitions, mining, overly generalized reforestation practices, invasive plants and animals, road and rail construction, and land-use or development changes. Respondents also spoke to the decimation of Native American communities through the introduction of human diseases, and later marshalling onto reservations, which significantly reduced ignitions and cultural fire uses by native aboriginal people. Human impacts vary with degree of access via roads and trails, but even remote areas have been influenced by people. For example, selective and clear-cutting timber harvests have widely affected dry and moist mixed-conifer forests, where the favored commercial species principally grew.

Many respondents noted that the impacts of these different activities are known to have varied over space and time, posing difficulties for generalized characterizations of human impacts over broad geographical areas or forest types. In other words, there was strong consensus that geographical context matters, and this influences the local assortment of human impacts. Some respondents noted that wilderness areas and actively managed forests often have had different human use histories, including Native American influences, and therefore different trajectories. Wilderness areas, along with some national parks and large roadless areas, offer examples of potentially different human influences, and related opportunities for both research and management. A few respondents elaborated on similarities

[8] Fire suppression is the act of extinguishing or fighting fires. Fire exclusion has partially eliminated fires from the landscape using fire suppression and other land uses, such as grazing, settling in valleys, road and railroad building, and agricultural conversion of most native grasslands.

between the effects of some human activities (e.g., fewer fires may be due to active fire suppression, reduced Native American ignitions, and/or grazing that removed surface fuels) in certain ecosystems, while most noted that dense recruitment of shade-tolerant species has been a direct result of nearly-ubiquitous fire suppression efforts, or logging of large, fire-tolerant trees across many western ecosystems.

A notable point of common ground among many respondents and a chord that was detected throughout the literature was that human impacts have been most detectable and pronounced in dry and many moist mixed-conifer forests, where the most commercially desirable species were logged. This logging, along with fire suppression, has resulted in generally altered and often more-homogenous forest compositions and structures. Such homogenization of forests is often due to harvest of larger and older trees and species (like western white pine, sugar pine, western larch, Douglas-fir, ponderosa and Jeffrey pines) followed by regeneration of higher density, young shade-tolerant forests (of grand fir, white fir, subalpine fir, Douglas-fir, red fir, and incense cedar, or mixes of these species), or due to fire exclusion and a variety of other related mechanisms. Less agreement exists on the degree and causes of homogenization with regard to cold subalpine forests. Regardless, this relative consensus about where human impacts have been most pronounced hopefully provides a stepping-stone for further discussion and common ground.

Many also recognized that climate change at broad scales is a dominant human influence affecting fires and fire effects in all ecosystems. We address it here and in sections F and G because it is the one common denominator affecting all forest types and all fire regimes.

Areas of Divergence

Key areas of divergence of opinion among respondents included:

- The general applicability of “thinning and prescribed burning remedies” to offset human influences.
- The significance of human impacts on forest successional conditions in moist and cold forests.

The questionnaire was intended to elicit a wide variety of responses about the generalized applicability of forest thinning and prescribed burning techniques, in response to changes in fire regimes and forest successional and fuel properties that have occurred across different forest types, and in different geographic locations. These topics might have been better separated, which could have made the areas of agreement and disagreement more distinct. Regardless, there was a general pattern among respondents, based on whether they viewed the fire regime of the forest in question as more driven by fuels versus weather and climate (see also Topic F).

For low-elevation ponderosa pine forests and woodlands and to a lesser extent in dry mixed-conifer forests, respondents generally viewed thinning and prescribed burning to have wide utility, both for ecological and social reasons. However, some asserted that, even where such activities may be useful and justified, their effects may be better accomplished primarily through wildfire.

While a majority of respondents agreed with the statement that cold subalpine forests have been little affected by fire suppression, many studies highlight that human impacts on forest successional conditions have been significant in dry, moist, and cold forests in ecoregions of the northern Rockies, Inland Northwest, Pacific Southwest, and Inland Southwest. In particular, there is evidence in these ecoregions that once-complex cold subalpine forest patchworks composed of early, mid, and late-seral forest conditions have been simplified by extensive timber harvesting, fire exclusion and fire suppression, but also to a lesser degree by livestock grazing of the often widespread wet and dry meadows, and road development.

Implications

There is general consensus that human impacts vary widely across western US forests in terms of type of activity and associated ecosystem effects. Although some human activities had similar influences on many forest ecosystems, failure to recognize the heterogeneity of human impacts can lead to overly generalized prescriptions for forest restoration and management. Thus, there is likely no one-size-fits-all management or restoration approach—available to all conditions—due to the importance of locally-coupled human-natural histories, and current social or political considerations. Most fire scientists assume prehistoric Native American influences on fire and forests to have been relatively widespread, but to varying degrees in different landscapes and habitats. However, more clarity is needed about differences in how Native American and more modern human influences shaped forests of today.

The importance of local context in the management of fire-prone landscapes underscores the need to move away from oversimplified narratives that encourage application of fire research beyond its original scope of inference. Nonetheless, a widespread challenge facing land managers is the need to make forest management decisions in the substantial areas of landscape where fire-vegetation history research has not been conducted; this is a major future research need. General agreement about drier forests being the most impacted by human activities could provide a path forward among those disagreeing about the extent of high-severity fire in these ecosystems. Human impacts have been pronounced but with different effects and implications for moist and cold subalpine forests. Additional studies of landscape changes, and of vegetation response to fires and fuel treatments in these forest types, will inform discussions about forest landscape restoration and management.

To apply knowledge of the relative human impacts on local vegetation conditions, managers need to develop a clear understanding of the specific impacts geographically, their period of influence, and some understanding of their relative strength (also see Topic D). Important human impacts to date include:

- domestic livestock grazing, period of grazing, and density and types of animals grazed;
- introduction of non-native plants or animals, their distribution, and influence on herbivory and the local fire regime;
- wildfire suppression, including the number, locations, and timing of wildfires suppressed;
- timber harvest, type of timber harvest, and frequency of harvesting;
- presence of roads and railroads, their density, and the period of road impacts;
- historical frequency of Native American burning and time since that burning ceased;
- other changes in patterns and trends of anthropogenic (e.g., recent EuroAmerican) and natural (lightning) fire ignitions;
- conversion to cropland, exurban, or urban development, other conditions.

Research shows that the presence or absence of even a single one of these human influences can have profound effects on the resulting vegetation and fire behavior conditions. For example, the absence of timber harvest in some studied wilderness areas reveals significant differences in species composition and tree density in comparison with harvested locations growing in similar climatic conditions and forest types. Knowledge of the local human impacts, their period, and relative intensity can help guide the selection of areas needing and not needing restorative treatments, and it can aid in the selection of appropriate management tools.

Topic C. Fire is a keystone process[9] that occurs in almost all western US forest types

Common Ground

Key points of common ground among respondents to the questionnaire included:

- Low-, moderate-, and high-severity fires historically occurred in nearly all forest types.
- Fires of all severities play important ecological roles.
- Since nearly all western US forests are significantly fire-influenced, fire is a key driver of ecosystem patterns and processes.
- Burn severity patterns and resulting successional and fuel bed conditions have changed due to human activities in most forest types.
- In many western forests, a period of fire exclusion persists, reflecting successful passive and active suppression of the vast majority of ignitions (95-98%) over the past century.

There was consensus among respondents that various combinations of low-, moderate-, and high-severity fire occur in nearly all western US forest types, and associated agreement that fires of all severities play important ecological roles in each forest type. Unsurprisingly, there is also consensus that fire has been, is, and will continue to be an essential ecosystem process across nearly all western US forest types. A key challenge for researchers has been to estimate the proportions of fires that could be classified into one of the three commonly-used descriptive severity classes (low, moderate, high), and how those proportions may have changed over time.

An increasing emphasis in fire research conducted over the past 20 years has specifically aimed at estimating proportions of areas historically affected by low-, moderate-, or high-severity fires, but there remain uncertainties about the actual variability of burn severity historically. Some of this uncertainty is due to methodological limitations, especially in the case of high- and moderate-severity fires, where much of the evidence of past fires is destroyed. This renders fire history studies that exclusively use fire scars less useful under these conditions. However, much progress has been made in recent years by combining fire-scar data with extensive tree age data, tree growth release data, and data on tree mortality events, to provide a more nuanced understanding of the history of fire effects. In addition, aerial photographic reconstructions were employed in the interior Columbia Basin and East-side Forest Health Assessment studies, and these have provided expanded insights into the proportion of patches burned with low-, moderate-, and high-severity fires of those studied ecoregions across the 20th century (Topic H).

[9] A keystone process is one upon which other species and processes in an ecosystem largely depend, such that if it were removed or significantly altered, the ecosystem would change drastically.

Varying degrees of increased continuity of forest in all forest types (i.e., loss of early seral grass- and shrublands, and sparse woodlands and savannas) have been observed with implications for increased vulnerability to larger and more continuous crown fire disturbances, particularly in combination with successful suppression of all but the largest fires. A highly promising area of current research is the integration of dendroecological studies with the existing aerial photographic reconstructions currently covering millions of hectares across the northern Rockies and Inland Northwest. Recent research focusing on proportion of area affected by various burn severities and the emergent patterns represents an important improvement over the former focus almost exclusively on past fire frequencies.

There also was consensus that in many western US forests, there has been dramatically less fire activity over the last century than in prior centuries and millennia, tied to intense and pervasive societal efforts to actively suppress and exclude wildfires. Respondents broadly agreed that patterns of fire occurrence have changed in relation to historical patterns, especially in many dry forests, but also in some other forest types and locations. This is a response to changes in climate and/or fuel properties, recognizing that both extreme fire weather and combustible fuels have always existed to some degree (see Topic F).

There are many existing studies of fire history based on stand-origin mapping over study areas of many tens of thousands of hectares. However, a commonly held view in the fire science community is that even larger areas (i.e., many hundreds of thousands of hectares) are required for effective analyses—combining multi-century fire history data with landscape ecological approaches—to understand past fire patterns and simulation of future fire patterns. A fertile area of future research is analysis of large regional and local landscape historical patterns and patch size distributions of burn severity, and how these varied with topography, climate, prior disturbance, and other influences. Such research is needed because inferences are generally drawn from historical fire frequency, rather than pattern analysis.

Areas of Divergence

Key areas of divergent opinion among respondents included:

- Relative proportions of low-, moderate-, and high-severity fire within western US forests historically.
- Magnitude of changes in fire frequency, severity, sizes, and their consequences for various forest types since the 19th century.
- Magnitude of recent changes in forest patterns relative to historical conditions.
- The urgency, scale and overall need for various active and passive management options.

Key areas of divergent perspective among respondents centered on the relative importance of the various fire attributes that everyone agreed were generally important. For example, whereas numerically dominant perspectives can be identified, there was no consensus about the historical proportions and sizes of differing burn severity classes in some forest types, nor agreement about the magnitude of changes in fire frequencies, severities, and sizes; thus changes in the absolute significance and relative importance of different fire regimes in various landscapes is still debated. It is noteworthy that spatial reconstructions of historical proportions and sizes of differing burn severity classes in various forest types are relatively lacking in the literature for some ecoregions, which is likely a key reason for divergent opinions on this topic.

In particular, perspectives on historical patterns and changes in the occurrence and effects of both low-, moderate-, and high-severity fires in dry and moist mixed-conifer forests were a key area of divergence, with most respondents concerned over the negative effects from historical fire suppression, resultant fuel accumulation, and recent increases in high-severity fire. These observations contrasted with some respondents who highlighted climate and extreme fire weather over fuel accumulation as the main driver of high-severity fire, debated the historical relative importance of low- versus high-severity fire, and emphasized the ecological values and importance of past and present high-severity fires in all forest types, but less so in the driest forest types. Notably, respondents did not try to integrate the concomitant effects of weather, climate, topography, and fuel abundance.

We note that many studies use climate covariates to predict trends in annual area burned. These studies generally do not include fuel covariates, and lacking any evidence of the contribution of fuels covariates, conclude that weather and climate drive area burned. More important are area burned by severity class and changes in patch size distributions of severity classes, which lead to changes in patch size distributions of successional conditions. The lack of data on potential changes in the role of fuels may have fostered disagreements regarding the relative urgency and risks of various active (fuel treatment) versus passive (wildfire only treatment, suppression of human ignitions) management options, the appropriate locations and scale of desirable management actions, and the desirability and trade-offs among alternative forest fire management goals and actions.

Implications

Uncertainties associated with relative proportions of different burn severities and patch-size distributions combine to cloud key points of consensus that have important management implications. There is consensus that various combinations of low-, moderate-, and high-severity fire are important to ecological processes in almost all western US forests. Likewise, there is consensus that these combinations of burn severity, and their variability over space and time, contribute to seral stage pattern and complexity, and the future flammability of the landscape. Therefore, given that landscape patterns of successional and fuel conditions aid in controlling and are to a large extent controlled by fire, and that ecosystem function is altered in the absence of fire, the recent reduction of fire activity in many areas has important ecological implications. Managers are open to using fire on the landscape, but they often are unable to use fire alone. They have intimate knowledge of their landscapes and fuel characteristics, and many acres are not amenable to fire-only prescriptions. Managers wish to use combinations of tools, as is appropriate to the fuel conditions and the land management allocations, to restore more natural patterns of burn severity and of successional conditions that will support them down the road. They can use biophysical and topographic templates to tailor desired treatment patch sizes and intensities to their landscapes. And, they will have to accept some uncertainty about the effectiveness of their fire mitigation procedures under different future climates.

Public land managers throughout the western US are concerned with calibrating fire regimes in many forest types. Central to this idea of calibration is geographically pertinent knowledge of historical patch size distributions of seral stages, burn severity patches, and patterns of lifeform and physiognomic conditions. Nevertheless, paleo studies of fire covering multiple centuries to millennia show significant variability in area burned so that expectation of a long-term stationarity in fire patch sizes is unrealistic. Despite the likely lack of long-term stationarity, these landscape conditions and their variability contribute to the patterns and variability of fire regimes. Specific geographic knowledge of these conditions is often lacking and instead managers often apply knowledge of related or nearby systems, often with less than adequate precision. To learn how to better calibrate relative proportions of each burn severity and patch size distributions, managers should work closely with fire and landscape ecology researchers to improve their local characterizations of these historical conditions. Future proportions of low-, moderate-, and high-severity fire will depend strongly on local context, which includes the HRV, societal and political objectives, prior land-uses, climate and weather, topography, vegetation, and other factors.

Topic D. Knowledge of historical range of variability (HRV) is useful but does not dictate land management goals

Common Ground

Key points of common ground among respondents to the questionnaire included:

- Knowledge of the HRV provides essential context for discussion of land management decisions but it does not set management targets.
- There is no single model of the HRV of forest successional and fuel conditions and fire effects that can be applied across the western US.
- Because the HRV differed greatly from place to place, HRV findings from one area may or may not have relevance to another.
- Understanding the determinants of the HRV is useful in assessing future ecosystem responses to climate change and land-use practices.
- Although appropriate time frames of the HRV are often difficult to define, time frames must be specified for the HRV of particular attributes.
- Deep understanding of the HRV may require application of multiple research methods (see Topic H).

The HRV refers to the variation of ecological conditions and processes over spatial and temporal scales that are essential for understanding current ecosystem conditions[10] and their current departures. While historical patterns of fire and associated vegetation patterns are often the focus of HRV studies, comprehensive HRV studies also examine historical variability of many other factors including climate, impacts of forest insects and pathogens, and land uses. Interpretations of changes in fire regimes may thus be related to numerous potential drivers. These interpretations require consideration of climate variability as well as a broad range of land-use practices such as grazing, logging, mining, and management explicitly aimed at altering fire activity.

The HRV describes *a body of knowledge about historical conditions* without any explicit prescription for how that body of knowledge should be applied. In the sense of understanding how current landscape conditions reflect effects of historical biophysical processes and past human impacts, the HRV provides essential insights for how processes create and maintain spatial patterns of forest and non-forest conditions, and how those patterns in turn drive the processes of interest. Examples of the utility of HRV knowledge include understanding of how

[10] This definition and application of HRV is taken from: Hayward et al. (2012) Challenges in the application of historical range of variation to conservation and land management. Chapter 3 in: Wiens et al. (eds). Historical Environmental Variation in Conservation and Natural Resource Management. P. 32-45. Wiley-Blackwell.

past climate change and land-use impacts have affected modern landscape pattern and structure. Teasing apart the effects of land-use impacts such as grazing, logging, and/or fire exclusion on forest conditions from the effects of climatic variation on wildfire activity and forest conditions requires historical ecological understanding.

The respondents' comments reflected a strong agreement among scientists that knowledge of the HRV provides essential insights for decision-making in land management, in the context of current and future ecosystem responses to climate change. Hypotheses about climatic drivers of future ecological change can be developed and tested with HRV data covering a range of time frames.

Retrospective studies of fire are essential for developing a mechanistic understanding of disturbance-mediated ecological changes, including those driven by climate variability, which in turn supports the development of simulation models of future landscape dynamics driven by climate change. Some respondents stressed relatively abrupt or extreme changes in both historical and modern ecosystem conditions under climate variability as a basis for expecting future "surprises" in ecosystem conditions in the face of climate change. Other respondents suggested that future vegetation predictions from regional and global change models are still crude, particularly if those predictions do not consider fire feedbacks from altered fuel complexes and patchworks, and do not represent adequate advances in understanding sufficient to warrant reduced consideration of the HRV of any geographic area.

Respondents emphasized that knowledge of past natural variability is an essential reference for evaluating impacts of modern land-use practices such as grazing, fire suppression, and logging on current ecosystem conditions and processes. They noted the continuing challenge of distinguishing among the relative effects of past logging or grazing from effects of active fire suppression.

Many respondents stressed that the insights synthesized in an HRV assessment are intended to inform discussions of potential management goals that incorporate social values for decision-making. The value judgments involved in a deliberative decision-making process are improved by knowledge of HRV, but adoption of management goals is not dictated by environmental history.

Areas of Divergence

Key areas of divergent opinion among respondents included:

- In practice and in communicating with the public, static representations of the HRV often continue to be inappropriately emphasized.
- The applicability of HRV knowledge from well-studied regions to similar but less studied forest types in other geographical regions.

The areas of divergence reflected in comments of both survey respondents and in broader discussions with stakeholders appear to reflect different views on how HRV information should be applied to management decision-making. HRV studies are increasingly viewed as scientific and analytical tools useful in decision-making, not as the management goal. In that context, some stakeholders and fire scientists assume that the primary purpose of an HRV study is to reconstruct a set of vegetation parameters (e.g., tree sizes, stand densities, tree spatial patterns) as representing past "natural" conditions and suitable "reference conditions." Other fire scientists stress that such reconstructions may only be "snapshots" in time in the sense that their relevance is time dependent, for example possibly depicting conditions that may have existed ephemerally, but are not fully representative of the range of ecosystem conditions over a longer time period. Still others have shown that HRV conditions, when reflected via a space-for-time substitution sampling methodology, can adequately reflect historically extant variation in forest spatial patterns as reconstructed or simulated by state-transition models. These responses highlighted the importance of comparing alternative methods and time periods that may be used to predict or reconstruct variability of an HRV.

Many respondents emphasized that oversimplified models of the HRV are often applied indiscriminately across a diversity of landscapes so that actual ranges of variability are underappreciated. Numerous respondents identified cases where oversimplified models of HRV did not apply either to an entire study area or were inappropriately applied to landscapes where the model had not been tested through sufficient data collection, independent calibration, or observation. Some respondents noted that divergent views of the HRV reflected the transfer of general models and interpretations from regions that had been well studied, to regions lacking any similar studies that might highlight differences related to unique geography. This is often done based on the assumption that an HRV should be similar in broadly defined cover types.

Implications

The HRV is most useful as a guide to management. Although the HRV can provide invaluable insights about how various processes and patterns interacted in the past, each HRV is but one reference range – it can vary widely across different locations and temporal scales. Managers should exercise caution when applying HRV information collected in other landscapes, recognizing that there is no single HRV model that can be generalized across the entire western US or generally to certain forest types. Despite debates about specific methods and applications of HRV, there was widespread agreement that understanding the climatic, land use, and other determinants of past fire activity and fire effects is useful in assessing future ecosystem responses to climate change and land-use practices.

One of the difficulties facing public land managers is their concern about how to address climate change, wildfire area burned, and burn severity predictions for the mid-21st century, given the high uncertainty associated with those projections, especially projections of future vegetation and lifeform changes, which are thought to be some of the most uncertain. This uncertainty forces managers to generally lean on HRV predictions to hedge their bets going forward. Nonetheless, managers have tools to estimate near-future precipitation, water deficit, plant-available water, and evapotranspiration conditions over the next few decades, and these estimates can be used to condition their understanding of desired forest successional, lifeform, and fuel patterns, and patch-size distributions in light of HRV estimates.

Topic E. Forest structure, composition, and fuels have changed, affecting burn severity and fire extent

Common Ground

Key points of common ground among respondents to the questionnaire included:

- Historical landscape and disturbance ecology strongly influence fuel patterns and legacies of live and dead forests.
- Forest structure and composition have been homogenized in many places by timber harvest, fire suppression, grazing, mining, road-building and other activities.
- Fire behavior is patchy in space and time, and resulting patch-size distributions are important to understanding its effects on the landscape.
- Landscape patch configuration (heterogeneity) is important and is a key determinant of fire regimes, fire behavior and ecosystem function; not every configuration will do.
- Several spatial scales and types of vegetation and fuel heterogeneity exist, and each scale has important and different ecological functions.

In the western US, historical patterns of forest structure, composition, and fuels—collectively making up successional conditions—resulted from recurring wildfire, insect, disease, and weather disturbances that kill trees and regenerate forests. Through time, wildfires repeatedly affected most western forests. Burn severity varied with seasonal weather, previous fires and regional climatic conditions, but also topographic, biotic, and geomorphic conditions. Burn severity patches occurred in predictable frequency-size distributions, which captured the spatio-temporal variability of disturbance and effects on local and regional successional patterns. Within this historical context, respondents generally agreed that fires were prevalent and greatly influenced forests, though fire frequencies and effects varied. Further, respondents all agreed that this historical ecology needs to be incorporated into our understanding and management of forest landscapes.

Respondents identified a number of recent studies showing that successional patterns of many western US forests have been altered by 20th-century management. Management actions included timber harvests, wildfire suppression, domestic livestock grazing, mining, and road and railroad building, which generally fragmented successional patchiness, increased forest area and density, and created novel successional and fuel patterns. Chief among these changes was increased abundance and connectivity of dense, multi-layered young forests, with greater proportions capable of supporting crown fire. However, the degree of these changes has varied across forest types and ecoregions. There was general agreement that these changes occurred in many western ecoregions, especially in the dry ponderosa pine, Jeffrey pine, and in some dry mixed-conifer forests (see Topic B).

Several respondents commented on patch and landscape-level feedbacks, noting that landscape-level feedbacks mediated the frequency-size distributions of future low-, moderate-, and high-severity fire, whereas patch-level feedbacks influenced the likelihood of low- and moderate-severity fires. Prior fires were likely complex patchworks of already burned and recovering vegetation, which increased or decreased the size and severity of future disturbances.

Respondents noted that reconstructed historical landscape patterns, fire history studies, and simulation studies show how landscape successional and fuel patterns and their variability may have supported particular historical fire regimes. Unique ranges of vegetation and fuels patterns were the result of interactions among regional climate, topography, landforms, geology, and biotic communities of an area, along with associated meso- to fine-scale pattern heterogeneity. This pattern of heterogeneity was unique and important to facilitating local variation in burn severity patterns, habitat patterns, and was of central importance at all spatial scales.

Areas of Divergence

Key areas of divergent opinion among respondents included:

- The extent to which future fires and forests are constrained by forest and landscape legacies.
- Importance of bottom-up versus top-down variables in fire regimes.
- The relative amount of forest structural change of an area (e.g., increased density and more complex tree layering leading to increased vertical continuity of fuels that can propagate fire upward).
- Costs and benefits of fuel treatments at necessary spatial and temporal scales.

Respondents disagreed about the extent to which structural change and successional forest patterns have been altered by 20th-century management, as well as the relevance of these legacies for future fire regimes. For example, large landscape assessments in the Inland Northwest showed that the increased abundance and connectivity of dense, multi-layered young to intermediate aged forests, with high crown-fire potential, has occurred in dry, moist, and cold forests. In cold subalpine forests this has occurred via the elimination of formerly complex early-, mid-, and late-seral forest patchworks. In dry and moist forests in the Inland Northwest, this has occurred via increased area of forest (as meadows, sparse woodlands, and some shrub vegetation has been encroached upon by forests), and increased density of a once more-complex patchwork of open and closed canopy forests. In contrast to these patterns, respondents and the peer-reviewed literature for the Colorado Front Range, for example, agreed that for the lower elevation areas of dry ponderosa pine forests there has been a substantial increase in woody fuel connectivity. However, respondents noted that the peer-reviewed literature demonstrates a much smaller shift towards increased woody fuel connectivity in mid-elevation dry mixed-conifer forests and even less in the cold subalpine forests. These respondents noted that for dry mixed-conifer forests of the upper montane zone, abundant research does not support a pattern of significant shift towards a higher percentage of the landscape capable of supporting crown fires today in comparison with historical fire regimes, which also included moderate- and high-severity fires.

Overall, divergence of perspectives on the degree of change in vegetation structure and fire potential often reflects studies conducted in similar forest types but different geographical regions, although in other cases, there are fundamental disagreements over the validity or interpretation of evidence for the same landscape using different methods.

Another area of divergence can be traced to a lack of dialogue and theory integration between climate and landscape ecology researchers. A significant body of landscape ecology research shows that "emergent" properties have central importance to ecosystems and their pattern and process regulation, whereas climate scientists are less focused on local-scale feedbacks and emergent patterns. This creates a fundamental problem in linking climate change and landscape ecology research. Climate models assume that top-down climate covariates drive temperature, precipitation, and solar radiation conditions. Landscape ecology research shows that those top-down inputs can be highly modified by meso- and fine-scale bottom-up environmental controls to produce climatic conditions that are strictly speaking neither the top-down or bottom-up inputs, but are influenced by these inputs. Until the processes that produce such emergence are incorporated into downscaled climate modeling, and until landscape ecology studies incorporate the full suite of realistic climate futures, these uncertainties will remain a problem in applying climate change science to landscapes and their restoration.

Implications

There is consensus that landscape pattern, which is influenced by vegetation, topography, climate, and past fire disturbances, is nearly always an important mediator of fire size and burn severity. A variety of management and land-use activities have altered western US forest landscapes at multiple spatial scales, and essentially created a new landscape template for 21st century fire regimes. Successional and fuel patterns will influence future fires, including size and burn severity of patches. When historical patterns are unknown, efforts to create locally representative reconstructions may be needed.

Forest structure, composition, and fuels have changed to varying degrees in different areas, and in some forest types there is broadly shared common ground that these changes are affecting burn severity and fire extent. While changes observed in some dry forests became a prime motivator for agencies to act, and for Congress to focus financing on restorative actions, there is less common ground about the degree of these changes West-wide in other forest types. However, informed dialogue among scientists and managers, and in some cases additional research, can help to improve common understanding concerning the degree of change and appropriate restorative action for other forest types. Monitoring and adaptive management are needed, especially where reconstructions of representative historical patterns and predictions of future patterns are hard to come by. This is a prime opportunity for scientists to work closely with managers in support of resilience-oriented management. In these cases, a significant monitoring component will facilitate learning. Information gained may be used to initiate restoration of forest structure, composition, and fuels, using the tools that best fit the circumstances. Because simply applying the best available science will not always be sufficient to gain assent from stakeholders and interested parties, collaborative dialogue that factors in local social values and emphases tempered by that science may provide an adequate way forward.

Topic F. Climate and fuels both influence current fire sizes and their severities

Common Ground

Key points of common ground among respondents to the questionnaire included:

- Climate and weather are now and will continue to be primary drivers of fire size and annual area burned.
- Surface and canopy fuels are important drivers of burn severity.

Global and regional climates vary over centuries, decades, and between years, including conspicuous oscillations between the relative dominance of warm-dry versus cool-moist weather patterns. As recently as the late 20th century, a sizable portion of the ecological literature assumed relative stationarity in climate, but increasingly abundant and diverse lines of evidence overwhelmingly demonstrate that the Earth's climate, and that of its many ecoregions, has constantly varied over multiple time scales.

Changes at decadal, centennial, and longer time scales have the potential to redefine biophysical settings. Hence, maps of plant associations, environments, existing and potential vegetation, and physiognomic types are now all seen as shifting patchworks. In landscape ecology, this is an accepted view and is wholly consistent with its body of theory. However, in forest, plant, and rangeland ecology, this view of shifting environmental or biophysical settings has stretched thinking for many practitioners and researchers. Relating projected climate changes to anticipated changes in forest fuel conditions and fire regimes adds further complexity (see Topic G).

Operating within this broader context of changing climate and landscapes, respondents agreed that woody fuel quantity, arrangement, and moisture are important to both the current flammability of western US landscapes, and to the ecological effects of fires. Changes in fuels along with topography drive changes in energy release, fireline intensity, flame length, burn severity, and emissions. Respondents agreed that widespread increases in the area that is forested and in the fuel quantity and vertical and horizontal fuel continuity in many ecoregions and forest types have increased the likelihood of large forest fires and higher burn severities via increased likelihood of crown-fire initiation and spread.

Regional climatic variability and extremes also influence wildfire size and burn severity. Based on the last several decades of research, respondents noted that annual, decadal, and multidecadal climate variability has always been important to fire size, and annual area burned. Respondents also agreed that the largest fires have always been driven by extreme fire weather, and they will continue to be. However, within large historical fires, including those burned under extreme conditions, burn severity was often patchy in response to topography and vegetation (i.e., fuels) conditions. The result was variably-sized patches of low, moderate, and high severity within burn perimeters. These patchy burned areas have changed into the 20th and 21st centuries, and more areas are being burned under high severity than is often typical for the forest types. While this view is supported by many respondents and published studies, there are other studies that question its generality. For example, some research based on historical aerial photography in the northern Rockies on burn area and severity from the 1880s to the early 2000s showed that over this long record, the proportion burned with high severity did not increase, despite extensive area burned in recent decades. Likewise, studies based on satellite imagery, while generally showing trends of increasing burn area since 1984 across the western US, do not show increases in burn severity for all ecoregions or even in a majority of regions. However, we note that in pre-1900 low-severity regime landscapes of the southwestern US and low-elevation Colorado Front Range ponderosa pine ecosystems, the most spatially extensive fire years and likely the largest fires occurred in dry years that followed one or more wet years, which apparently supported buildup and broad-scale continuity of fire-spreading fine surface fuels. Smaller fire sizes and low- and moderate-severity fires are generally associated with milder fire weather and moderating climate conditions.

What has changed most significantly since about 1985 is the frequency of large fires in association with warming temperatures and drought. While some of the increase in the frequency of large fires is expected from increased woody fuel continuity, broad-scale studies based on robust research designs are still needed to tease apart the roles of changing climate and changes in fuels in the observed trends in frequency of large fires. Some respondents argued that the loss of the patchwork created by the historically superabundant small fire-affected patches also has contributed to larger patch sizes of recent forests, and in fact this is a key focus of much current research. In many forests, not just dry mixed-conifer forests, some respondents also noted that fire suppression has resulted in loss of the most numerous smaller and most extensive (in some landscapes) lower-severity fires, which has removed an historical resilience mechanism that once had regulated the frequency and severity of the largest fires by controlling fire growth. Expectations under projections of continued climatic warming include more effective fuel drying during years or seasons of reduced precipitation, as well as more extreme short-term events such as heat waves, driving extreme fire activity. This coupling has the ability to significantly alter the size distribution and burn severity of burned patches and functioning of affected landscapes, including their future physiognomic types[11] and patterns of species composition. What is apparently most important is that increasingly extreme fire weather is increasing the frequency of large and severe fires, and quite small increases in the frequency and extent of large high-severity fire patches can result in tipping points for ecosystems.

These points of common ground coincide with increasing evidence that when recent wildfires severely burn large areas of forest, local elimination of conifer tree seed sources and reduced tree regeneration under emergent warmer-drier conditions can occur. As a result, large areas of forest increasingly are converting to persistent grasslands or shrublands post fire in some regions.

Areas of Divergence

Key areas of divergent opinion among respondents included:

- With respect to current fire regimes, the relative importance of landscape changes in vegetation and fuel properties in comparison with weather and climatic changes.
- The degree to which the frequency of large, high-severity fires and large, severely burned patches within fires has increased, and over what time frames.
- The extent to which landscape tipping points have been reached as a result of high-severity fires.

[11] Examples of physiognomic types include evergreen broadleaf forest, deciduous broadleaf forest, evergreen needle-leaf forest, deciduous needle-leaf forest, grasslands, shrublands. From: 1) Kuchler (1949) A Physiognomic Classification of Vegetation. Annals of the Association of American Geographers, 39(3), 201-210; 2) Box (1981) Predicting physiognomic vegetation types with climate variables. Vegetatio 45: 127-139.

One core area of divergent opinion is the relative importance of landscape change to current fire regimes. Empirical research in some landscapes shows that landscape abundance and horizontal and vertical continuity of woody surface and canopy fuels has increased in many western US ecoregions, which when combined with empirical and modeling research on fire behavior, supports an inference of increased fire intensity, longer flame lengths, increased crown-fire ignition and spread potential, and burn severity (i.e., *fuels affect fire behavior and burn severity*).

On the other hand, much recent research concludes that trends in annual area burned or in numbers of large fires are explained by weather and climatic influences on fuel availability. In these latter studies, drought and related time series are used to predict annual area burned. Models generally show fair to good prediction of a positive climate involvement (i.e., *climate drives the recent increase in area burned*). However, more complex statistical models that show multi-way and multi-scale interactions among fuel properties, fire weather, topography, and climatic predictors of fire extent and burn severity are needed.

A critical limitation on this front has been the lack of quantitative data, for some ecoregions, on changing fuel properties geographically and by forest type. Currently, in some ecoregions, we know more about how area burned and fire extent are influenced by climate than how the ecological effects of fires are affected by both changing climate and fuels. We also know that burn severity varies with fire weather, topography, vegetation, and time since fire (or other disturbances), even when large fires are burning under relatively extreme weather. However, there are few studies that show the relative contributions of each of these factors and climate together to burn severity. Recent reports of increasing burn severity for some ecosystem types are mostly, but not entirely, limited to the 1984-present period, due to the limited temporal depth of Monitoring Trends in Burn Severity (www.MTBS.gov) data. In addition, some respondents were concerned about adequate validation of the MTBS data for that period.

A second core area of disagreement hinges on the degree to which the frequency of large, high-severity fires and large, severely burned patches within fires has increased, and how this differs for dry, moist, and cold forest types. Many respondents believe that the frequency of large fires has increased in association with *both* climatic warming and increased woody fuel abundance and continuity, but as noted, broad-scale analyses of the relative contributions of climate parameters versus altered fuels to observed fire trends remains an important research challenge. Nevertheless, for landscapes with documented large-scale increases in woody fuel connectivity, there is a widely shared concern that increased abundance of large high-severity wildfires has expanded the potential for creating broad-scale shifts in dominant physiognomic types.

Implications

There is broad agreement that both climate and fuels are critical regulators of fire regimes in western US forests. In extreme weather, fires are likely to be large and severe, and managers should be mindful that extreme fire weather is expected to become increasingly common in the 21st century. Under milder conditions, however, fire behavior is mediated by complex interactions among climate, weather, topography, vegetation type, and fuel properties that vary spatially due to successional patch structure and patch size distributions. Further, prior fires (both managed and wild) can alter the extent, burn severity, and patch size distribution of subsequent fires depending on time since fire, topography, climate, and other factors.

In many, but not all, portions of the West (including the Inland Northwest and Pacific Southwest, Colorado Front Range, and monsoonal Southwest), scientists and managers have a reasonably large range of studies documenting changes in forest fuel and seral stage patterns of interior forest types, especially those leading to altered fire regimes. It is likely that restoration activities that seek to reduce fuels and restore successional conditions and their altered spatial patterns can be adequately informed, in particular if appropriate attention is paid to the differences in forest type and habitat.

Topic G. The role of changing climatic conditions is increasingly important

Common Ground

Key points of common ground among the respondents to the questionnaire included:

- Climate variability is a key driver of historical and current fire regimes, with distinctive historical patterns of climatic drivers of fire activity evident in different landscapes.
- The western US has recently been affected by a rapidly warming climate, characterized by reduced snowpack, earlier springs, longer fire seasons, hotter droughts, and more frequent periods of extreme fire weather.
- Recent trends in many western forest regions of more large fires and more area burned are linked to recent climatic trends of hotter droughts and longer, more severe fire seasons.
- Projected climate changes toward substantially hotter and drier conditions in the western US are expected to become increasingly significant drivers of amplified forest fire activity and severity; associated climatic interactions with vegetation and fuel conditions will also increase in significance.
- Climate changes, along with other anthropogenic drivers of global change, affect many vital climate-driven forest processes that will interact with changes in fire activity.

Questionnaire respondents noted that climate variability is now accepted as a driver of both historical and current fire regimes in all western US forests. Distinctive historical patterns of fire activity—driven by periods of hot and dry climate—are evident and well-documented in numerous western US landscapes (see Topic F). This important consensus coincides with the broader scientific consensus that the current western US climate has trended hotter and effectively drier in recent decades. This hotter and drier climate has fostered reduced winter snowpacks, milder winters, earlier springs, more rain-on-snow events, longer fire seasons (at times 40 to 80 days longer), drier fuels, and more instances of extreme fire weather—all generally consistent with regional model projections of future climatic change. Some western ecoregions now have nearly year-round fire seasons.

Consensus also emerged from the questionnaire that these recent climatic trends are linked to changes in fire activity since about 1980-85, contributing to larger fires, more area burned, and more moderate- and high-severity fire in some western US forests. Projected future climate changes toward progressively drier fuels and more extreme fire weather conditions in the western US are expected to amplify forest fire size and area burned. Proportion of high-severity fire may follow different trends as burn severity is more affected by topography, vegetation, and fuel beds, and less by climate than area burned (see discussion about the relative importance of fuel treatments; Topic E). We note that climate and fire weather largely determine the moisture content of vegetation and surface fuels, which has a strong effect on the availability of fuels to burn, energy released by the fuel complex, and resulting flame length, fireline intensity, and smoke emissions. Given projected climate warming and drying in the West, current forest fuel accumulations will be reduced through time by anticipated increases in fire activity (although surface fuel loads typically spike within a decade as standing post-fire snags [i.e., dead boles and branches] fall down amidst diverse vegetation regrowth), by constraints on forest regrowth under a hotter and drier climate, and by forest transitions to non-forest vegetation over increasingly large areas. In some of these areas, afforestation due to lack of fire has occurred, which reduces vegetation flammability and rate of spread. Anticipated future changes in forest fire activity and fire effects ultimately will be modulated by these feedbacks among fire, fuels, vegetation succession, and climate.

Respondents also indicated that emerging climatic changes also widely increase tree physiological stress, and adversely affect tree regeneration, growth and mortality losses, and associated insect and disease outbreaks. Thus, ongoing and future climate-induced changes in forest extent, forest fire extent, severity, and effects must be understood in relation to these additional biotic, abiotic, and anthropogenic factors.

Areas of Divergence

Key areas of divergent opinion among respondents included:

- There remains a divergence of opinion over the relative contributions of climate change and fuel accumulation to current patterns and trends of wildfire activity.
- Effectiveness of fuel treatments under projected climate futures and associated more extreme fire weather.

All respondents agreed that climate change is occurring and likely to continue. The main divergence among respondents involved perceptions of the relative importance of climatic versus fuel factors as drivers of changing fire activity, both now and in the future. This basic divergence in perspectives emerged repeatedly in questionnaire responses, as noted in Topics E and F, despite a general lack of scholarly work to explore joint contributions of climate and fuel to fire extent and burn severity.

This divergence in perspectives about the relative importance of climatic versus fuel factors as drivers of changing fire activity also extends to a related divergence in views on the effectiveness of fuel treatments under projected climate futures and associated more extreme fire weather; this area of divergence is presented under Topic I.

Implications

There is wide agreement that climate has long been a principal regulator of wildfire activity and therefore there is broad consensus that climate change via decreased fuel moisture and more extreme fire weather will considerably impact future wildfire activity. There is also wide agreement that fuels are a principal regulator of wildfire activity and fire effects. Divergent opinions emerge with respect to the relative importance of climate and fuel accumulation. Looking ahead, managers should expect climate change to create conditions of declining favorability to historically dominant forest communities, including warmer droughts, reduced snowpack and other phenomena. These general climatic trends are likely to be conducive to longer fire seasons and greater fire activity in the 21st century. Increasingly extensive vegetation transitions to more drought-tolerant and better fire-adapted species and/or lifeforms are anticipated. Although fuel properties directly influence fire behavior and fire effects, managers require in-depth knowledge of all determinants of fire behavior, including expected climate-related effects on fuel moisture and vegetation and other ecological changes, to determine the extent of possible feedbacks with climate change.

Anticipated changes in western US wildland fire activity have the potential to disruptively challenge the sustainability of historical forest ecosystems and our linked human societies. We expect that a broad range of fire-related adaptation measures will be considered in many western forest landscapes, ranging from increased regulation of human land use activities (e.g., disincentives for exurban development, building codes, seasonal recreation restrictions), implementation of diverse vegetation treatments (including managed wildfire, prescribed burning, and strategically-placed mechanical treatments), to management of forest stand structures, tree species compositions, and genetic variability, in order to foster resilience to growing drought stresses and associated disturbances (fire, insect outbreaks, tree regeneration failures). We expect increased societal attention and preference for such adaptation efforts in order to increase the likelihood of favorable forest adjustments to increasingly novel climate and other emerging environmental stresses.

Topic H. Multiple fire ecology and fire history research approaches can be useful to characterizing fire regimes

Common Ground

Key points of common ground among the respondents to the questionnaire included:

- It is desirable to use multiple methods to reconstruct historical fire regimes. More can be learned using multiple approaches and considering data from diverse temporal and spatial scales.
- Integrating and interpreting findings derived from diverse methods, data sources, and different scales of inquiry can be challenging.

The interpretation of any research evidence and the scope of related inferences is limited by scaling and sampling concerns associated with the methods, and these limitations apply to all research methods. Respondents to our survey strongly agreed with the statement that "*New and important insights should be possible through studies that use and compare alternative sources of data, and results may be used to examine fire history and fire effects in the same study areas.*" Respondents disagreed with the statement, "*Even if we find many different study areas where alternative sources of data are available, there are too many uncertainties or incompatibilities among them to make such comparisons useful.*" Thus, respondents recognized the high potential value of using and considering multiple approaches, data sets, and scales of observation to more robustly assess historical fire regimes. Broadly speaking, this reflects widely-accepted scientific views on the general benefits of using multiple lines of evidence when possible, with increased confidence in conclusions when most results are in agreement.

For this project, we decided to focus on the evidence regarding fire regimes of recent centuries, although substantial paleoecological research using sedimentary charcoal and pollen data has been essential in expanding our understanding of long-term variations in fire regimes. All methods for reconstructing historical fire regimes are necessarily indirect. They may include, but are not limited to, interpreting evidence of past fires or the extent of fire-dependent ecosystems from historical documents, land surveys, aerial photographic reconstructions, fire-scar and growth-release data from tree rings, tree age and death dates from tree-ring data, climatic data linked with past fires, charcoal and pollen deposits, current characteristics of stands (i.e., structure, species, and stand age distribution), fire perimeter mapping, historical timber survey data, and use of statistical distributions for modeling stand-replacing fire. In addition to utilizing multiple methods, the use of clear and shared terminology is needed for effectively combining research approaches to characterize fire regimes. Similarly, the use of diverse archaeological, anthropological, and cultural resource research methods that address the extent and impact of aboriginal fire uses in landscapes can provide useful information in support of restoring culturally important landscapes and their fire-maintained cultural resources.

Respondents noted that multiple methods enhance the potential of inferring the severity and other ecological effects of past fire events, which is central to current debates about the relative proportions of fires of different severity in the past. There are diverse examples where western fire researchers have used multiple methods to characterize historical fire regimes. Commonly, there is general agreement among studies about characteristics of historical fire regimes, particularly for ecosystem types that have had a history dominated by either low-severity fires (e.g., leaving scars but not killing many adult trees) or high-severity fires (killing many adult trees).

In recent decades, we have increased our learning about the strengths and weaknesses of diverse methods and data sources for analyzing high-severity fire, and also the scope of spatial and temporal inference limits for reconstructing historical fire regimes and forest conditions in varied western US landscapes. A particular challenge has been elucidating historical spatial patterns, such as patch sizes, shapes and arrangement. Much of this expanded insight has come on the heels of examining relationships between documented fire histories and associated forest successional or cohort conditions. In particular, further developing studies that cross-walk dendroecological fire histories with aerial photo interpretation and cohort age structure analyses offer much promise. These methods too can be combined with simulation studies that may offer additional insights. Respondents recognized that a more productive approach to multi-methods analysis might be for research laboratories that specialize in one method or another to collaboratively join their strengths in designing, implementing, interpreting, and documenting results of such research through joint work in multiple landscapes.

Areas of Divergence

The areas of divergence in opinion among respondents included:

- The introduction of new methods for reconstructing historical fire regimes has, in recent years, resulted in unresolved debates regarding the limits and usefulness of some new and old methods.

  There currently is significant debate about the validity and thus utility of some new approaches using historical (General Land Office, GLO) and current (USFS Forest Inventory and Analysis, FIA) land and timber survey data to infer the amount of high-severity fire, forest species composition, and the density and age structure of historical forests. Similarly, extrapolating from historical tree-ring and fire-scar point data across much larger areas has been a topic of some debate, but the disagreements are quite different. In the former case, disagreements center around the usefulness of the land survey data to the ends applied. This results from doubts regarding differences in interpretations of historical fire regimes based on tree-ring or other data versus historical land survey data. In some cases these differences are large but in other cases the percentages of a landscape classified as having an historical fire regime of mainly low-severity versus mixed (or higher) severity fire are relatively slight. The validity of reconstructing historical forest conditions and fire regimes in particular from all types of historical land or timber survey data has been critiqued. Such scrutiny of the validity of methods is a normal part of the scientific process, and highlights the need for continued research based on cross-validation from multiple types of data and methods.

Implications

The use of multiple methods for characterizing historical fire regimes, combined with increasingly clear and shared terminology, can improve our understanding of HRV patterns and processes in western forests. However, there can be significant challenges associated with bringing together evidence about historical fire regimes from differing methods and data sources. Each line of evidence has a different scope of spatial and temporal inference, and issues about the nature of the data captured in each sample. In addition, there is substantial skepticism about the utility of some methods for HRV reconstruction purposes, which will have to be resolved. Nonetheless, one new frontier of fire ecology research is the exploration of multi-method approaches by collaborating labs toward more-nuanced understandings of diverse fire regimes. For example, in mixed-severity fire regime forests, by combining time series derived from diverse dendroecological data sources (e.g., fire scars, death dates of trees, establishment of postfire cohorts, growth releases on surviving trees), land survey data, aerial photographic interpretations of successional and past fire severity conditions, landscape panoramic photos, and simulation modeling, stronger inferences may be possible about the ecological effects of past fire events.

Topic I. Many existing fire management tools and strategies can be useful for managing fire going forward

Common Ground

Key points of common ground among the respondents to the questionnaire included:

- Many tools can be useful to fire managers for reducing human vulnerability to fires and increasing ecosystem resilience.
- Managed wildfire is underutilized but viable ecologically and socially in many areas.
- Managing fuels is important and fuels are one contributing factor that can be influenced through management.
- Thinning alone without managing the resulting fuels increases surface fuels and does not mimic many of the ecological effects of fire.
- Firefighter and citizen safety, degree of smoke production, financial costs, and effective scales of treatment must all be considered.
- Land-use and financial incentives could be used to reduce human vulnerability to wildfires in and near the WUI.

Many respondents stressed that a wide variety of tools and policies can be useful to increase forest resilience and reduce human vulnerability to future fires. Suppressing fires to protect highly valued resources is important, but managers need a full suite of active and passive management strategies and tools because different management situations often call for different approaches. There was strong support for managing wildfires to accomplish resource benefits and also support for prescribed burning[12]. We agree. However, there was very little discussion of how and where wildland fire use can be effectively implemented to foster desirable patch size distributions, particularly where climate and forest conditions have changed, and surface and canopy fuels have accumulated over the period of fire suppression. Broad-scale landscape planning for wildland fire use will be essential to better understand special circumstances and clear opportunities for its use.

Wildland or prescribed fire use can be effectively complemented with fire suppression strategies and with thinning to reduce vertically and horizontally continuous fuels that contribute to fire hazard. Tools such as the Wildland Fire Decision Support System are used to make effective fire management decisions considering landscape conditions, jurisdictions, fire weather, values at risk and local management objectives.

Increasing education and outreach, managing post-fire to reduce soil erosion potential where values are at risk, decommissioning roads, creating snags where they are in short

[12] Wildfires are ignited by people or lightning. They may be suppressed, either aggressively or with more limited efforts, depending on management objectives, values at risk, costs, firefighter risk, and other factors. Managed fires are those that achieve resource objectives. They are monitored and parts may be actively suppressed while other parts are managed with less aggressive suppression. Prescribed fires are ignited by management actions under certain, predetermined conditions to meet specific objectives, such as reducing hazardous fuels, improving habitat, managing cultural resources, firefighter training, fire behavior experiments, or restoring forests. Prescribed fires are nearly always conducted under written, approved plans.

supply, and other tools can further help accomplish management objectives, while protecting people and property from fire and fire effects. Other strategies for helping communities become more fire-adapted include altering residential development in highly fire-prone environments, and making existing homes safer from wildfires. Land-use (e.g., applying the national WUI building codes proactively and retroactively, zoning to concentrate development in lower fire danger environments) and financial incentives (e.g., tax, insurance, mortgage restrictions, fees, assistance with fuel treatments around homes and towns, support to mitigate structure ignition vulnerabilities) could be used to reduce vulnerability to wildfires in and near the WUI.

Certainly, fire managers must consider financial costs, firefighter safety, public safety, and smoke. These and other societal and operational management constraints vary geographically, so managers must look for opportunities to adapt and use multifaceted strategies. There was widespread agreement among respondents that the suitability of different tools is highly context specific. In discussing strategies, both the often significant beneficial and detrimental consequences of taking no action must be considered.

There is strong consensus that more fire is needed on the landscape, but not all wildfire behavior or extent will do. Managers need assistance and funding to create landscape conditions that favor more desirable fire behavior at spatial scales and extents that can make a difference to current conditions.

Respondents generally indicated that the scale of landscape change in western US forests is quite broad, and that it could be difficult to overcome (i.e., a high level of landscape inertia), especially with the current level of defunding of public land management agencies. The cost of fire suppression has risen from 17 to nearly 60% of the entire Forest Service budget in the last 25 years, greatly limiting the financial capacity of the agency for proactive work at any meaningful scale. Treatments need to be of sufficient scale and pattern to be effective at restoring patch-size distributions of low-, moderate-, and high-severity fire, and at reducing what is seen by many as an increasing risk of unusually large, high-severity patches within fires. Although fuel treatments can be prioritized across very large landscapes to be potentially effective in managing wildfires to accomplish resource benefits, such treatments must be designed consistently with other ecological and management goals including riparian corridors, habitat for listed species, and the like. Restorative treatments likely need to occur at the scale of the landscape changes to change current fire regime conditions. Due to widespread existing habitat reserve commitments, opportunities for strategically allocated treatments are substantially limited.

Given the profound influence of the type and amount of fuel on fire behavior (Topic F), the type, location, timing, frequency, and maintenance of fuel treatments[13] will all influence their effectiveness. Forest thinning is one commonly applied fuel treatment. Most cutting methods that are applied to reduce future burn severity are thinning treatments where emphasis is on removal of the less fire-resistant trees (usually the smaller ones especially of shade tolerant species). The intensity of thinning determines the amount of branches and tree tops (slash) left behind. There is consensus that follow-up burn treatments of this slash are critical, however, this can be logistically and financially challenging because of highly restrictive smoke management policies. Post-harvest slash burning typically involves burning of piled slash concentrations, and in some cases, broadcast burning of remaining fuels. Prescribed burning

[13] Fuels treatments and fuels management include planned prescribed burns, mechanical treatments such as mastication or thinning, and silvicultural treatments and other treatments designed to change or reduce wildland fuel quantity and arrangement, the intensity of future fires, and increase the ease of fire suppression.

can also be done independently of thinning to reduce surface and ladder fuels, and to reintroduce more natural fire to the ecosystem. There are often significant constraints to this sort of prescribed burning though. For example, where surface fuels are too abundant, and where tree density and layering are significant, burn-only treatments are difficult to execute with any certainty. Burn-only treatments are also highly influenced by favorable fire weather (moderate conditions are best to accomplish goals), availability of fire crews, and smoke management restrictions. Respondents support efforts to overcome these roadblocks so that more fire can be reintroduced. Additional prescribed burn considerations for managers include improving public support for them, helping to design fuel treatments that mimic historical fires, using more fire during the fire season, enlarging the number, size, and positive effects of burns, and decreasing undesired effects of slash burning. Prescribed burns also consume less fuel and are far smaller than large wildfires, thus they produce far less smoke and smoke exposure to the particle sizes that are most harmful to human health.

Many respondents noted that managed wildfire is underutilized. It can be a viable tool ecologically, despite operational constraints. Ideally, this will result in more area burned under less than extreme weather conditions, and more moderate-severity fire effects resulting in heterogeneity that can be more consistent with both the historical range of variability and long-term management goals, if only for altering where and how future fires burn. Practically, there are large areas where mechanical thinning is neither allowed nor feasible, for example in wilderness and roadless areas. Managing wildfire may be useful there for reducing fuel quantity and altering vegetation composition and heterogeneity consistent with management objectives and enabling policy.

Wildfires can sometimes be managed at less cost and less risk to firefighters in areas where other fuel treatments are neither feasible nor desirable. Advanced planning is needed, as is accepting long-term risk and smoke when such fires burn for many days. Public lands are sometimes mapped into zones designated for particular management, included allowing fire. Challenges include societal constraints (e.g., smoke, fear of fire, concerns about shifts in weather, and distrust of managers and scientists) and operational constraints (e.g., costs, long-term risks, timing, and suitable weather). Smoke from fires poses human health hazards and visibility issues. Despite best efforts, some managed wildfires will not go as planned. The biggest challenges are the expanding area of WUI, public and political perceptions of fire and smoke, and unpredictable changes in fire weather. When homes burn, the fear of wildfires and their smoke often fuels political support for aggressive fire suppression, which reinforces the current predicament. But there are beneficial aspects of wildfire smoke too. For example, in northwestern California, Mid-Klamath Basin tribes recognize benefits of canyon smoke inversions for reflecting direct sunlight, and cooling air and river temperatures that can benefit native salmonids. Smoke is also a naturally occurring fumigant that reduces nut, seed, and acorn infestations by forest insects, and along with fire, facilitates seed germination of some native plants if smoke occurs during the natural fire season.

Managing wildfires to accomplish resource benefits may be one important way to achieve relatively widespread vegetation change at the spatial scales and in the short time frame needed to make a difference in the short-term. Depending on the situation, this will typically require strategically pretreating a portion of the landscape using prescribed fire—sometimes coupled with thinning—to reduce vertical and horizontal continuity of fuels, and to anchor managed wildfire or prescribed burning treatments. Such strategies can help manage risks and help society be more comfortable with less aggressive fire suppression, especially in or near the WUI. In remote locations far from the WUI and most vulnerable infrastructure, fairly typical mixes (for the fire regime of interest) of low-, moderate-, and high-severity fires may be a desirable and achievable outcome that is compatible with forest resilience, despite the many challenges managers face in managing wildfires.

Where there is a high concentration of values at risk and sensitive human populations within the WUI, aggressive fire suppression and fuel treatments may be the only socially acceptable strategies. In these situations, managing forests abutting the WUI with thinning and prescribed or pile burning, and aggressive fire suppression, will be appropriate.

Areas of Divergence

Key areas of divergent opinion among respondents included:

- Appropriate locations, scale, and effectiveness of thinning aimed at reducing fire hazard.
- The scale of thinning that can be feasibly and repeatedly implemented relative to the scale of the need.
- Advantages and disadvantages of managed wildfires, including acceptable levels of risk.

Communities often feel a strong sense of urgency and need for hope in the face of threats from wildfires. For areas distant from the WUI and municipal watersheds, some respondents disagreed with the degree of urgency and scale of need for thinning and prescribed burning.

Another area of divergent opinion is the role that forest restoration and fuel treatments might play in charting a new course for forest resilience, especially where public lands are considered. Arguments for restorative treatments range from concerns that prescribed burning or other treatments are needed where the condition of many forests before wildfires can result in undesirable burn-severity and patch-size distributions, to the belief that treatments are not restorative because large areas can only be effectively restored by proactively working with wildfires that are assumed to be “natural.” A range of other arguments falls somewhere on this continuum. One challenge is that fuel treatments may not be performed at a necessary pace and scale, especially when coupled with operational maintenance costs over time. Another view is that fuel treatments are less important in areas that would have experienced some degree of high-severity fire, and these areas may have been widespread and have greater positive influence on biodiversity and wildlife than is currently understood. This is underscored by strong opposition to partial to complete post-fire logging (salvage) of fire-killed trees, because some snag forests provide valuable habitat, and there are concerns about ecological integrity. The crux of this disagreement is whether the dead trees are most useful for their commercial or ecological values. Another view shows that some areas of high-severity fire tend to burn again at high severity, and that efforts to treat fuels and re-create more varied successional and fuels mosaics can help break this cycle. Yet another view asserts that in some instances, burned forests would benefit from removing dead smaller trees that could constitute critical reburn fuels.

Some scientists’ opinions diverge regarding the relative importance of climate and weather (fuel moisture and availability to burn), and fuel quantity (Topic F). For example, for some, there is more acceptance of the utility of fuel treatments within dry forests than in cold subalpine forests. Further, many scientists differed on the scale of treatment needed to influence high-severity fire at landscape scales because of questions about treatment effectiveness given the large amount of fire that burns under extreme weather conditions. Indeed, most current large wildfires are not even finding fuel treatments at the current low level of application. There can also be problems with non-native invasive species increasing in abundance following thinning and/or fire, particularly in lower-elevation forests. Many disagreed on the extent to which levels of high-severity fire and landscapes have changed, and the degree to which fuel treatments far from the WUI are a net benefit. The degree of divergence differs by forest type and landscape context, with stronger agreement about landscape change for dry mixed-conifer forests, and less for landscapes dominated by cold subalpine forests. Another argument by some for not actively managing landscapes outside the WUI is that even where there is strong support for treatments, the cost and difficulty of implementing and maintaining existing treatments may already be too great for society to absorb; this consideration is beyond the scope of this report. Of course, societal cost and practicality must be considered in the context of potential loss of forests, fire-adapted biota and other resource and social values. Further, reduced reliance on fuel treatments might imply an increased use of managed wildfire, but there is currently no consensus framework for weighing the costs and benefits of managed wildfire.

Some divergent opinions derive from establishing forest treatment targets, especially when those targets are not yet socially acceptable. For instance, thinning from below (removing many smaller, fire-intolerant trees while leaving older, larger trees) will reduce fire hazard under many circumstances, and can be a first step in ecological restoration treatments in many dry mixed-conifer forests. However, these treatments must be followed by prescribed burning, and a certain amount of smoke production, to reduce fuels and potentially restore ecosystem processes in the short-term. In some cold subalpine forests, however, where fires are more often limited by weather than by fuels, fuel treatments beyond the WUI may be relatively ineffective when and where fires spread by long-range spotting.

Some respondents noted that current landscape conditions reflect suppression of most fires, effects of past logging, and land uses that have often resulted in landscapes that are more homogeneous fuel-wise, notwithstanding widespread fragmentation by roads. Some respondents argued that these more-homogenous landscapes are more vulnerable now to very large patches burned with high-severity fire relative to historical conditions. Others saw less divergence between present and past high-severity fire potential (see areas of divergence Topics B, E). Careful analysis is needed in each unique geographic location.

Another challenge is that treating large areas is difficult when there is strong level of distrust. Collaboration with diverse groups has in many cases strengthened trust, especially when treatment approaches have been altered through a consensus-building process.

Implications

Managers seeking to reduce human vulnerability to wildfire and enhance forest ecosystem resilience should have available to them a flexible set of management options that includes suppression, thinning and other fuel treatments, prescribed burns and managed wildfires, as well as broad education on both the essential roles of fire and on prevention of undesired human-caused fires. The uses of these various tools should depend highly on management priorities and local context, including vegetation structure and composition, legacies of past fuel treatments and land use, the historical range of variability, presence of houses and resources people highly value, and acceptance by people. In the future, prescribed fire and managed wildfire will be useful to increase or maintain forest structural heterogeneity and restore associated ecosystem processes. Fires can limit the extent and severity of subsequent fires.

Fires respond to interacting influences of climate, weather, fuels, topography, legacies of prior disturbances, and management. The relative importance of these factors varies across landscapes and through time. Those who express that increasingly extreme fire weather with climate change will increasingly override the importance of fuels argue that fuel treatments should be focused around the WUI with limited fuel treatment elsewhere. Their logic is that direct protection of human assets is the top priority on which to focus, and that fuel conditions are less important as fire weather becomes more extreme. Those who emphasize the importance of fuels to fire behavior urge strategic fuels management in both WUI and non-WUI forest landscapes, using a variety of tools and prescriptions as needed across dry, moist, and cold forest types. They also assert that fuels are the main landscape characteristic that management can change. Where fuels and vegetation patterns have changed to foster more contagious fire spread, fires will be widespread and often large when fire weather and fuel moisture are conducive, particularly where grass fuels are continuous.

Going forward, monitoring is important to assure that fire management supports long-term vegetation management goals, particularly in the context of climate change, or to modify management to better align it with goals. We need to learn where fuel treatments are effective under different environmental conditions and where they are not, and then we must adapt management informed by monitoring. Scientist-manager partnerships could be particularly useful here to develop useful monitoring frameworks.

Where managed wildfire is not socially acceptable, more aggressive fire suppression and fuel treatments will be appropriate, along with prescribed burning. Many wildfires will occur and some will be large. With thoughtful management, we may be able to influence their severity and spatial extent under many but not all fire weather conditions.

To address future challenges in the face of expanding WUI, longer fire seasons, and altered forest conditions, managers need many different tools to balance ecosystem needs, costs, risk to firefighters and the need to protect people and property from fire. Federal fire policy allows this flexibility, and fire managers need it if they are to reduce societal vulnerability to fire and smoke, while also limiting costs and risks to fire personnel, and managing for ecosystem values. Addressing the vulnerability of the WUI depends on other approaches as well. Thus, policies to make current WUI communities more fire adapted are critical, as are changes in land use policies that influence where and how future WUI areas develop.

Conclusions

We found much common ground that will be useful to scientists, managers, and others for moving forward. There is wide agreement among scientists that fire is one of the most essential and pervasive influences on the forests of the western US. Further, fires can produce more positive benefits and fewer negative impacts when they burn with an ecologically appropriate mix of low, moderate, and high severity, and in patch size distributions that reflect the natural variability of fire behavior and fire effects.

Many questionnaire respondents suggested that the real challenge is to face the twin realities of increased abundance and connectivity of woody fuels and a changing climate. Not surprising, there were differing opinions about trade-offs between social values and the ecological benefits of fire. For example, smoke from wildfires or prescribed fires is a great concern that can have important influences on how various fire treatments are applied. There was wide agreement on the need for land management strategies that reduce societal and ecosystem vulnerability to negative consequences of wildfire, while providing for the essential role and benefits of fire in forests.

Areas of agreement outnumbered areas of disagreement. Respondents agreed that geographical context is very influential and that human impacts vary, and therefore there is no single one-size-fits-all management prescription. There was strong support for utility of the historical range of variability (HRV) for fostering understanding of how and why ecosystems have changed, and how they respond to fires of varying severity. Despite rapidly changing conditions, HRV will continue to be useful as a guide, but not a prescription for future landscapes. From HRV we can learn how ecosystems respond to wildfires, and the HRV of landscapes and ecosystems forewarns about ecosystem capacities and limitations in response to varied climate and disturbance drivers. As a guide for managing future landscapes, history does not provide precise prescriptions, but does offer precautionary principles. We fully recognize that adaptive resilience for the future will require applying what we learn from history to some future range of variability, where fires burn and ecosystems respond in both similar and different ways. There was strong support for prescribed burning, coupling thinning with prescribed burning, and for managing wildfires to accomplish resources objectives. This is common ground.

Forest structure, composition, and fuels have all changed, affecting burn severity and successional patch size distributions. Climate and fuels together with topography will influence future fires and their effects. There was consensus that many fire management tools and strategies will be useful moving forward, and no tools should be excluded.

We challenge managers and scientists to overcome the tendency to oversimplify historical fire regimes across and within ecoregions and forest types: there is no single model of historical fire regimes. Managers should exercise caution when applying scientific understanding developed in different landscapes and recognize that this may result in erroneous scientific underpinnings and failure to meet local objectives. Rapidly changing circumstances suggest that future management should be highly adaptive, incorporating learning from what works well and poorly. To adopt an adaptive management stance though, managers will need to engage in ongoing monitoring to detect and learn more about the best and poorest methods and outcomes. Scientists can work with managers in these practices, and such partnerships could provide a potent resource for managers. Scientists must also clarify the importance of place when characterizing and presenting knowledge about historical fire regimes, and scientists and managers would both benefit from sharing methodological approaches and collaborating across ecoregions. Scientists and managers should work together with science communication experts to create training and reference materials that capture appropriate levels of simplification and complexity.

Broader discussions center on issues where there is less common ground, including:

High-severity fire

There was strong common ground that for dry pine and some dry mixed-conifer forests, there has been either an observed increase in high-severity fires or an increase in the potential for fires of elevated severity. These changes have occurred as the result of increased area and density of forests, and increased connectivity of woody fuels since the late 19^{th} century. In contrast, for cold subalpine forests the majority of survey respondents agree with the statement that these forests have been less affected by fire suppression. Yet, large-scale landscape assessments of forest spatial patterns in the Inland Pacific Northwest show that recent (i.e., post 1984) patterns of high-severity fire and changes in patch size distributions in many moist mixed-conifer and cold, subalpine forests reflect significant departures from longer-term patterns linked to both climate, increased forest area, and increased density, layering, and connectivity of these forests. Expanded woody fuel connectivity is a result of synchronized successional conditions as a consequence of fire suppression and fire exclusion. Suppression of wildfires in moist and cold forests has yielded much lower prevalence of early seral conditions, and increased connectivity of mid- and late seral conditions, which has concomitantly increased landscape connectivity of conditions that are conducive to initiation and spread of crown fires. Conclusions differ for some cold subalpine forests in the Southern Rockies based on published studies and survey responses. Unfortunately, we don’t have similar information on landscape change across moist and cold subalpine forests in some other ecoregions. Reasons for these different perspectives on the degree of long-term change in the extent of higher severity fire are varied and complex. Some of the variability in scientific perspectives is empirically attributable to geographical differences in the factors determining historical and modern fire regimes. Others reflect disagreements over methods of examining changes in fire regimes and the interpretation of the evidence of past higher severity fire. Still others reflect the goal of influencing management.

Dry mixed-conifer forests (including areas once dominated by pure or nearly pure ponderosa pine), moist forests, and cold forests have all changed in recent decades. The degree of change is not the same everywhere, yet fires interacting with climate and current forest conditions have the potential to create very large patches and a relatively high proportion of areas burned with high severity. This has implications for post-fire tree regeneration (without which forests convert to non-forest), soil burn severity, and related erosion and watershed change, and other ecosystem services valued by society and affected by varying plant successional processes and trajectories. Non-forest vegetation may be maintained by fire where it is not suppressed; even in the absence of fire, however, forests may not regenerate if seed sources are not available. In some areas, forests have increased and non-forest decreased, due to fire suppression.

Both fuel and climate are important as increased woody fuel connectivity in combination with a warming climate trend is setting large areas of landscapes on fundamentally new trajectories where very large patches burn with high severity. Climate is of increasing importance.

Empirical and simulation studies and landscape ecology theory suggest that even small increases in the frequency of the largest high-severity patches can have a semi-permanent influence on future local and regional landscape habitat configurations and wildfire frequency, severity, and spatial extent. Thus, individual fire events can change the broad-scale resistance of the landscape to future wildfires. How these scenarios will play out under continued warming and more fires is highly uncertain.

We suggest that resolving many disagreements depends on greater consideration of specific geographical context. A logical suggestion is to increase in-depth cross-regional field research experiences of the fire research community. Cross-regional comparisons of top-down and bottom-up determinants of fire activity in similar forest cover types is a fertile area of future research to examine how differences in seasonality, productivity, understory fuels, land use history, and other factors may explain some of the reported geographical differences in historical fire regimes in broadly similar forest types. Likewise, systematic regional comparison of the timing and nature of land-use practices by Native Americans and European settlers on fire regimes would improve our understanding of how changes in anthropogenic ignitions, fire exclusion, logging, ranching, mining, and landscape fragmentation may have contributed to geographic differences in historical fire regimes.

There are several reasons for the disagreements about patterns of past fire severity. First, both scientists and managers often uncritically transfer concepts and findings from one place to another (see Topic A). We know that fire effects at a point depend to some degree on the surrounding landscape and forest composition. Some of the disagreement derives from debates over the relative utility and validity of different scientific methods; nonetheless we believe that application of diverse research approaches is useful in HRV reconstructions. We challenge fire scientists who do not share similar perspectives on historical fire regimes in particular ecosystems to engage in civil discourse to better understand the reasons for their disagreement and to objectively communicate those reasons to managers and other stakeholders. We are heartened by the positive outcomes achieved by some previous attempts when small or large groups work together to find common ground.[14]

WUI and beyond

Respondents strongly agreed on the need for fuel treatments and aggressive fire suppression within and adjacent to the WUI. The strategies for managing wildfire will be quite different within and adjacent to the WUI than in areas far from the WUI. However, what fire managers do beyond the WUI has implications for forest resilience, smoke production and its human impacts, water quality, and many other ecosystem services people value.

Fuels management alone, especially if limited to public land, will not be sufficient to address the vulnerability of WUI communities to fires. Fuels management will be important for influencing the resilience of the future forest, and for influencing the behavior of wildfires that approach the WUI. Thus, policies to make current WUI communities more fire adapted (e.g., implementing current WUI codes) are a critical piece of the puzzle, as are changes in land use

Colorado Forest Restoration Institute.

policies that influence where and how future WUI areas might develop, and the spatial extent and arrangement of managed and wildfire fuel treatments.

Pattern and Process for Fires in Forest Landscapes

Heterogeneity of fire effects, including the pattern of patches created by fires and other disturbances, is important to forest resilience to future fires (see Topic E). There are potentially profound implications for forest function and carbon sequestration if the proportion of area burned with high-severity fire changes. Even more importantly, as the patch size distribution changes greatly, particularly with respect to the proportion and size of the largest patches burned with high severity, there are multiple ecological consequences. For instance, the proximity of seed sources from surviving trees of fire tolerant species can affect forest regeneration, and the future flammability of the forest. Wildlife habitat use will change, both for those species dependent on hiding and thermal cover adjacent to more open areas and for those thriving in recently burned forest openings. Similarly, the fire refugia that many species depend upon to bridge fire disturbances will all be greatly affected. Further, soil erosion potential is often higher when large patches burn with high severity.

Fires are essential to ecosystem function. Largely missing from many western landscapes are the historically most numerous small- and medium-sized fires that burn under less-than-extreme conditions of weather and fuels. Even when they don’t burn much area individually, such fires cumulatively shape landscape heterogeneity, the resistance of the landscape to wildfire growth, the frequency of large fires, and landscape capacity to respond to future large fires. Simulation modeling in forested landscapes suggests that even relatively small changes in the proportion of large patches alters system behavior. Thus, the patch-size distribution of low-, moderate-, and high-severity fires is of prime concern to policy makers, scientists, and managers.

Climate, Fuels, and the Implications of Landscape Change

Because fuels, weather, and topography dictate fire behavior, fuels management is important to efforts to mitigate fire behavior. However, mechanical treatment of fuels alone is not enough. Thinning without follow-up prescribed burning will typically worsen the problem. More flexible and extensive management of wildfires and prescribed fires will be essential, depending on local objectives and conditions, to increase the footprint of land areas showing reduced surface and canopy fuel abundance and connectivity. More extensive use of prescribed burning combined with thinning will be helpful, where forest fuel conditions (both surface and canopy fuels) are not currently manageable via wildfires and prescribed fires alone. The influence of prior fires on the extent and severity of subsequent fires, even when those fires burn under extreme weather and fuel moisture conditions, is a reflection of the importance of fuels. In some areas, forest conditions are such that some manipulation of fuels is needed so that key ecosystem elements are not lost in extreme fires. Many respondents accept that a proactive approach to fire and fuels management on public lands will reduce overall costs and improve climate change adaptation in the long-term. Some respondents questioned the practicality and effectiveness of fuel treatments under a changing climate; however the literature is clear that fuel reductions reduce flame length and fireline intensity, which reduce the likelihood of high-severity crown fires. Sound, science-based monitoring needs to be coupled with adaptive management to provide locally appropriate stewardship of our forests.

Decades of research in landscape ecology show that emergent properties have central importance to ecosystems and their pattern and process regulation, whereas many recent studies of climate-driven fire and vegetation change are less focused on local-scale feedbacks and emergent patterns. This creates a fundamental problem in linking climate change and landscape ecology research. Climate models assume that top-down climate covariates drive temperature, precipitation, and solar radiation conditions. Landscape ecology research shows that those top-down inputs can be highly modified by meso- and fine-scale bottom-up environmental controls to produce emergent climatic conditions that are strictly speaking neither the top-down or bottom-up inputs, but are influenced by these inputs. Climatic forcing alone poorly explains the shifts in landscape patterns because lagged patterns of historical disturbances continue to influence emergent patterns, under all but the most extreme events. The path forward to more effective projection of future fire and landscape change includes better integration of feedbacks from landscape ecological models into climate-driven models of future fire and landscape change.

In many landscapes, the increased abundance and connectivity of forests and fuels is favoring larger fires, and larger patches burned with higher severity. This is widely shared common ground for ponderosa pine forests and in some ecoregions is also applicable to dry mixed-conifer forests. This view is also commonly applied to moist and cold forests in the Inland Northwest, Pacific Southwest, Northern Rockies, and the Inland Southwest, whereas much less increase in fuel connectivity is believed to have occurred in the cold forests of the Southern Rockies. Regardless of uncertainties about departures from historical landscape conditions, there is a coherent argument based on first principles of fire spread that increasing forest patch heterogeneity could foster resilience to future fires, even as the climate changes. Thus, encouraging heterogeneity at various scales and in various processes is important for biodiversity, reducing connectivity of woody fuels, and increasing resilience with future climate change.

Effective management will depend on both science and trust

Our understanding of historical fire regimes can inform decision-making; indeed, such evidence-based decision-making can build trust. However, fire science points to complex patterns that vary with local conditions, so no single solution, such as logging or limiting all logging, will accomplish desired objectives in all forests. Further, no intervention also has consequences, so all decisions need monitoring to support the assumptions of management. Effective monitoring can improve knowledge, and through collective learning can build common understanding and trust.

Fire management can become more proactive and strategic. Existing tools, such as mechanical fuel treatments, prescribed fire, prevention of accidentally-ignited human fires, and managing wildfires will all be useful, but adaptation and mitigation responses to climate change and changing fire activity will require using these tools in strategic ways to fit area-specific goals. Some past disagreements about fire and fuel management strategies may be due to lack of clarity about specific goals, such as resident and firefighter safety, cost reduction, biodiversity issues, and ecosystem resilience under a changing climate.

The timing of fires is important, particularly in the context of a changing climate. While recognizing that wildfire seasons are long and getting longer, we must also take advantage of the milder fire weather and associated effects of fires in the “shoulder seasons.” Managers may find that both less-aggressive fire suppression and expanded use of managed wildfire under relatively moderate weather conditions can aid them where reducing the vulnerability of people and natural resources to fires is the objective.

One of the grand challenges of fire management is balancing the reality that wildfires will occur and are needed by western forest ecosystems, yet people, property, and economies need protection from the adverse effects of fire. Another grand and fairly urgent challenge is discovering the tipping points of transformative change for various forest landscapes in their respective geographies, where large, high-severity fires (regardless of whether they are considered unprecedented or not) may tip forest ecosystems into persistent non-forest states by constraining tree regeneration opportunities. Particularly as climate changes, we also need a deeper understanding of which landscapes may not be able to sustain forests in the future and how fast such transitions are likely to occur. It is clear that our western history of substantial forest fire activity will continue, one way or another: many fires will occur in the future and some will be large. Ultimately, we must find ways to sustainably use and live with fires that are well-adapted to both ecosystem and societal needs of local landscapes.

Ecosystems (1998) 1: 535–545

ECOSYSTEMS

Compounded Perturbations Yield Ecological Surprises

Abstract

All species have evolved in the presence of disturbance, and thus are in a sense matched to the recurrence pattern of the perturbations. Consequently, disturbances within the typical range, even at the extreme of that range as defined by large, infrequent disturbances (LIDs), usually result in little long-term change to the system's fundamental character. We argue that more serious ecological consequences result from compounded perturbations within the normative recovery time of the community in question. We consider both physically based disturbance (for example, storm, volcanic eruption, and forest fire) and biologically based disturbance of populations, such as overharvesting, invasion, and disease, and their interactions. Dispersal capability and measures of generation time or age to first reproduction of the species of interest seem to be the important metrics for scaling the size and frequency of disturbances among different types of ecosystems. We develop six scenarios that describe communities that have been subjected to multiple perturbations, either simultaneously or at a rate faster than the rate of recovery, and appear to have entered new domains or "ecological surprises." In some cases, three or more disturbances seem to have been required to initiate the changed state. We argue that in a world of ever-more-pervasive anthropogenic impacts on natural communities coupled with the increasing certainty of global change, compounded perturbations and ecological surprises will become more common. Understanding these ecological synergisms will be basic to environmental management decisions of the 21st century.

Key words: altered community states; dispersal; multiple disturbances; recovery intervals; scaling disturbances.

Introduction

All natural assemblages are perturbed by both physical and biological forces. These agents of change occur with different intensities, frequencies, and spatial distributions. Some essentially scour the landscape, resetting the successional clock to time zero. More commonly, disturbances leave a residual assemblage that provides a legacy on which subsequent patterns build. We consider the range of single perturbations, from small-scale/frequent disturbances to large/infrequent catastrophes, to be central to much traditional ecology; such directional or cyclical changes stimulated the development of ecology's first paradigm, succession (Cowles 1899; Clements 1905, 1916). A century of accumulated detail on the interplay between pattern and process has provided descriptors for the nature of successional change and system-dependent rates of recovery. There are few surprises embedded here: depending on the time frame of interest, species arrive and depart, canopies or other structures develop, and the system "recovers," converging on the predisturbance state at a rate reflecting the spatial extent and intensity of the disruptive forces. Such patterns have been extensively reviewed (Pickett and White 1985), and variation in recovery dynamics can be attributed to different processes acting independently or in concert (Drury and Nisbet 1973; Con-

Received 14 July 1998; accepted 18 September 1998.

nell and Slatyer 1977). Even large, infrequent disturbances (LIDs) do not appear to override the biotic mechanisms that structure eventual recovery. For example, the 1988 Yellowstone National Park fire, which burned 36% of the park and was an order of magnitude larger than comparable large, infrequent fires, has to date generated no ecological surprises: "the postfire ecosystems are shaping up to be essentially the same as those that prospered before the flames" (Stone 1998: 1527). We argue that cycles of disruption and recovery are the usual state of affairs and submit that rapidly compounded perturbations have more serious implications for long-term alterations of community state, occasionally or even often generating a different assemblage of species.

Physical agents of change are well documented and described by such terms as windstorm, landslide, forest fire, flood, hurricane, and volcanic eruption. Many of these are primarily of terrestrial importance and leave their signature on landscapes as sites with recognizable boundaries and measurable shapes and areas. Biologically based counterparts—clear-cutting of terrestrial forests and trawling on the ocean floor—generate similar map properties. Populations are also subject to biological disturbances that vary from slight to catastrophic. Although these may lack spatially discrete boundaries, their implications for community structure can be at least as profound. Here we combine, when appropriate, biological disturbances like pestilence, population eruptions, invasions, and overharvesting with the more traditional physical forms of disturbance. In so doing, we add an animal and therefore a trophic dimension to a subject traditionally dominated by plant ecologists.

Figure 1 is a heuristic portrayal of our approach. In the top panel, a single large disturbance is followed by eventual return to some baseline condition at which point the assemblage can be considered "recovered." The diverse literature on succession is primarily concerned with this pattern and its underlying mechanisms. The following panels identify our focus. In the middle panel, two large disturbances are shown to occur nearly simultaneously or in close progression. We believe that recovery, if possible, is often substantially delayed under such conditions, and we provide examples below. In the bottom panel, a major disturbance is superimposed on an assemblage already maintained in an altered state, usually by anthropogenic processes. Current examples could include populations depressed by persistent overfishing, whole systems altered by chronic pollutants, or the developing impacts of climate change, such as the apparent increases in frequency and intensity of major storms

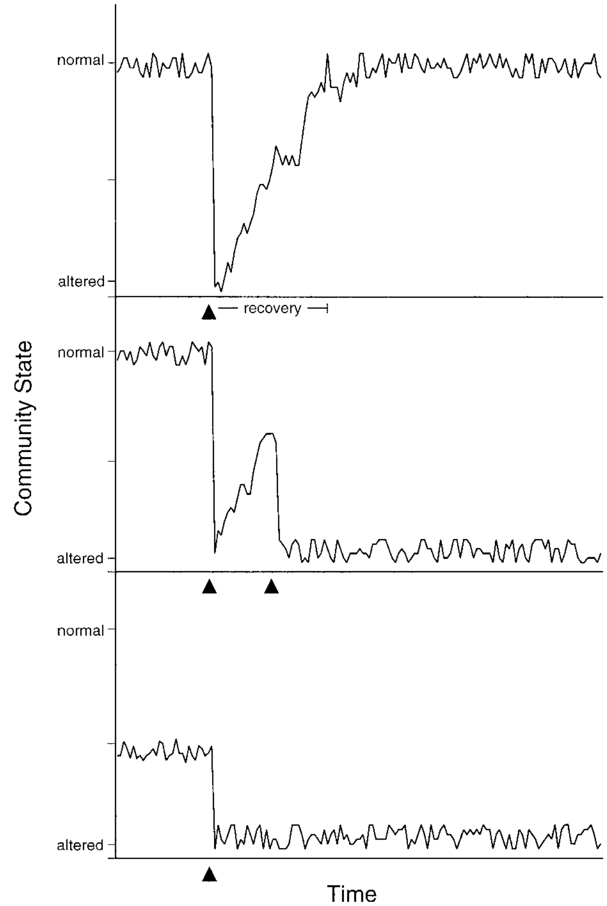

Figure 1. Schematic representation of the effects of large, infrequent disturbances (LIDs) on community state. Top, A normal community is subjected to a single LID and subsequently recovers. Middle, A normal community undergoes a second (or multiple) disturbance(s) before recovery from the first is completed; the combined effects lead to long-term alteration in community state. Bottom, A major disturbance is superimposed on an assemblage already already altered by anthropogenic processes or disease; again the combination of stresses leads to long-term alteration of comunity state. Arrowheads mark the disturbances.

and other climate extremes with increasing temperatures [for example, see Flavin (1996)]. Jansson and Velner (1995: 332), for example, suggest that in the Baltic Sea, a brackish body of water with minimal connection to the North Sea, which has been heavily impacted by eutrophication and toxic inputs, "pollution has reached the point where damage may be irreversible."

The scenarios discussed next include systems that appear, albeit temporarily, to have entered a new ecological domain; that is, they have not recovered. They share two features in common. First, all have been subjected to large (based on duration or spatial magnitude) and severe (quantified as a major mortality event) perturbations that may be physical or biological in origin. Second, these have occurred either simultaneously or in a sequence rapid enough that recovery from the single pulse has not significantly progressed. In some instances, three or more pulses appear to be necessary to initiate the changed state. Another way to describe our concern is to recognize that the community effect of compounded perturbations is multiplicative, not additive. If true and general, ecological surprises should be increasingly commonplace, prediction of recovery rates and trajectories less certain, and management more difficult.

Quantifying Disturbances and Their Frequencies

We adopt the definition of disturbance used by White and Pickett (1985: 7): "A disturbance is any relatively discrete event in time that disrupts ecosystem, community, or population structure and changes resources, substrate availability, or the physical environment." Pickett and White (1985) make the point that *disturbances* span three orders of magnitude of time (years) and ten of space (m^2). Disturbances, while causing spatially identifiable mortality to some species, usually provide open or invadable space for others, often renewing resources in the process. Sometimes, they can be identified by the resultant patchiness, recognizable by shape, size, postdisturbance internal composition, and spatial distribution. These patterns also have a dynamic, especially frequency of formation and rate of return toward the predisturbance state. Turner and colleagues (1997) suggest that it is also necessary to recognize the roles that individuals or species surviving a disturbance event can play in mitigating the event's impact. They suggest that only events characterized by few "residuals" be considered as large. We concur.

Disturbances can mean high mortality, often death of all individuals in the disturbance area. LIDs have different meanings for different ecosystems. For example, a large disturbance in the tidal zone may be on the order of tens of square meters, whereas in a forest it may be thousands. Hence, some scaling relationship must be used to ensure that these terms have equivalent meanings between systems. If, for example, we choose population dynamics as the processes of interest, disturbance size and frequency could be scaled by birth, death, or immigration (dispersal). Dispersal seems a particularly significant scaling metric for it governs the rate of recolonization of the disturbed site. Thus, ruderal (fugitive) species are typically both early invaders and excellent dispersers. Greene and Johnson (1989) applied a scaling metric involving seed terminal velocity, height of seed release, and mean horizontal wind speed to make dispersal comparable between species with different characteristics. For instance, ashfall accompanying the eruption of Mount St. Helens in 1980 greatly reduced many insect and spider populations. Because adult female leafhoppers (*Errhomus*) lack long-distance dispersal, they were slow to return to preeruption abundances in contrast with spiders (Showalter 1985). Similarly, on rocky marine shores, the poorly dispersing brown alga *Postelsia* can be driven locally extinct (Paine 1988 and unpublished), whereas local extinction is highly improbable for the associated barnacle *Balanus glandula,* whose larvae can traverse hundreds of kilometers. Thus, defining when a disturbance is large depends on the interplay between the spatial magnitude of the area disrupted and the dispersal (reinvasion) ability of the species of interest. Similarly, the frequency of disturbance could be scaled by some measures of generation time or age of first reproduction. In contrast, scaling on the basis of size of the dominant organisms does not appear to be a useful metric; for example, consider giant kelp (*Macrocystis pyrifera*) and terrestrial trees: sizes are comparable but time scales for age to first reproduction and life spans differ by orders of magnitude.

Ecological evidence seems to indicate that most LIDs do not override the biotic mechanisms governing species composition: in many disturbances, the postdisturbance composition is similar to the predisturbance composition (Turner and others 1997). This result might have been anticipated if size and frequency of disturbance had been scaled in terms of dispersal distances and generation times instead of the quantity of hectares and years as usually used.

Two other kinds of disturbances lack spatially explicit features but can have equally significant consequences: (a) Populations can be thinned commercially or reduced to mere vestiges of their original abundances by disease. For example, the majority of commercial fish stocks in US and Canadian coastal waters have been overexploited or are currently at maximum sustainable yield levels (NOAA 1993). Rinderpest decimated herds of African ungulates, especially buffalo (Sinclair 1977). The community changes resulting from density shifts of dominating species, often of high trophic status, can be extensive. They are a biologically based disturbance and often leave no immediate spatial signature. (b) Global climate change, a more cosmic form of disturbance, will surely have a substantial though currently unquantified and debated impact. It will provide a background of change in which both physical (for example, fire) and biological (for instance, harvesting and disease) disruptive forces will operate, and it might become the dominant influence on community structure and change in the coming decades despite its subtlety.

When do changes in community composition occur or under what conditions can they be anticipated? We believe that such dramatic shifts are most likely when both the spatial extent and especially frequency of disturbance are at the extremes of normal expectations. Multiple, usually sequential occurrences of these extreme and rare events can produce alternative stable states, that is, abnormal conditions or ecological surprises that defy the norm. The following scenarios describe communities that have been subjected to multiple perturbations and appear to have entered (or be facing) new domains.

Compounded Perturbations in Ecological Time

El Niños, Storms, and Kelp Bed Recovery

El Niño–Southern Oscillation (ENSO) events are large-scale oscillations of the tropical Pacific Ocean–atmosphere system with far-reaching climatic and economic impacts. The 1982–83 El Niño was widely considered the strongest of the century and had a corresponding impact on forests of giant kelp along the coasts of Alta and Baja California. Winter 1982–83 was the most severe storm season in many decades, as atmospheric teleconnections linked to the warming of the eastern equatorial Pacific Ocean affected the Aleutian low-pressure center, generating a large number of severe storms from an unusual southerly direction. These storms devastated kelp forests throughout the range of *Macrocystis pyrifera,* an economically valuable kelp. Anomalous poleward flow of warm, oligotrophic waters that rendered upwelling ineffective led to nutrient depletion, massive loss of kelp biomass, and extensive summer mortality in the southern half of *M. pyrifera*'s range. The severity of the warm-water effects was related to latitude. In South America, anomalies were as high as 11°C during 1982–83; there was mass mortality of *M. integrifolia* and associated animal populations in Peru and northern Chile (Dayton and Tegner 1990). In the southernmost part of the range in Baja California, giant kelp went extinct in some areas and site preemption by lower standing kelps prevented its recovery after the ENSO.

In the San Diego region, the combined effects of the storms (ENSOs can be storm free) and the 4°–5°C warm-water anomalies constituted the most severe disturbance of a giant kelp forest community ever documented, yet recovery was rapid once conditions returned to normal (Tegner and Dayton 1987; Dayton and others 1992). At the other end of the range in central California, the intensity and duration of the warm event were smaller and conditions remained within the suitable range for kelp [reviewed by Tegner and Dayton (1987), Dayton and Tegner (1990), and Dayton and others (1992)]. Kelps are well adapted to winter-storm disturbance, with correspondingly timed reproduction, spore dispersal tied to water movement, and success of the propagules a function of open space. The more problematic warm-water effects result from the severity and duration of the events and probably the frequency, as well.

ENSOs are natural climate variations to which communities have been subjected for at least hundreds of years, but there are major questions about whether the intensity and/or frequency of these events may change as a result of global warming (Trenberth 1995). The observational record indicates that ENSO events have changed in frequency and intensity in the past century, but the frequency of strong events appears unchanged back to 1625 (Enfield 1988). Coupled ocean–atmosphere general circulation models find that ENSOs will continue to exist in a warmer world, but have yet to address frequency and intensity. Trenberth (1995) suggests that because these events have the effect of creating droughts and floods in different parts of the world and global warming tends to enhance the hydrological cycle, there is a real prospect that future ENSOs will be accompanied by more severe droughts and floods. For Northern Hemisphere kelp forests, the question may be whether ENSO thermal additions to already warmer water conditions [for example, see Roemmich and McGowan (1995)] in the future can push kelps beyond the range of recovery, especially in the southern end of the range.

Climatic Extremes and Exotic Species in San Francisco Bay

San Francisco Bay, at the mouth of rivers draining 40% of California, is considered to be the major estuary in the United States most modified by human activity (Nichols and others 1986). Many alterations of the ecology and the bay, such as loss of habitats, water-quality changes, introduced species, and excessive freshwater diversion, date to the 19th century, yet recent disturbances have led to profound changes. In late 1986, the euryhaline Asian bivalve mollusc *Potamocorbula amurensis* was first sampled in San Francisco Bay (Carlton and others

1990; Nichols and others 1990). Within 2 years, it had spread throughout the estuary, on all sediment types and water depths, and reached densities at some sites exceeding 10,000 m^{-2}. This invasion almost certainly resulted from the discharge of seawater ballast from cargo vessels.

Two years of climatic extremes apparently contributed to this remarkable population explosion (Nichols and others 1990). Before *P. amurensis* was discovered, the benthic community in Suisun Bay (northern region of the bay) varied predictably with river inflow: years of normal or high flow were characterized by brackish or freshwater species, and years of low flow by estuarine species. The end of the 1984–85 dry event was marked by an extreme but short-lived flood that eliminated the estuarine species. Thus, when *P. amurensis* was introduced, the Suisun Bay region was inhabited by a disturbed and depauperate community that may have contributed to the initial success of the invader. The invader's timing after the flood guaranteed it months to exploit the available space before the dry-period species would return, and by 1988 the near absence of the dry-period community demonstrated how well *P. amurensis* had displaced the former community. The ability of the invader to live in low-salinity water suggests that it will not be displaced with the return of normal river flow and that the benthic community is permanently altered (Nichols and others 1990).

Carlton and colleagues (1990) predicted significant community changes as this abundant consumer, competitor, disturber, and prey altered the interactive trophic webs in San Francisco Bay; these are beginning to unfold. Within a year, chlorophyll concentration and adult abundance of three common copepod species had declined by 53%–95%; these values persisted through 5 years of study (Kimmerer and others 1994). Before 1987, chlorophyll concentration varied with river flow; after mid-1987, it remained low despite variations in flow. The effect on copepods appears to be via direct clam predation on nauplii; egg production was not affected. Estimates of clam clearance rates are consistent with the reduction in copepod abundance. Although it may be premature to forecast permanent changes in the zooplankton populations, Kimmerer and colleagues (1994) voice serious concern: several species of fish that pass their larval lives in the upper estuary are also in serious decline. Moyle and coworkers (1992) list five species, including those in valuable sport and commercial fisheries, in which poor first-year classes correlate with reduced freshwater outflow, presumably because of decreased survival of larvae and juveniles. A sixth, the delta smelt, which is federally listed as threatened, feeds primarily on copepods, has a narrowly defined habitat in the mixing zone between fresh and salt waters, is an annual species very sensitive to environmental fluctuations, and has declined in concert with increasing water diversions since 1984 (Moyle and others 1992). Thus, the compounded effects of two major disturbances—one biological (the successful establishment of a nonindigenous species) and the other physical (drought followed by an extreme flood)—have initiated sweeping and probably permanent changes in ecosystem structure.

Boreal Forest Wildfires, Forest Fragmentation, and Logging

Fire frequency in the boreal forest is primarily controlled by large-scale climate processes, specifically persistent midtropospheric anomalies that at the surface are expressed as blocking high pressures (Schroeder and others 1964; Newark 1975; Street and Birch 1986; Flannigan and Harrington 1988; Johnson and Wowchuk 1993). In this century, however, agricultural settlement in the southern fringe of the boreal forest and logging further north have resulted in a new multiple-disturbance regime that has caused significant changes in forest composition.

In the last three centuries, fire frequency in the boreal forest has changed several times, each time associated with large-scale climate changes (Johnson 1992). The changes in the early 1700s and the 1800s were a result of the Little Ice Age (Grove 1988). In the boreal forest, this period had more frequent fires than the periods before or since (Bergeron and Achambault 1993). These changes in fire frequency appear to be associated with increased numbers and length of persistent midtropospheric anomalies. Years with large areas burned are known to have more sequences of days during the fire season with warmer, drier weather, which are associated with upper-level ridges. These persistent upper-level ridges over the boreal forest are *teleconnected* (spatially and temporally correlated) to upper-level troughs in the North Pacific and eastern North America. This teleconnection is called the Pacific North America pattern (Rogers 1981; Wallace and Gutzler 1981; Knox and Lawford 1990; Johnson and Wowchuk 1993). Similar patterns have been described in the southwestern United States as a result of ENSOs (Swetnam and Betancourt 1990).

The transition periods between different fire frequencies, for example, at the end of the Little Ice Age, seem to have been periods in which fires occurred more erratically for a decade or more. Often these periods were marked by clusters of years with very large areas burned and many persistent upper-level ridges. One could speculate that the large areas burned in the boreal forest since the 1980s are a result of one of these transition periods, perhaps related to global warming. However, more understanding of these transient processes is required before anything definitive can be said.

These climate-driven changes in fire frequency have generally been part of the ecosystem dynamics of the boreal forest for millennia. In this century, two new classes of large-scale disturbances were added to the climate-driven fire frequency. These anthropogenic forces were agricultural settlement in the southern boreal forest and logging.

Homesteading in the early 1900s led to progressive clearance of forest in the southern fringe of the boreal forest in western Canada (Vanderhill 1958). The effect on the forest north of the fringe was to increase the frequency of fires above that of the natural lightning fire regime. The increase was due to escaped clearance fires spreading from the settlement areas north up to 50–60 km into the unsettled forest. The result of this major increase in fires meant that trees that required longer time to reach sexual maturity, did not have serotinous cones, had little or no vegetative reproduction potential, were greatly reduced in abundance, and in many areas were locally exterminated (Weir 1996). For example, white spruce (*Picea glauca*) and balsam fir (*Abies balsamea*) both became relatively unimportant trees in many forests and trembling aspen (*Populus tremuloides*) significantly increased in abundance. Also, change from a mixed-wood (conifer–deciduous) to primarily deciduous forest has caused many other changes in plant and animal species (Weir 1996). At the same time that this forest was being subjected to an increase in the frequency of fire, high-grade logging (cutting of only large trees) of the white spruce was further reducing this dominant boreal species.

The southern boreal forest today has a significantly different composition than it did a century ago. This change has been due to multiple perturbations: a natural lightning fire regime augmented by settlement fires spreading from adjacent areas and logging.

Early Succession and Exotic Species

Volcanic eruptions clearly embrace the concept of disturbance, either by presenting new landscapes and initiating primary successional processes, or by altering preexisting ones via ashfalls, pyroclastic scorching, and the like. The end result of the recovery/regeneration process seems fairly predictable: Turner and colleagues (1997) compare the assembly of the plant community on Mount St. Helens (WA) following its 1980 eruption with other single large infrequent disasters. On this barren landscape, some degree of successional uncertainty may well characterize the early stages of the recovery process. Morris and Wood (1989) found in experiments on lupine, a nitrogen-fixing pioneer species, evidence that two other invaders could be either facilitated or inhibited. Such stage dependency complicates the successional process; it probably does not alter the ultimate community composition, although insufficient time has elapsed since the eruption to evaluate the consequences of these initial uncertainties.

The Hawaiian Islands are also of volcanic origin and, despite being earth's most isolated archipelago, have been invaded by 4600 exotic plants, 86 of which represent serious threats to the native ecosystem (Vitousek 1990). The successful invasion of a nitrogen-fixing exotic (*Myrica faya*) on the slopes of Hawaii Volcanos National Park provides a classic example. A 1959 eruption deposited 1–2 m of ash on the native vegetation, thinning it substantially. *Myrica* invaded and initiated a series of changes including the identity of the dominant tree, nutrient cycling, and productivity. For instance, Woodward and coworkers (1990) showed that native Hawaiian birds, while visiting *Myrica,* rarely feed on its fruit. Nonnative species visited, fed, and effectively dispersed viable seeds. *Myrica* itself is fecund: Vitousek and Walker (1989) estimate the seed rain at 4.6 million/ha under 21 adult *Myrica*/ha. In addition, the mean adult growth of these invaders is approximately 15 times that of a native tree (Vitousek and Walker 1989). *Myrica* is quadrupling the input of soil nitrogen (Vitousek 1990); earthworms are 2–8 times as dense under it than under native vegetation, which will change litter-processing dynamics and the rate of accumulation of soil organic matter (Aplet 1990).

As Vitousek (1990; Vitousek and Walker 1989) has demonstrated, the changes in whole ecosystem-level function are substantial. One major speculation is that when, or if, *Myrica* is replaced during primary succession, it will be replaced by another exotic. The competitively aggressive strawberry guava is a likely candidate species. Because, in general, sites with more fertile soils—higher concentrations of soil nitrogen in a system where N is a limiting resource—are conducive to invasion, "nitrogen fixation by *Myrica* will ultimately favor invasion by a broader range of exotic species" (Vitousek and Walker 1989: 261). Finally, as these authors note, invasion changes the ground rules governing coexistence of native assemblages recovering from or responding to disturbance. The problem is of great pragmatic importance to conservation biology: it further signals the existence of surprises at ecosystem levels when disturbances, in this case volcanism and biological invasion, are compounded.

Hypoxia in the Northern Gulf of Mexico

Oxygen depletion, long known from confined bodies of water, such as basins, fjords, bays, and estuaries, is increasingly reported from coastal ocean environments (Boesch and Rabalais 1991; Diaz and Rosenberg 1995). This may take the form of anoxia, where dissolved oxygen concentrations are essentially zero and hydrogen sulfide (toxic to metazoans) is detectable, or more commonly hypoxia, where oxygen concentrations on the sea floor are reduced to levels low enough to cause severe stress and mass mortality of benthic and water-column fauna. Varying with the severity of the oxygen depletion, effects on the biota range from avoidance of the affected area, to mortality of more sensitive taxa such as crustaceans and echinoderms, to emergence of the redox potential discontinuity from the sediments, a condition where only chemoautotrophic bacteria can live. Diaz and Rosenberg (1995) report that no other variables of such ecological importance to coastal marine ecosystems have changed so drastically in such a short period of time. Increasing evidence of oxygen depletion in coastal ecosystems is associated with anthropogenic eutrophication and, when eutrophication is coupled with adverse meteorological and/or hydrodynamic events, hypoxic events increase in frequency and intensity.

The inner and middle continental shelf of the northern Gulf of Mexico from the Mississippi River Delta to Texas is the largest and most severely affected area in North America subject to seasonal hypoxia [operationally defined by dissolved oxygen levels less than 2 mg/L or less than 1.4 ml/L (Rabalais and others 1991)]. From 1985 to 1988, hypoxic waters were found from April to October, from 5 to 60 m water depth, from 5 to 60 km offshore, extended up to 20 m above the bottom, and covered up to 9500 km^2. Hypoxia in this region is coincident with strong, salinity-controlled stratification during the warmer months of the year, which restricts reoxygenation of the bottom waters. Large quantities of decomposing phytoplankton biomass fueling intense water-column and benthic respiration rates enhance the effects of stratification on oxygen depletion. Although hypoxia did not cause extensive mortalities on the northern Gulf of Mexico shelf until 1978, it has occurred almost annually since it was first discovered in 1973 (Diaz and Rosenberg 1995). Severity and extent vary interannually with river flow, shelf circulation, and tropical storm mixing (Rabalais and others 1991).

The importance of the extent and duration of the hypoxia on the Louisiana shelf relates to fishery landings from this state, which constitute 28% of the US total (Rabalais and others 1991). Abundances of finfish, shrimp, and swimming crabs are severely depressed in hypoxic areas, and the period of oxygen stress includes critical life-history periods of several commercially important species. The macrofauna either succumb or move to avoid stressful conditions; typically, demersal species have been observed high off the bottom where mortality due to predation is undoubtedly high (Boesch and Rabalais 1991). When hypoxia persists, only highly resistant taxa such as some polychaetes and nematodes survive. Posthypoxia community dynamics depend on the extent of the mortalities, age of affected populations, timing with respect to availability of recruits, size of the affected area relative to short-dispersal recruits, frequency of hypoxic stress, and degree of organic carbon buildup. Because of the recurrent nature of hypoxia in the northern Gulf of Mexico, there are few large or long-lived sedentary species, and the benthic community is dominated by opportunistic species characteristic of an early successional state (Boesch and Rabalais 1991; Diaz and Rosenberg 1995). Intensified commercial fishing on the continental shelf in the 1970s and 1980s has been accompanied by alarming declines in the estimated sizes of remaining fish stocks; although overexploitation is clearly important, Darnell (1992) suggests that habitat deterioration is affecting both nursery areas and food chains for commercial species.

The Mississippi River and its distributaries drain 40% of the coterminous United States. Nitrogen concentrations in the rivers, the major source of "new" nutrients to the offshore phytoplankton, have more than doubled since the mid-1950s (Rabalais and others 1991). Turner and Rabalais (1994) recently demonstrated a close coupling between riverine loading and phytoplankton production; changes in biologically bound silica in the sediments below the river plume were virtually coincident with increases in nitrogen loading. After major flooding in 1993, the Gulf of Mexico hypoxic zone doubled to 18,000 km^2 and has not shrunk much since (Kaiser 1996). On 12–13 August 1996, winds forced oxygen-depleted water from the offshore dead zone below the mouth of the Mississippi River close to shore. This caused a "jubilee" along 36 km of Louisiana coastline, a condition where shrimps, crab, and finfish crowd close to shore to escape the oxygen-deficient water—highly increasing their susceptibility to fishing (Buck 1996). Kaiser (1996) reports that the US federal government may be finally waking up to warnings that the Gulf of Mexico hypoxic or "dead zone" may be one of the nation's worst ecological problems. A multiagency committee has been convened to discuss the problem and recommend management steps, such as voluntary reductions in fertilizer use in the Midwest. Again, compounded perturbations—coastal eutrophication exacerbated by extreme meteorological events—have produced an altered community state.

Phase Shifts in Jamaican Coral Reefs

Like all communities, coral reefs are subject to occasional intense natural disturbances: plagues of the starfish *Acanthaster* (Birkeland 1982), hurricane devastation (Woodly and others 1981), and high temperature stress (Gates 1990). Long-term studies of reef structure along a depth gradient at Discovery Bay, Jamaica, provide a clear and sobering view of phase shifts in assemblage structure associated with a compounded series of severe disturbances.

Baseline data at the main site exist from the 1950s (Goreau 1959), and the site has been repeatedly examined quantitatively since then (Andres and Witman 1995). A sequence of events initiated in the early 1980s, but set against a subtler background of increasing coastal pollution and extreme harvesting pressures on herbivorous fishes, has led to what Hughes (1994) calls "large scale degradation" and vividly portrays as a phase shift in community structure. Depending on the depth at which corals are sampled, percent cover has decreased from 30%–60% in 1977 (Huston 1985) to approximately 5% at depths less than 30 m in 1992 (Andres and Witman 1995). Conversely, algal cover, accounting for less than 5% cover in 1982, comprised approximately 70% cover in 1992. As a result of algal preemption of space, larval recruitment of all corals failed after 1984 (Hughes 1994).

The compounded disturbances—two major hurricanes (Allen in 1980 and Gilbert in 1988) and mass mortality of an ecologically significant grazer, the sea urchin *Diadema,* from 1982 to 1984—occurred well within the normal recovery interval of reefs. Hughes (1994) suggests that reef regeneration was initiated shortly after Hurricane Allen despite reduced grazing fish populations. The *Diadema* dieback delivered the coup de grâce and the recovery trend was reversed. Andres and Witman (1995) suggest that Hurricane Gilbert only slowed the developing domination of algae and therefore failed to enhance coral recovery. Furthermore, these authors imply that if urchin and fish populations had retained their pre-Allen levels, coral recovery and domination of the benthos would have occurred. With continued depression of herbivore populations, recovery of the coral assemblage is not forseeable.

In this case, a variety of disturbances, occurring rapidly relative to coral regeneration capacity, have yielded a novel community state—one that would not have developed if the disturbance events had occurred individually at intervals appropriate for reef recovery.

Discussion

A world of ever-more-pervasive anthropogenic impacts on natural communities coupled with the increasing certainty of climatic response to human activities suggests that compounded perturbations and ecological surprises will become more common. The frequency of disturbances is often scaled in terms of severity and return intervals: for example, the 30-year flood or the 100-year storm. The large number of record weather events in the news in recent years raises the issue of climate change and its interactions with LIDs. We reiterate our belief, and concern, that ecologists must refocus their interest from the ordinary (for instance, recovery sequences between normally spaced disturbances) to the extraordinary (for example, rapid sequential disturbances occurring against a background of increasing climate change).

We do not question the capacity for single LIDs to distort ecosystem structure and functioning temporarily. They obviously do, and merit investigation in their own right. On the other hand, the ecological literature is replete with underappreciated studies of compounded disturbances. Here we identify two more to suggest their ubiquity. Zedler and colleagues (1983) describe the interaction of fire and an annual grass planted to control erosion. Their conclusion that (p. 817) "We doubt if traditional climax-oriented successional theories can be of much use in predicting the outcome" resonates with our theme. In addition, several of the case histories developed in Gunderson and coworkers (1995) suggest that maladaptive management actually decreases ecosystem resilience, thus increasing susceptibility to subsequent disturbances, perhaps even facilitating disturbances and thwarting effective management.

The 1995 Intergovernmental Panel on Climate Change report (IPCC) (Houghton and others 1996), the international consensus summary of climate science, reviews the low probability that observed changes could be caused by natural factors alone, the average rate of warming for the 21st century that is likely to be warmer than any seen in the last 10,000 years, and projections for sea-level rise. Globally, existing data do not offer statistical evidence that extreme weather events or climate variability have increased in the 20th century, although there is clear evidence on regional scales. The IPCC review of model results finds agreement on predictions of general warming with regional variability and an enhanced global mean hydrological cycle. Regional forecasts are more problematic, but the incidence of floods, droughts, fires, and heatwaves is expected to increase in some areas and decrease in others as temperatures rise (Houghton and others 1996).

Our scenarios were chosen to identify the range of possibilities and the resulting ecological surprises. We have made no attempt to be encyclopedic. Rather, our list is characterized by events with blurred or no discernible borders, except as dictated by local geography (San Francisco Bay, for example) or study at a specific location (for example, Jamaica). Missing entirely are those great disturbances with sharp spatial boundaries as often characterize tornado paths or intertidal mussel-bed destruction. Missing also are references to the human condition, for instance, the interplay between malnutrition and disease. The growing evidence for unusual meteorological events leading to outbreaks of disease infectious among humans, such as hantavirus, cholera, and plague (Linden 1996), provides numerous examples. In one well-studied case, Colwell (1996) relates the massive cholera pandemic that struck South America in 1991 to the transport of zooplankton in a freighter's ballast water to the coast of Peru at the onset of an El Niño event. The El Niño brought rain and the influx of nutrients from land as well as warm sea surface temperatures, factors associated with the initiation of plankton blooms. This El Niño event, which lasted from 1990 to June 1995 and is the longest on record since 1882, may also be associated with the cholera bacterium remaining endemic in the region (Colwell 1996).

Present and future global climate-change effects on the environment may be debatable, but this is not the case for increasing human impacts: population growth, urbanization, deforestation, eutrophication, overfishing, loss of habitat, and so on. In ironic contrast with many political leaders, the insurance industry has recognized the significance of the nexus of these issues. Faced with rapidly escalating insured costs for increasing numbers of severe catastrophes over the last decade, that industry is realizing that it must demand political action to protect the climate to prevent its own financial ruin (Flavin 1996; Munich Re 1996). Our perspective is that societies and ecologists must begin to prepare themselves for novel and unanticipated consequences of previously well-understood phenomena. Jamaican coral reefs may not recover, Hawaiian volcanic slopes may develop a novel flora, and San Francisco Bay appears to be acquiring a new and not necessarily desirable invertebrate assemblage, in the process losing native species. Global warming may accelerate the effects of oxygen deficiency and enlarge affected areas in the Gulf of Mexico. These altered and possibly alternative states (Lewontin 1969; Sutherland 1974) may or may not be persistent (stable). On the other hand, mounting evidence suggests that sequential, large-scale disruption of the current state will make these altered states the ecological reality of the future. Understanding the role of compounded disturbances, some natural and others of anthropogenic origin, will be basic to environmental management decisions in the 21st century.

What's Eating the Pando Clone?

Two Weeks of Cattle Grazing Decimates the Understory of Pando and Adjacent Aspen Groves

by Jonathan B. Ratner,[1] Erik M. Molvar,[1] Tristan K. Meek,[1] and John G. Carter[2]

EXECUTIVE SUMMARY

The Pando Clone is an aspen grove on the Fishlake National Forest in south-central Utah that was heralded in 1992 as the world's largest single living organism. Adult trees that are joined by a single rootstock and share identical chromosomes comprise the Pando Clone and, like many aspen groves across the West, it has suffered for a number of years from die-back and failure to regenerate new shoots to replace the aging adult trees for a number of years.

The U.S. Forest Service created fenced exclosures to protect a portion of the Pando Clone from herbivory (browsing - the consumption of woody growth - by mule deer and domestic cattle), and initiated some small-scale vegetation treatments. Aspen regeneration has responded inside the exclosures in both treated and untreated areas, while outside the exclosures, on public lands leased for livestock grazing, regeneration failure and die-backs continue to plague the Pando Clone as well as other aspen groves subjected to the same pattern of livestock and mule deer hebivory, and die-back continues.

Western Watersheds Project initiated a one-year monitoring project in order to quantify ungulate use in the area, using stationary motion-sensing cameras to quantify by species the use of the area and document levels of herbivory by both domestic cattle and mule deer over the 2018 growing season in the unfenced portions of the Pando Clone and in adjacent aspen groves. At our monitoring sites, we documented 4.5 times the amount of cattle use herbivory in two weeks than the mule deer use over six months. Forage utilization by mule deer prior to the onset of livestock grazing was unobservable, while forage utilization by livestock (plus mule deer) during the 2 weeks of cattle grazing consumed 70 to 90 percent of the understory vegetation's annual production.

Cattle have a greater propensity to consume aspen sprouts in autumn, when the nutritional quality of other understory vegetation declines, and the virtual elimination of understory vegetation by this high intensity livestock use may also cause mule deer to switch to aspen shoots, further amplifying the impacts. Our results show that the brief but intense cattle grazing appears to be a major contributor to the decline of the Pando Clone, as well as other aspen groves in the immediate vicinity, in addition to the much lighter continuous herbivory by mule deer. Based on comparisons of the exclosures with the area open to both livestock and mule deer that this high level of use in the unfenced areas effectively eliminates regeneration. A previous study (Rogers and McAvoy 2018) attributed the failure of the Pando Clone to regenerate solely to mule deer, but our results indicate that cattle are also having a major impact on understory vegetation. Our results suggest that livestock herbivory may be having a synergistic interaction with mule deer foraging to suppress aspen sprout growth, and that trampling of soils by livestock may also play a role in depressed aspen recruitment in unfenced portions of the Pando Clone and adjacent aspen stands.

Based on our results, we recommend removal of livestock from the Pando Clone area to protect this globally significant organism, and also recommend that livestock be removed from public land pastures elsewhere where aspen groves show signs of depressed regeneration.

Introduction

Aspen (*Populus tremuloides*) stands are found across the interior West from southern Arizona to the Canadian Rockies, and typically occur in montane or sage steppe environments, often in association with abundant soil moisture. Aspen groves range along a spectrum from fire-dependent transitional communities that regenerate through periodic fires to stable communities that do not require fire for persistence (Shinneman et al. 2013). Reproduction via seeds happens most commonly in conjunction with severe disturbance such as fire (Long and Mock 2012). More frequently, aspens reproduce by sending up new shoots, or "suckers," from the existing rootstock, and the resulting aspen grove may persist for thousands of years (Jones and DeByle 1985a).

Aspen groves are frequently clones, where a single root system sends up hundreds or even thousands of individual stems (Barnes 1975), with each "tree" being a genetically identical surface expression of one large organism connected through its common root network. Gardner (2013) found that areas with high clonal diversity in aspens occurred in areas with a more frequent fire history, while areas with low aspen clonal diversity, often larger clones, corresponded to areas with less frequent fires. Clones may be long-lived; Kay (2003) hypothesized that aspen clones in north-central Nevada have maintained their presence for thousands of years via vegetative regeneration. As aspen trees age (i.e., exceed 100 years of age), they generally produce relatively few suckers (O'Brien et al. 2010).

For the purpose of clarity, it is useful to define some terms that will be used throughout this report. Aspens growing from a common rootstock are called *ramets*, a term that encompasses fully-grown adult ramets ("trees") as well as immature, regenerating trees rising as *adventitious shoots* ("shoots" or "suckers" in this report). Both new shoots with terminal buds and branches that have lateral buds can be referred to as "stems." The term "seedling" is used in this report exclusively to refer to young aspens growing from a seed, and excludes young aspens growing from adventitious buds on an existing rootstock. Aspen reproduction can be sexual ("seeding") or asexual ("suckering") from buds on the root system. Aspen recruitment occurs when young plants grow above the upper browse level of large herbivores. Clusters of aspen are referred to as "groves." Where such clusters are comprised of genetically identical trees joined by a common root system they are called "clones" and represent a single organism with many adult trees, sometimes thousands. "Regeneration" occurs when the recruitment of aspen suckers replaces the die-off of adult trees.

Aspens commonly grow where soil moisture is relatively abundant. However, in forested areas, sites containing aspens may be wetter simply because they transpire less water into the atmosphere than do conifers (Jones and DeByle 1985b). Aspen groves often contribute more water to drainage systems than do coniferous trees because they transpire only during the part of the year when they have leaves (versus year-round transpiration for conifers) and collect more snow in the understory than do conifers (DeByle 1985c). Aspens also have chlorophyll in their stems, and can photosynthesize throughout winter when leaves are absent (Grant and Mitton 2010). Presumably, water loss is minimal during winter when leaves are absent.

Aspen groves are hotspots of biodiversity and a number of bird species appear to be dependent on aspen habitats. Aspen groves harbored the greatest number of native species (45) of any habitat type in Grand Staircase – Escalante National Monument (Bashkin et al. 2003). Red-naped sapsucker, black-capped chickadee, house wren, warbling vireo, and northern saw-whet owl are closely associated with aspen woodlands (Hejl et al.,1996). Loose and Anderson (1995) found that 30 of 33 woodpecker nests in their Sierra Madre study area were found in aspens, and among these, there was a significant preference for large, old trees. According to Winternitz and Cahn (1983), 40% of species that inhabit aspen are cavity nesters, with a significant preference for large trees over 100 years old and trees infected by heartrot fungus. Heartrot-infected aspens are easier for birds and mammals to hollow out to create cavity nests. Aspens also are of critical importance as a food source for beavers (Williges 1946).

Jones and DeByle (1985c) compiled a thorough analysis of the role of fire in aspen ecology. According to these biologists, almost all even-aged aspen stands in the western U.S. appear to be the result of severe fire, presumably in coniferous forests. In Yellowstone National Park, Romme and Knight (1982) found that fire suppression has led to denser coniferous forests, a decrease in aspen, and an increase in sagebrush in meadow areas. Forest fires can foster aspen regeneration because fallen timber provides refugia for aspen seedlings to escape browsing by ungulates (Ripple and Larsen, 2001).

Strong aspen regeneration typically occurs even after severe burns. An abundance of aspen woodlands in the coniferous forest zone often indicates the prevalence of past stand-replacement fires. But Fornwalt and Smith (2000) noted that old, multi-storied aspen stands can maintain their productivity over time and are in many cases self-perpetuating. Thus, previous assumptions that aspen stands require periodic disturbance to maintain themselves are not universally true, and some stands (particularly old, multi-story stands) perpetuate themselves in the absence of any management treatment.

Although aspen habitats are viewed as valuable grazing resources by the livestock industry, these areas are very sensitive to overgrazing. Meuggler (1985b) reported that heavy grazing by domestic sheep can turn the rich and diverse herbaceous understory that occurs in ungrazed stands into a depauperate understory of grasses. In aspen stands that are overgrazed, invading, unpalatable plants can form a stable grazing disclimax (an unnatural, disturbed plant association that can persist indefinitely), reducing the wildlife habitat value of the grove (Mueggler 1985a). In addition, in older stands, heavy livestock grazing can prevent regeneration and speed the decline of the aspen stand itself (DeByle 1985a). Cole (1993) found that aspen-forb communities are highly susceptible to trampling damage even from human foot traffic. The physical trampling of nests and habitat degradation associated with livestock grazing can be detrimental to ground-nesting birds that prefer aspen habitats, such as the hermit thrush, junco, white-crowned and Lincoln's sparrows, veery, ovenbird, and nighthawk (DeByle 1985b). Because livestock grazing is currently permitted on more than 232 million acres of federal public land in the western United States (Beschta et al. 2013), the potential for ecological damage from livestock grazing is widespread.

The Pando Clone

The name "Pando" comes from the Latin "to spread." Kemperman and Barnes (1976) originally proposed the Pando Clone as a single living thing covering approximately 108 acres in area and made up of approximately 47,000 *ramets*, or stems. Grant et al. (1992) concluded that the Pando Clone represents the largest single organism in the world, with an areal extent of approximately 106 acres (43 ha) and an estimated weight of more than 6,600 tons (6 million kg). The Pando Clone was confirmed through genetic testing to be a single massive organism by DeWoody et al. (2008). Some of the trees in the Pando clone show triploid chromosome patterns (in effect, possessing a third set of chromosomes), and these individuals have a competitive advantage over diploid stems in terms of height and diameter growth (DeRose et al. 2015). This gives these stems an advantage in the 'self-thinning' stage of stand development, when only the most fit stems survive to attain tree form.

The age of the Pando Clone is a matter of substantial scientific debate. Kemperman and Barnes (1976) hypothesized that the Pando Clone was originally established more than 8,000 to 10,000 years before present. Aspen clones in this southern, unglaciated portion of the species' range, including Utah, can be unusually large and of much greater age

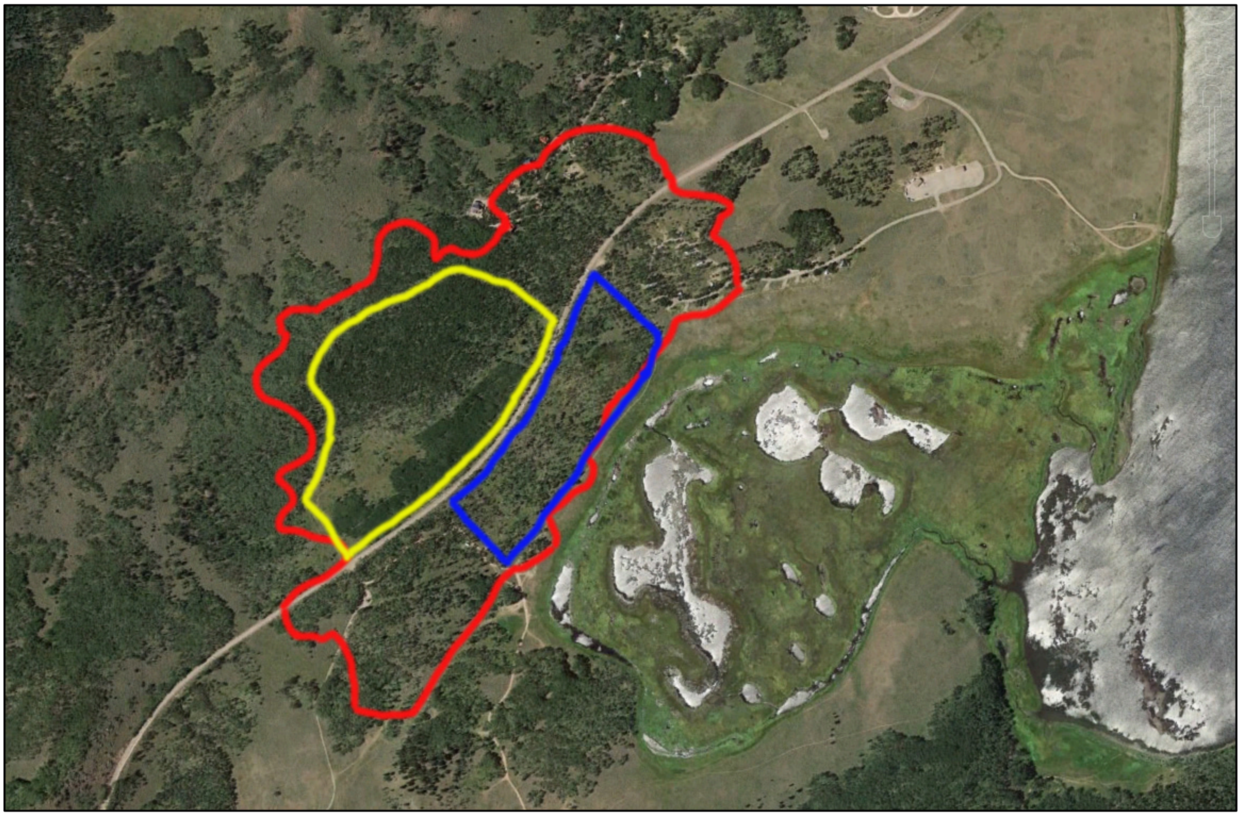

Figure 1. The boundary of the Pando Clone, in red (after Kemperman and Barnes 1976), showing the 2013 exclosure fence (in blue) which more successfully excludes mule deer, and the 2014 exclosure fence (in yellow) which has been less successful in excluding mule deer. State Highway 25 can be seen bisecting the Pando Clone, and Fish Lake appears at the right of the image. Image courtesy Google Earth.

(Barnes 1975). Mock et al. (2008) identified a number of other genetically distinct aspen clones along the fringes of Pando, and hypothesized that the relatively few mutational variants within the Pando Clone may indicate a much less ancient age for Pando. DeRose et al. (2015) hypothesized that the Pando Clone initially became established as recently as the 1880s. However, this conclusion is based on core sampling of existing trees; it is unlikely that the 108-acre root system of the Pando Clone arose spontaneously in a single year or two; indeed it is far likelier that the clone spread gradually over a long span of years. Thus, the definitive overall age of the Pando Clone remains undetermined at this time. Grant and Mitton (2010) estimated the age of the Pando Clone at 80,000 years.

On the Fishlake National Forest, where the Pando Clone grows, aspen cover has declined by 60% from historic levels (Wooley et al. 2008). Fragmentation of the Pando Clone stand itself is currently occurring, due to browsing by herbivores suppressing sapling recruitment, rural real estate development, and a fungal infection called sooty-bark canker (DeWoody et al. 2008). As a result, sapling recruitment in unfenced portions of the Pando Clone is failing to replace aging adult trees. According to Rogers and Gale (2017: 9), "Judging from the near-complete lack of recent recruitment (> 2 m height) and mid-story aspen throughout the study area, it has been many years, likely even decades, since this amount of stand renewal [0.5 ramets per overstory tree] has taken place at Pando." As overstory trees continue to die without replacement by sucker recruitment, the overall size of the Pando clone ultimately will shrink (*id.*). Mule deer and cattle affect the Pando Clone and its ability to regenerate through browsing adventitious suckers and trampling.

Elk do not appear to be affecting the Pando Clone. According to Rogers and Gale (2017: 11, internal citation omitted), "While elk browsing of aspen is a serious concern regionally, we did not see elk or record their scat at Pando." Rogers and McAvoy (2018) reported that "[e]lk sign is evident in the broader area" and used that as a basis for asserting that elk were presently accessing the Pando Clone, but documented no elk sightings and no elk scat during the course of their study.

In 2012, the Forest Service issued a decision to fence 67 acres (22 ha) of the Pando Clone's 108-acre (43-ha) extent (see Figure 1) to prevent herbivory from domestic and wild ungulates and authorized some small-scale, experimental cutting inside the exclosures to stimulate suckering (USFS 2012). The exclosures were built of 8-foot tall woven wire topped with a barbed-wire strand. One exclosure of 17 acres (7 ha) was constructed in 2013 to the east of State Highway 25, and it appears to mostly exclude both mule deer and livestock (Rogers and Gale 2017, Rogers and McAvoy 2018), although Coles-Ritchie documented deer sign and evidence of browsing inside this exclosure. Aspen recruitment is progressing well inside the Pando Clone ungulate exclosure, even though the presence of mule deer has been documented inside the exclosure (Coles-Ritchie 2018). A second exclosure of 37 acres (15 ha) was constructed in 2014 to the west of the highway, incorporating a 22-year-old section of fence, and mule deer appear to be able to enter this fenced exclosure (Rogers and McAvoy 2018). Rogers and Gale (2017) found that the portions of the Pando Clone that had been fenced to exclude large herbivores showed a positive response in terms of regeneration (irrespective of cutting treatments), while the remaining 52 acres (21 ha) of the Pando Clone outside the exclosure showed no improvement. Rogers and Gale (2017) found that fencing alone resulted in an average of 550 regenerating suckers per acre inside the 2013 exclosure, a level sufficient for stand replacement according to earlier scientific findings (Mueggler 1989).

Aspen Declines

The regeneration problems experienced by the Pando clone mirror widespread declines in aspen regeneration, both on the Fishlake National Forest and throughout the West. In addition to the gradual replacement of aspen woodlands through the invasion of conifers in certain areas, aspen die-offs also occur in the absence of conifer encroachment. These die-offs can eliminate adult stems within a period of two years, and are often accompanied by an absence of sapling recruitment (Bartos 2008). On Cedar Mountain in south-central Utah, aspen stands showed depressed sucker recruitment and almost one-fifth showed crown dieback greater than 20% (Rogers et al. 2010). Evans (2010) found that drought weakened aspen on Cedar Mountain, Utah, making them more susceptible to a long-term decline that reduced the area of aspen woodland by 24% over a 23-year span. Many aspen stands in northern Nevada are in poor condition and have not regenerated in more than 100 years, due primarily to heavy livestock browsing (Kay 2003). Brown (1995) attributed the decline of aspen in eastern Oregon and Washington to intensive grazing and fire exclusion. Fairweather et al. (2007) documented a sudden decline of aspens on the Coconino National Forest in Arizona following a severe frost event, followed by a severe drought and an outbreak of tent caterpillars. Smooth brome, an invasive perennial grass, may affect aspen suckering (O'Brien et al. 2010). Overall, multiple factors can contribute to the decline of adult aspens, but reproduction through suckering typically occurs unless it is suppressed be herbivory by non-native livestock or by native herbivores such as deer and elk.

While the gradual decline of aspen groves over time may be widespread, aspen die-offs also occur that eliminate adult stems within a period of two years, with an absence of sapling recruitment (Bartos 2008). Sudden Aspen Death syndrome is associated with aspens at high altitude under water stress (Worrall et al. 2010). The decline of the Pando Clone appears to be of the more gradual variety, rather than Sudden Aspen Death syndrome.

Aspens most commonly reproduce adult stems via suckering from the rootstock; its seeds, while abundant, are short-lived and have demanding germination requirements (Schier 1981, Kay 2003, Long and Mock 2012). As a result, seedling establishment typically occurs only during extremely wet summers (Jones and DeByle 1985b).

Schier (1975) described the dynamics of sucker production as governed by apical dominance, a phenomenon whereby hormones from the terminal buds of aboveground stems (auxins) inhibit hormones in the root system that stimulate sucker growth (cytokinins). When disturbance of the stems reduces the flow of auxins, the cytokinins can initiate the regenerative process. However, when aboveground stems weaken and die, the root system dies back due to a lack of photosynthate being furnished to the roots. Schier (1976) suggested that sucker regeneration is proportional to above-ground disturbance, citing examples from clearcut logging studies where the number of suckers generated is proportional to the number of stems removed by logging. Where suckering is suppressed by ungulate browsing, the die-off of adult aspens can result in areal reductions in aspen habitats across the landscape.

Shepperd (2001) proposed hormonal stimulation, a proper growth environment, and sapling protection as the three elements of an aspen regeneration triangle. Natural disturbances such as fire can stimulate suckering and regenerate aspen stands, but if livestock are not excluded from the aspen grove for several years following fire, their browsing can severely suppress sucker growth (Kay 2003).

The Role of Herbivory in Aspen Declines

Heavy ungulate browsing over extended time periods can cause regeneration failure over spans of many decades, resulting in an even-aged grove of older trees that is less resilient to drought and other stressors (Lindroth and St. Clair 2013). In the Book Cliffs of northeastern Utah, Rogers and Mittanck (2014) found that only three of 77 aspen stands (less than 4%) contained adequate levels of recruitment to perpetuate the stand, due substantially to browsing by wild and domestic herbivores. Herbivory by both domestic livestock (sheep and cattle) and wild ungulates (deer and elk) can suppress aspen shoot recruitment, and thus impair regeneration.

In some circumstances, large herbivore grazing and/or browsing in aspen stands may not put significant pressure on aspen reproduction. For example, Beck and Peek (2005) found only a 3% dietary overlap between spring and summer mule deer and cattle diets in aspen stands, with deer preferring browse and cattle preferring grasses and forbs, and also found that elk and cattle did not have significantly different diets. However, this study found that all of the herbivores studied had a 0% dietary consumption of aspen, with the exception of spring diets in one of three years, which showed <1% aspen contribution to the elk diet. Mower and Smith (1989) found that elk and mule deer diets in northern Utah were quite similar, and although shrubs made up a significant component of both, aspens were not noted as a significant component of the diet. Notwithstanding the preference of native and domestic ungulates for other forage plants, overbrowsing of aspen shoots to the point of regeneration failure is widespread.

Aspens have defensive compounds – phenolic glycosides and tannins – that provide adequate defense against insects and mammalian herbivores when browsing is light, but which is an inadequate defense under heavy browsing, which results in high levels of damage to the trees (Lindroth and St. Clair 2013). Elk may respond negatively to increasing phenolic glycoside content (Wooley et al. 2008). However, the scientific consensus is that while the tannins and phenolic glycosides present in aspens evolved as a defense against herbivory, they are insufficient to prevent browsing by either domestic or wild ungulates.

Deer and Elk Browsing

Aspen communities often are an important source of protein for mule deer in summer, whereas Utah serviceberry and big sagebrush communities may only provide maintenance amounts of protein (Austin and Urness 1985). This dietary advantage of aspen communities may contribute to mule deer preference for them. Severe browsing by elk and deer virtually eliminated sapling recruitment during an aspen die-off in northern Arizona (Fairweather et al. 2007). Additionally, population irruptions of mule deer on the Kaibab Plateau of northern Arizona in the 1920s had, between 1953 and 1962, completely suppressed aspen recruitment on the Kaibab Plateau of northern Arizona (Binkley et al. 2006). In Michigan, Randall and Walters (2011) found that increasing densities of white-tailed deer in aspen stands suppressed suckering and reduced forb density and species richness.

Livestock grazing in aspen groves may come at a cost for resident mule deer. Loft et al. (1991) suggested that as a result of livestock grazing, displacement of mule deer from these habitats and expansion of deer home ranges resulted in a lowering of inclusive fitness for mule deer. According to Loft et al. (1991: 22, internal citation omitted), "Once aspen stands had been occupied by cattle for a few weeks, there was little forage or hiding cover available, and deer essentially quit using the habitat." These studies indicate the likelihood that forage removal by cattle or domestic sheep can alter mule deer habitat selection and/or diet choices.

The likelihood of suppressed aspen regeneration from concentrated elk browsing appears to be greater than for mule deer. Compton (1974) found that elk in the Sierra Madre Range in Wyoming concentrated their summer use in subalpine parks, and found heavy autumn use in aspen cover types. Beck et al. (1997) reported that aspen made up 10% of elk summer diet, versus 3% of domestic sheep summer diet, in north-central Utah. Elk foraging on winter ranges has been shown to depress growth and prevent reproduction of aspen in Rocky Mountain National Park (Baker et al. 1997, Suzuki et al. 1999, Binkley 2008). Aspen are likely to be suppressed where elk density exceeds four elk per square kilometer (Painter et al. 2018). Elk also damage aspens by browsing new shoots, rubbing flexible saplings with their antlers, and by gnawing tree bark to get at the phloem underneath (Fairweather et al. 2007).

In the absence of large native predators, elk can suppress aspen sapling recruitment (Binkley 2008, Beschta and Ripple 2009). Ripple and Larsen (2000) found that due to heavy browsing by elk, following removal of wolves, only 5% of the current overstory aspen in the Northern Range of Yellowstone National Park originated after 1921. Painter et al. (2018) found that the percentage of aspen suckers browsed annually in Yellowstone National Park was 80-100% in 1997-98, decreasing to 30-60% in 2011-15 after the re-establishment of a wolf population. Elk shifted their habitat use and herbivory intensity away from Yellowstone National Park and toward the lower Madison River Valley in response to increasing wolf populations in the Park (Painter et al. 2018). However, in some localities within Yellowstone National Park, elk densities have remained high enough to continue to suppress aspen suckering (*id.*). White et al. (1998) found that elk browsing suppressed aspen recruitment in Canadian Rockies national parks, except under conditions when elk densities were reduced by wolves. There is now a broad scientific consensus that the absence of large native predators can result in depressed recruitment of aspen and other woody species (Beschta and Ripple 2009, Painter et al. 2018).

Browsing Pressure from Domestic Livestock

Livestock often concentrate their grazing activity in aspen groves due to the availability of shade and preferred understory forage species. In the Sierra Nevada mountains, cattle utilized meadow riparian and aspen habitats most strongly, selecting them over other habitats (Loft et al. 1991). According to Kay (2003: 41), "Even on allotments where livestock use has been controlled, aspen stands near water may still be in poor ecological condition because cattle tend to concentrate in those areas." Bailey et al. (1990: 213) found that cattle impacts on aspen are so severe that livestock can be used as a means to suppress aspen reproduction, stating "Overgrazing is generally considered to be detrimental to range stability and productivity over the longer term, but short duration heavy grazing may have a place in forage establishment and control of woody species." These researchers (*id.*: 214) recommended, "Clearly, for immediate control of aspen suckers, top removal or defoliation must be timed similarly to the late grazing treatment in this study. However, aspen suckers are suitable forage for cattle provided they are maintained within reach."

Beschta et al. (2014) found that aspen recruitment rates plummeted in the late 1800s with the onset of cattle grazing on the lands that would become Hart Mountain National Wildlife Refuge in southern Oregon, and increased by an order of magnitude after livestock were removed in 1990. These researchers attributed the decline of aspen groves on Hart Mountain to top-down forcing by cattle browsing, which suppressed aspen sapling recruitment, rather than climate changes. On Monroe Mountain in south-central Utah, Bartos and Campbell (1998a) provided photographic documentation of the effects of livestock preventing aspen regeneration using fenceline contrasts of a previously burned and logged area which remained barren in the presence of livestock and failed to regenerate. Across the fence, on habitats accessible to native herbivores but where livestock were excluded, dense regeneration was evident. Alexander (1995) documented that trampling by livestock broke 40% of aspen samples under both moderate and heavy grazing in his Alberta study; trampling caused damage in the form of basal scars that were present on 25% of surviving aspen saplings. By the second spring of cattle grazing, aspen sapling mortality in this study was 25%, 70%, and 89% for the ungrazed, moderately grazed, and heavily grazed sites, respectively.

Cattle selection for aspen shoots differs by season. According to Kay (2003: 32), "Year-long or season-long grazing is particularly detrimental to aspen, while early-season or dormant-season use may allow aspen to successfully regenerate." According to Jones et al. (2011: 629), "Aspen suckers received no early-growing season use by cattle but received the heaviest late-growing season use of all three vegetation types. Utilization was the same for all vegetation types at mid-growing season. Mean late-growing season use of aspen suckers was greater than 60%, and some stands received 100% use." Jones et al. (2011: 630) observed, "By mid-growing season, the quality of meadow and aspen understory vegetation approached minimum nutritional levels required for cattle." Alexander (1995) found that aspen suckers that have not yet begun to lignify, or become woody (i.e., one-year-old suckers), are a palatable forage for cattle, while two-year-old suckers were "not readily used" by cattle.

Even moderate levels of livestock grazing can suppress aspen regeneration. Alexander (1995) found that moderate and heavy grazing by cattle were equally effective at preventing aspen regeneration, with both moderate and heavy grazing both had a significant negative effect on understory biomass production in aspen stands.

Methods

We quantified ungulate use of the Pando Clone area with two motion-triggered cameras (Cameras 2 and 3) that were placed in portions of the Pando Clone outside the fenced exclosures, and two cameras that were placed in neighboring aspen groves (Cameras 1 and 4) subjected to the same pattern of livestock and mule deer herbivory. The cameras were sited in areas open to grazing and browsing by both domestic livestock and wild ungulates. The cameras were set to take photographs of all motion-triggered events separated by at least 1 minute. Cameras were installed on May 11th, 2018 and retrieved on November 22nd, 2018 to record herbivore activity throughout the growing season. The cameras were more sensitive to motion than expected. As a result, two of the cameras (Cameras 1 and 4, the cameras sited in neighboring aspen groves) ran out of battery power well before the end of the monitoring period, and therefore failed to record photographs during the livestock grazing period. These cameras, when remaining operational throughout the summer and into the fall, provide useful comparisons of forage utilization during cattle-free and cattle grazing periods, but could not be used to compare animal unit equivalents between deer and cattle due to the absence of livestock records.

After retrieval, the photographs were individually examined and the counts of ungulates were tallied for each camera. In order to more accurately compare total use by ungulate species, use was calculated based on body size/forage consumption by the Animal Units Equivalents (AUEs). A literature search found a range of estimates for mule deer, ranging from 0.2 (Pratt and Rasmussen 2001, NRCS 2003) to 0.17 (Ogle and Brazee 2009). For our calculations, we used 6 deer per 1 cattle animal unit (AU) (0.167), which is conservative being based on a 1,000-pound cow with calf. Cattle weights have increased significantly over the last 40 years with current average slaughter weight is presently 1,382 pounds (628 Kg) as of December 2017, (NASS 2018). We graphed the AUE data by week to display use over the monitoring period. It should be noted that the ratio of six deer per cow greatly underestimates the difference. A 1,382-pound (628 kg) cow consumes 3% of its body weight per day, or 41.6 lbs (18.9 Kg) (Ogle and Brazee, 2009). A 150-pound (68 kg) mule deer consumes 1.5 kg/day (UWSP 2019). This current information indicates a mature cow consumes 12.6 times the forage demand of a mule deer. However, we used the lower value to provide a conservative comparison.

We created time lapse videos of the photographs from each camera to help visualize conditions and herbivore use throughout the growing season.

The Interagency Landscape Appearance Method

This method's descriptions classify forage utilization into the following Herbaceous Utilization classes (USFS 1993; *see also* BLM 1996):

1. No Use (0-5%). The rangeland shows no evidence of grazing use; or the rangeland has the appearance of negligible grazing.

2. Slight (6-20%) The rangeland has the appearance of very light grazing. The key herbaceous forage plants may be topped or slightly used. Current seedstalks and young plants of key herbaceous species are little disturbed.

3. Light (21-40%) The rangeland may be topped, skimmed, or grazed in patches. The low-value herbaceous plants are ungrazed and 60 to 80 percent of the number of current seedstalks of key herbaceous species remain intact. Most young plants are undamaged.

4. Moderate (41-60%) The rangeland appears entirely covered as uniformly as natural features and facilities will allow. Fifteen to 25 percent of the number of current seedstalks of forage plants are utilized. (Moderate use does not imply proper use.)

5. Heavy (61-80%) The rangeland has the appearance of complete search. Key herbaceous species are almost completely utilized with less than 10 percent of the current seedstalks remaining. Shoots of rhizomatous grasses are missing. More than 10 percent of the number of low-value herbaceous forage plants have been utilized.

6. Severe (81-100%) The rangeland has a mown appearance and there are indications of repeated coverage. There is no evidence of reproduction or current seedstalks for key herbaceous species. Key herbaceous forage species are completely utilized. The remaining stubble of preferred grasses is grazed to the soil surface.

These videos can be accessed at https://www.westernwatersheds.org/pando-clone-time-lapse/. We also took photographs along the 2013 exclosure fence to document the contrasting rates of regeneration within and outside the exclosure.

Utilization of vegetation by herbivores was estimated using the interagency Landscape Appearance Method descriptions, an estimation procedure used on the Fishlake National Forest (USDI Technical Reference 1734.3), see accompanying box. Utilization was estimated at the photo location on the day prior to livestock entry, 7 days after livestock entry (half of the livestock use period) and again after livestock removal.

Results

The exclosures constructed by the Forest Service in 2013 and 2014 within portions of the Pando Clone provide a clear contrast between natural recovery rates inside the exclosures with the effects of this heavy to severe level of utilization outside the exclosures. The exclosures were built of 8-foot tall woven wire topped with a barbed-wire strand. Figures 2 and 3 are taken from the same location, with one looking into the interior of the 2013 exclosure and the other looking into the grazed allotment, and area used by both deer and cattle.

From the ongoing aspen recovery that has occurred since the exclosures were constructed in 2013 and 2014, and the complete lack of any recruitment of aspen sprouts occurring outside the exclosures, it is clear that current management outside the exclosures prevents the regeneration of the Pando Clone in areas open to livestock grazing. Inside the 2013 exclosure fence, we found successful aspen recruitment is occurring irrespective of any mule deer that may have found a way to enter the exclosure area.

Camera 1 recorded from May 11th, 2018 through August 13th, 2018, prior to the onset

of livestock grazing. Camera 2 recorded from May 11th, 2018 through October 9th, 2018.

Camera 3 recorded from May 11th, 2018 through November 22nd, 2018. Camera 4 recorded from May 11th, 2018 through September 22nd, 2018, prior to the onset of livestock grazing. The livestock use period began on October 4th and ended October 16th for a total of 13 days, during which domestic cattle were the type of livestock present in the project area. The area under study received use by mule deer (*Odocoileus hemonius*) throughout the monitoring period.

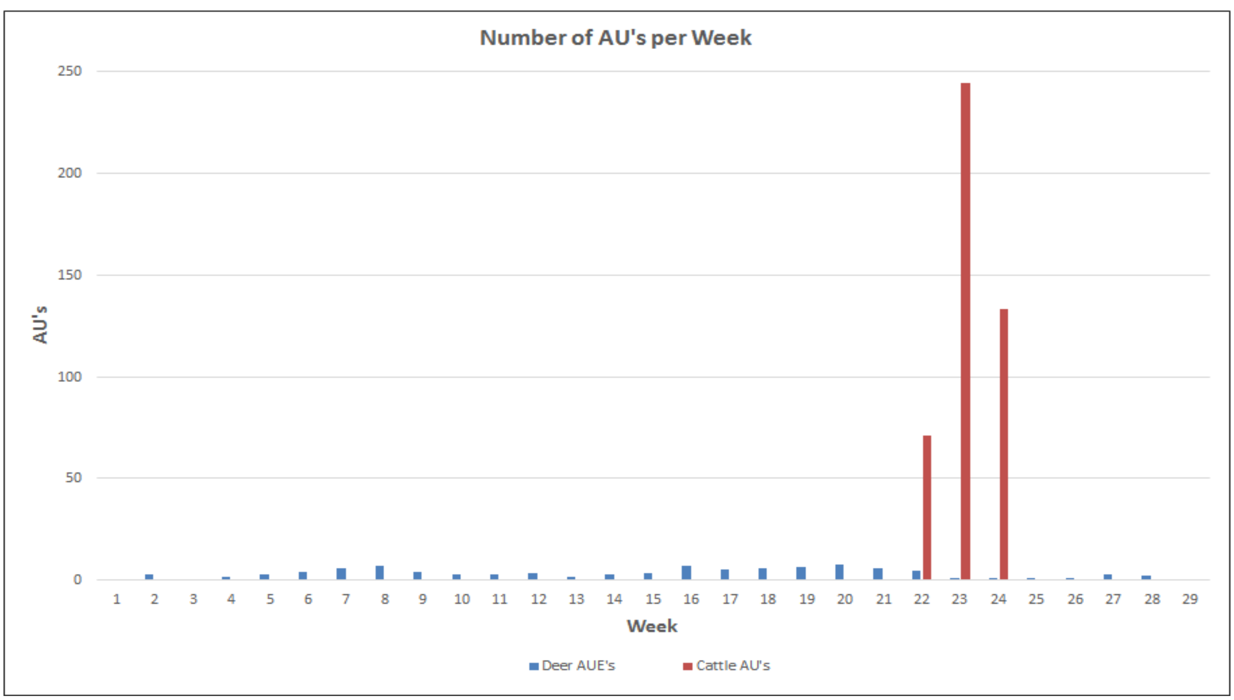

Figure 6. Camera 3, within an unfenced portion of the Pando Clone deer versus cattle Animal Units by week.

Rogers and McAvoy (2018) reported that "[e]lk sign is evident in the broader area" and used this as a basis for asserting that elk might presently be accessing the area. We documented no elk sightings in the Pando Clone, but Camera 1 recorded four elk in one instance in an adjacent aspen grove.

For Camera 1, motion from grass moving in the wind depleted the power supply by August 13th, 2018, so only forage utilization observations could be made. For Camera 2, deer use during the 6-month period totaled 42 AUE's, while cattle use during the 6 days (slightly less than 50% of the cattle use period) totaled 162 AU's. For Camera 3, deer use during the 6-month period totaled 101 AUE's, while cattle use during the 13 days totaled 448 AU's. For Camera 4, motion from grass moving in the wind depleted the power supply by September 27th, 2018, so only utilization observations could be made. On average, the index for animal use documented for cameras that lasted into the livestock grazing season was found to be four times higher for cattle during the 13 days of livestock grazing than for mule deer over the course of the entire growing season. Camera 4, on the eastern shore of Fish Lake, documented a similar result.

During the months prior to the arrival of livestock all cameras documented no observable utilization of the vegetation, whereas within 7 days after the arrival of livestock utilization was in the "heavy" category (61-80% utilization) for Cameras 2 and 3, inside the Pando Clone. After livestock removal, use was in the upper "heavy" to mid "severe" (81-100%) categories at all four sites (see Figures 10, 16, 22, 27, 28, and 29).

Figure 10 shows conditions following livestock removal for Camera 1, in an aspen grove adjacent to Pando. Based on the descriptions in the Landscape Appearance Method this would fit in the upper end of the "heavy" (61-80%) category. Within the Pando Clone, patterns of herbivory by mule deer and livestock were essentially identical to Pando's genetically distinct neighboring groves. For Camera 2, livestock use was near the upper end of the "heavy" category by day 7, with significant utilization on rabbitbrush (*Chrysothamnus* sp.), which has low palatability (see Figure 15). By the time livestock were removed, forage utilization levels, based on

the descriptions in the Landscape Appearance Method grazing levels shown by Camera 2 this would fit in the mid to upper end of the "severe" (81-100%) category. By day 7 of livestock use documented by Camera 3 (see Figure 21), the large bunchgrasses had been completely grazed and only a small fraction of the seedheads remained. Note the difference in visibility of the fallen branches at ground level between Figures 20 and 21. Figure 22 shows conditions for Camera 3 following livestock removal. Based on the descriptions in the Landscape Appearance Method this would fit in the upper end of the "heavy" (61-80%) category. By the time livestock were removed, forage utilization levels shown by Camera 2 (see Figure 16) would fit in the mid to upper end of the "severe" (81-100%)

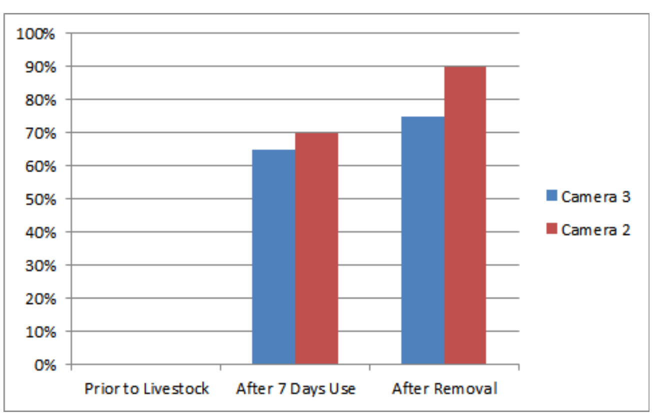

Figure 29. Forage utilization levels before livestock entry and after removal for Cameras 2 and 3, sited within the Pando Clone.

down to the same level as the rest of the forage base.

While we hoped to document direct herbivory by deer and/or cattle on aspen sprouts with the remote cameras, in fact we were unable to document any aspen sprouts at all during the growing season period over which our cameras were deployed. This is consistent with the findings of Rogers and Gale (2017), who also reported essentially no aspen sprouts outside the exclosure fence. Thus, like Rogers and McAvoy (2018), we are unable to measure direct herbivory of aspen by either mule deer or cattle, and are left with making inferences from indirect measures (in the case of this monitoring report, overall forage consumption and animal use). The level of trampling by cattle appears to be heavy in all locations we monitored.

Our findings support the conclusions of Loft et al. (1991), that the presence of livestock results in habitat abandonment by deer. Deer use dropped to nearly zero after the arrival of livestock and only returned after livestock removal and then at much lower levels than prior to livestock entry.

Discussion

We documented levels of herbivory by mule deer that were too light to quantify throughout the summer, measured by the Landscape Appearance Method used by the Forest Service to estimate forage utilization. This was followed by heavy to severe understory utilization by cattle that virtually eliminated understory vegetation during the 14-day period in October when cattle were turned out both in unfenced portions of the Pando Clone, and in neighboring aspen groves subjected to the same pattern of livestock grazing. The level of livestock forage utilization we documented (70 to 90%) was consistent with heavy grazing as defined by Alexander (1995), who classified 73% forage utilization by cattle as "heavy" and found this level – entailing the browsing of 95% of aspen saplings – to be sufficient to suppress aspen regeneration (see Figures 28 and 29). This is supported by scientific observations at Pando itself. Rogers and Gale (2017: 11) concluded, "A key message, then, is that while we cannot state unequivocally that there are 'too many' herbivores at Pando, we do know that there are too many for current conditions."

These heavy to extreme levels of forage utilization exceed the Forest Service allowable utilization level of 50% (USDA 2018). In addition, these levels are much greater than the 25% level supported by leading range scientists (Galt et al 2000).

By quantifying the ungulate use of the Pando area and tracking utilization over the study period, our data and analysis demonstrates, based on Animal Unit Equivalents, that more than 4 times the animal use occurs in the unfenced portion of the Pando Clone and in neighboring aspen groves from livestock than for mule deer. Nearly all of the observable forage utilization in the understories of aspen groves in this area during the monitoring period was the result of livestock. According to Rogers and Gale (2017: 6),

> we counted only one mule deer scat pile, but 219 cattle deposits in Year 1. In Year 2, we counted no scat piles of any species within the fence, but 72 cattle and five deer piles outside the exclosure. By Year 3, cattle deposits were 64 and deer scat was 14, all outside the exclosure.

Our results are consistent with these findings.

Our findings contrast with Rogers and McAvoy 2018, which concluded that mule deer are the primary factor in regeneration failure in the Pando Clone. The Rogers and McAvoy study used "browse level, and feces counts as a surrogate for ungulate presence." Its analysis identified deer presence (indexed by density of pellet groups) as the key factor relating to failure of aspen sprouts to recruit. Cattle presence as indexed by feces was negatively related to both recruitment and aspen density but was not identified as a major factor by this exploratory analysis. It is troubling that while pellet groups were negatively related to aspen regeneration in the Rogers and McAvoy study, browse level was not a significant factor. Browsing of aspen saplings would presumably be the direct means by which either mule deer or cattle would directly affect sapling survival and recruitment.

In addition, Rogers and McAvoy's identification of cattle concentration as an unimportant factor in aspen recovery runs contrary to earlier findings that aspen recruitment is lowest in portions of the Pando Clone accessible to livestock, and higher in fenced areas, whether these are accessible to mule deer or not (Rogers and Gale 2017, Coles-Ritchie et al. 2018). Rogers and McAvoy (2018) concluded that deer were the cause of regeneration failure. But in their analysis of regeneration, the 2014 exclosure was accessible to deer but not cattle, and had a browse level of 24%, while in the unfenced area, where both deer and cattle were present, the browse level was 55%. Furthermore, aspen recruitment was highest in the 2014 exclosure (1,204 stems/ha) in the presence of deer and lowest in the 2013 exclosure from which both deer and livestock were absent, further muddying this conclusion.

The season of livestock grazing can also have a major impact on regeneration. Livestock show greater preference for browsing aspen shoots in autumn than in spring (Fitzgerald et al. 1986). Aspen suckers have higher nutritional quality than other forage types throughout the year, but cattle focus their foraging on meadow and understory vegetation in early and late summer, increasing utilization of aspen suckers only late in the growing season when other forage types were of low nutritional quality and depleted by grazing (Jones et al. 2011). However, experimentally browsed aspens showed greater growth when browsed in the autumn than when browsed in early or late summer (Jones et al. 2009). Balancing aspen's greater resilience to livestock grazing in fall with the far greater tendency of cattle to select aspen browse at this same time of year thus becomes critical.

Late-season grazing by cattle (just before leaf drop) is the most effective season for cattle grazing to suppress aspen regeneration, and livestock grazing during this time of year can eliminate aspen seedling recovery after six consecutive seasons of grazing post-fire (Bailey et al. 1990). Jones et al. (2011) recommended avoiding late-season grazing by cattle in aspen stands to minimize browsing on aspens, and recommended that mid- and late-season grazing by cattle not occur in consecutive years. Jones et al. (2011) recommended avoiding late-season grazing by cattle in aspen stands to minimize browsing on aspens, and recommended that mid- and late-season grazing by cattle not occur in consecutive years. In the case of the Pando Clone, livestock use this pasture in the fall every year, at the very time of year when the greatest selection by cattle for aspen shoots occurs. In this case, cattle were turned out in the Pando Clone in early autumn, precisely the season when the tendency of cattle to browse on aspen saplings would be expected to be greatest based on the science.

In our monitoring, we found livestock use in the "heavy" to "severe" categories that would result in complete use on any aspen suckers that had emerged. Our cameras were unable to detect aspen sprouts – or either mule deer or cattle herbivory on them – but the end result was that aspen sprouts were virtually completely suppressed outside the exclosure fences, based on the absence of any aspen sprouts visible in our photographs. This finding is consistent with other reports documenting little or no aspen recruitment outside exclosure fences that prevent grazing by livestock (but do not always prevent access by mule deer).

Cattle grazing in parts of the Pando Clone outside the exclosure, and in neighboring unfenced aspen groves, may also have a synergistic effect with the herbivory by native mule deer, resulting in impacts to aspen recruitment that may be greater than simply adding the two types of impact together. Wild herbivores may be drawn to ungrazed areas where livestock have been excluded (O'Brien et al. 2010). Aspen habitats are preferred by mule deer when cattle are absent, but preference declines under moderate to heavy grazing to the point where deer use aspen habitats roughly in proportion to their availability (Loft et al. 1991). Mueggler and Bartos (1977) studied an exclosure accessible to deer but not livestock in which production of forbs, or broad-leaf understory herbs, occurred inside the exclosure. This abundance of forage likely concentrated deer foraging activity inside the exclosure, to the detriment of aspen suckers, which failed to survive to reach tree status between 1905 and 1934, based on subsequent tree-ring analysis.

Austin and Urness (1985) reported that aspen proportion in mule deer summer diets ranged from 0.2 – 3%, but increased to 9% in September. The heavy level of understory utilization by cattle in the unfenced parts of the Pando Clone and in nearby aspen stands (70-90% as found in our study) during a time of year when deer intrinsically increased their herbivory on aspen saplings may, through competition, further increase mule deer browsing on aspen shoots by leaving behind few alternative sources of forage.

Kay and Bartos (2000) studied exclosures on the Dixie and Fishlake National Forests that excluded deer and livestock both, or livestock only. Complete failure of new regeneration occurred in the presence of both livestock and deer herbivory outside the exclosures at 4 of the 5 sites where portions of the exclosures prevented access by both deer and livestock, and at 3 of the 8 sites having livestock-only exclosures new regeneration failed in areas where the livestock were excluded. Kay and Bartos found that excluding livestock and/or native herbivores increased recruitment of aspen saplings in the 2-meter to 5-centimeter diameter-at-breast-height range, with an average of 4,474 surviving aspen ramets under livestock and cervid exclusion, 2,498 ramets surviving by excluding livestock only, and an average of 1,012 surviving ramets outside the exclosures, where aspens were subject to herbivory by cattle, sheep, deer, and/or elk. Rogers and Gale (2017) documented a more than fourfold increase in aspen regeneration inside the Pando Clone's fenced exclosure compared with outside.

In this monitoring project, we found little visual evidence of aspen recruitment outside the exclosure fences, indicating either that aspen sprouts were browsed away prior to the onset of the growing season for grasses, or that deer and/or livestock herbivory was eliminating them prior to the point at which they would become visible to the camera. Given the extreme level of understory herbivory by cattle during the 13-day grazing period that we recorded in 2018, it is entirely possible that mule deer returning to the Pando Clone following cattle grazing would have found little understory forage, increasing the likelihood of 100% utilization of aspen sprouts that emerged prior to the onset of the following season. In this way, the overgrazing by cattle that we recorded within unfenced portions of the Pando Clone may be interacting with herbivory by mule deer to eliminate aspen recruitment outside the ungulate exclosures.

Bailey et al. (1990: 214) found fall cattle grazing to be an effective tool for eliminating aspen regeneration:

> Suckers defoliated by grazing in August, late in the growing season, were nearly eliminated after only 1 defoliation (FitzGerald and Bailey 1984) whereas suckers defoliated earlier in the season continued to regenerate and took 7 years to decline to 7% of original stem densities…. Schier (1976) indicated that repeated removal of tops and consequent initiation and growth of new suckers leads to a gradual depletion of nonstructural carbohydrates in the roots. Exhaustion of carbohydrates by annually repeated destruction of growing points appears to take from 6 to 8 years…. Clearly, for immediate control of aspen suckers, top removal or defoliation must be timed similarly to the late grazing treatment in this study.

These authors conclude by stating, "If the first priority is to nearly eradicate regenerating aspen suckers, then late season, short duration heavy grazing should be applied." Unfortunately, this is exactly what is happening within the unfenced Pando Clone and surrounding aspen groves.

Trampling damage by ungulates has often been implicated as a potentially significant cause of aspen regeneration failure (Schier 1981, DeByle 1990, Brown 1995). With regard to cattle, Weatherill et al. (1969: 5) concluded that "[c]onsumption reduces photosynthesis, trampling may break stems and leaves, while soil compaction can injure root systems and decrease soil aeration and water holding capacity." While Dockrill et al. (2004: 261) found that damage from cattle due to direct browsing and trampling damage killed individual aspen sprouts, these researchers concluded that "[h]igh mortality among stems without observed injuries might have been indirectly associated with cattle damage resulting from soil compaction, reduced root oxygen and subsurface severing of lateral roots." Because adventitious buds forming on lateral roots are the genesis of aspen sprouts, and because the level of trampling by cattle appears to be substantial based on our monitoring, more detailed study of the effect of trampling by livestock on the roots, adventitious buds, and initiation of suckering in the Pando Clone is necessary prior to concluding that herbivory by deer or livestock (or some synergistic combination of the two) is primarily responsible for the failure of sprout recruitment outside fenced exclosures.

Livestock appear to have the heavier impact than mule deer on aspen regeneration, based on exclosure studies that differentially exclude cattle and wild cervids. Based on a study of 30 grazing exclosures in aspen habitats in Nevada, Kay (2003: vi) stated,

> The [declining] status and trend of aspen communities in north-central Nevada, however, is not related to climatic variation, fire suppression, or browsing by mule deer. Instead, the condition of individual aspen communities is related to past and present levels of livestock grazing. That

> is, aspen is declining throughout most of north-central Nevada due to repeated browsing of aspen suckers by cattle and/or domestic sheep – repeated browsing eliminates sucker height growth, which prevents their maturation into aspen saplings and trees. Without stem replacement, aspen clones are consigned to extinction.

Livestock in mountain ranges of central Nevada contributed to poor aspen clone condition, and grazing by sheep and cattle accounted for 99.5% of the grazing pressure based on feces counts (Kay 2001).

While mule deer have been implicated as the cause of regeneration failure in the Pando Clone (Rogers and McAvoy 2018), the bulk of science thus far published (reviewed herein) does not necessarily support this conclusion, and our own monitoring photos show quite clearly that cattle, rather than mule deer, are having the heaviest impact on understory vegetation in the Pando Clone and on the understories of neighboring aspen groves.

Recommendations

We recommend eliminating livestock grazing during all seasons for the entire Pando Clone, and for aspen habitats generally, livestock should be removed if aspens are experiencing regeneration failure. This should be done until aspen regeneration is above browse height, and will require periodic repetition to prevent future aspen sprout suppression. Kay (2003) recommended fencing critical aspen stands or restricting livestock to only early-season grazing. According to Beschta et al. (2014: 36, internal citations omitted), "Our results indicate that for areas grazed by livestock and where aspen recruitment is either absent or occurring at low levels, implementing strategies that eliminate or minimize the effects of livestock herbivory may be needed. Given the vast amount of public land annually utilized by domestic ungulates and the large losses in aspen those lands have experienced to date, reducing livestock grazing effects within and across ecoregions may be required for attaining ecological restoration of herbivore-altered plant communities." According to Alexander (1995: 120), "even though aspen sucker density was still high after two years [cattle] grazing, it was the author's opinion that if the grazing treatments were continued, the prognosis for successful aspen forest regeneration would be poor."

Mechanical treatments such as coppice logging do not appear to be warranted in the Pando Clone based on the science. Aspen stands can reach high densities without stagnating because they are self-thinning (DeByle 1984). Thus, the thinning or logging of aspen stands is unwarranted from a silvicultural perspective. Bird species richness increases with aspen patch size (Johns 1993), suggesting that fragmenting aspen stands into progressively smaller patches through clearcutting may lead to a loss of bird diversity. In the Pando Clone, coppice logging of aspens might also inadvertently cause a loss of genetic diversity by completing the dominance of triploid aspens (DeRose et al. 2015). The successful regeneration of aspen saplings inside the Pando Clone's exclosure fence in the absence of mechanical treatments is proof positive that mechanical interventions are unnecessary.

The idea of eliminating grazers from aspen stands struggling to reproduce is not a new concept. Mueggler (1989) recommended protecting aspen groves with exclosures where the stand is heavily grazed or browsed. According to Shepperd (2001: 363), "Fencing is the only guaranteed means of directly protecting sprouts from browsing animals." O'Brien et al. (2010: 28) recommended, "In situations where the relative impact of domestic livestock versus wildlife has not been determined, a livestock exclusion fence alone (followed with monitoring) may be a reasonable first choice."

The significant role of cattle grazing in the Pando Clone has been acknowledged by scientific researchers. According to Rogers and Gale (2017: 11), "While we know that mule deer are responsible for a portion of aspen sucker browsing, cattle reduction and exclosure seem to also play an important role as evidenced by the combination of scat counts, browse levels, and overall regeneration response inside and outside our study area."

At a minimum, the existing exclosures should be expanded to encompass the entire perimeter of the Pando Clone, plus a quarter-mile buffer to allow for expansion, and livestock grazing should cease in this area. A better solution would be to permanently close the Dry Ponds pasture and any other pasture that encompasses the Pando Clone, to livestock grazing. Further research is needed to determine thresholds at which mule deer and/or cattle density reduce aspen recruitment below self-sustaining levels, and the degree to which soil trampling by livestock contributes to sprout suppression and root damage in aspen clones.

Aspens and mule deer have been evolving together for thousands of years. In light of our findings that heavy cattle utilization of aspen understories in the unfenced portions of the Pando Clone and in neighboring aspen stands, and the likelihood that this heavy level of grazing could work synergistically with mule deer browsing to suppress aspen regeneration, previous hypotheses that mule deer browsing alone is responsible for the decline of Pando Clone sucker establishment appear highly unlikely. Taken together, the evidence brought forward thus far suggests that livestock grazing and/or trampling may be the critical factor(s) tipping browsing pressure over the threshold at which aspen regeneration begins to fail. Removing livestock grazing from the pastures south of Fish Lake and measuring suckering and recruitment for a period of 5 years would be a logical method to determine whether the primary driver of the failure to recruit is deer or livestock.

forest policy

Implementing the 2012 Forest Planning Rule: Best Available Scientific Information in Forest Planning Assessments

C.M. Ryan, L.K. Cerveny, T.L. Robinson, and D.J. Blahna

National forests and grasslands in the United States are governed by land and resource management plans that should be updated every 15 years to reflect changing social, economic, and environmental conditions and to address new priorities. A new forest planning rule finalized in 2012 introduces new planning approaches and requirements, and several forests have completed the forest assessment phase of their planning process. Using document analysis and interview data, we analyzed four completed forest assessments to gain insights into early forest planning efforts under the 2012 rule. We found that forest assessments address the required topics, although the organization and depth of treatment varies across cases; government sources and academic publishers are relied on most often as sources of scientific information; and approaches to best available scientific information rely on peer-reviewed information, agency technical reports and syntheses, and personal expertise and judgement.

Keywords: early adopter, expertise, US Forest Service

Management of the 154 national forests and 20 grasslands in the United States is governed by land and resource management plans (also called forest plans), as required by the National Forest Management Act of 1976 (NFMA; 16 U.S.C. 1604). The forest plan functions as a guiding document that outlines goals, objectives, and strategies for management of the unit. Periodically, the rule related to forest planning is revised to reflect societal changes, new approaches and technologies, and scientific discoveries. For many years the US Forest Service (USFS), which manages the system of national forests and grasslands, has operated under a planning rule finalized in 1982 (47 FR 43026) despite several efforts (2000, 2005, and 2008) to revise and improve the rule (Schultz et al. 2013). A new planning rule issued in April 2012 (77 FR 21161) introduces several significant changes, including a renewed emphasis on collaboration, improved transparency, and a strengthened role for public involvement throughout the planning process. Of interest for our study is the requirement to use the best available scientific information (BASI) to inform the assessment, plan revision decisions, and monitoring program.

To date, little research has addressed implementation of the 2012 planning rule. Schultz et al. (2013) examined approaches to wildlife conservation planning under the new rule, raising concerns regarding potential extirpation of species. Another study analyzed public participation processes in 12 national forests (University of Montana 2015), and Schembra (2013) explored the role of standards and guidelines and how they are used in planning activities. Forest planning under the 2012 rule consists of three phases (assessment, plan development, and monitoring). The assessment phase is important, as it assembles relevant scientific information that planners will rely on to make decisions on forest management in the plan development phase. Our study contributes to this growing body of knowledge by examining the assessment phase of the forest planning process.

Eight "early adopter" national forests, along with several other forests, are currently developing their forest plans using the 2012

rule. These forests were designated as early adopters because they provide important benefits, had strong existing collaborative networks in place, and needed to revise their forest plans (USDA Forest Service 2012a). The eight early adopter forests are: Cibola (NM), Chugach (AK), El Yunque (PR), Nez Perce and Clearwater (ID), and three forests that are coordinating planning on a regional basis: Inyo, Sequoia, and Sierra (CA).

Although implementation is still in early stages, several of the early adopter forests have completed their forest assessments and draft forest plans, which presents an opportunity to study implementation of the planning process under the new rule. One forest (the Francis Marion in SC) has completed the full plan revision process as of this writing. We examined four forests that have completed their assessments, including three forests identified by the agency as early adopters and one forest that is keeping pace with this group. The study explored three questions: 1) What does the 2012 planning rule require regarding the structure, content, and process for forest assessments? 2) How have forests implemented the directives related to forest assessments under the 2012 planning rule? 3) How are forests approaching the requirement for the use of best available scientific information in their assessments?

Forest Planning under the 2012 Rule

The 2012 planning rule suggests an adaptive approach to forest planning, instructing managers to 1) *assess* forest conditions; 2) *revise or amend* plans if the assessment indicates a need for change; and 3) *monitor* plan implementation (36 CFR 219.5). The process is cyclical, with monitoring data feeding back into the assessment of conditions in the management unit (USDA Forest Service 2012b). During the assessment phase, planners are expected to "rapidly evaluate existing information about relevant ecological, economic, and social conditions, trends, and sustainability, and their relationship to the land management plan within the context of the broader landscape" (36 CFR 219.5(a)(1)). The second phase of the planning process is plan development, amendment, or revision, where planners use the results of the assessment to establish a need for change and generate planning alternatives (36 CFR 219.5(a)(2)), and the public has the greatest opportunity for input. The plan development phase includes environmental impact assessment, public input, and plan publication (36 CFR 219.5(a)(2)). The third phase (monitoring) is an opportunity to track and measure management effectiveness over time (36 CFR 219.5(a)(3)). The planning *process* under the 2012 rule is similar to the process specified under the 1982 rule, but differs in terms of the specific elements required for the *assessment* (2012 rule) and the *analysis of the management situation* (the assessment's counterpart in the 1982 rule).

We focused our study on the assessment phase of the planning process. The assessment phase is important because it requires the forest to assemble and synthesize the most recent, relevant, and highest-quality science on social, ecological, and economic conditions to inform the plan development. Not only does this provide planners an opportunity to evaluate changes in biophysical and socio-economic conditions based on the latest monitoring data, it also represents a chance to reflect on new concepts, models, and methods that result in new scientific information about the local forest environment. Under the 2012 planning rule, the assessment phase identifies existing conditions, trends, risks, uncertainties, and information gaps that are relevant to land and resource management issues in the unit (36 CFR 219.5–219.6). In the assessment phase, the planning unit is not required to generate new studies or information, but is expected to obtain pre-existing information that is publicly available or voluntarily provided (36 CFR 219.6). Information can come from government and nongovernment sources, and the rule instructs the Forest Supervisor to provide opportunities for stakeholders to provide information for the assessment (36 CFR 219.6). The primary product of the assessment phase is an assessment document that evaluates existing information for 15 specific topic areas (Figure 1). Although the general topic areas are mandated by the 2012 rule, the Forest Supervisor has discretion to determine the scope, scale, and timing of the assessment, assuming the other requirements in the planning rule are followed (36 CFR 219.6).

Role of Science in Natural Resource Management

Historically, natural resource management in the United States was guided by the idea of scientific management and Progressive-era approaches (Taylor 1896). In particular, Samuel Hays's "gospel of efficiency" relied on a rational and scientific method of making decisions through a single, central authority. The thought was to avoid conflict via a scientific approach to social and economic issues (Hays 1959, p. 267). The US Forest Service exemplifies the approach of technical rationality and empirical science as the basis for sound resource management practices (Wellman 1987; Kaufman 1960). Foresters and natural resource managers

Management and Policy Implications

Although implementation of the US Forest Service's 2012 planning rule is still in the early stages, several national forests have completed the assessment phase and moved on to the next phase of forest planning. Our analysis of forest assessments from several "early adopter" forests illustrates that forest planners are making serious efforts to address required topics and rely on the best available scientific information. Assessment reports were disproportionately heavy in science related to terrestrial and aquatic ecosystems, and more limited in treatment of infrastructure, land ownership and access patterns, cultural heritage, and areas of tribal importance. Ensuring that assessment teams include broad and diverse disciplinary experts will help address this challenge, recognizing that some forests may not have access to necessary disciplinary specialists. It is also possible that some of the topics (e.g., ecosystem services, tribal and cultural resources, land status and use patterns) simply do not have as much relevant and available information as other topics. Assessment teams may want to consider additional ways to interact with scientists and others to create functioning communities of practice related to science exchange for forest planning. In the same way, agency scientists may consider forging new and enduring relationships with planners and managers that could generate new science that is of immediate relevance. We found similarities across all forests in the most common approaches to identifying BASI in addition to other approaches such as data sharing meetings, a wiki review site, and requests for a science synthesis. Information from non-peer-reviewed sources was more difficult for planners to assess and evaluate. Sharing best practices, along with revised guidance for planning rule implementation, may help national forest planners improve the utility, efficiency, and quality of forest assessments.

- Terrestrial ecosystems, aquatic ecosystems, and watersheds
- Air, soil, and water resources and quality
- System drivers, including ecological processes, disturbance regimes, and stressors
- Baseline carbon stocks
- Threatened, endangered, proposed and candidate species; potential species of concern
- Social, cultural, and economic conditions
- Benefits people obtain from the planning area (ecosystem services)
- Multiple uses and their contributions to economies
- Recreation settings, opportunities, and access, and scenic character
- Renewable and nonrenewable energy and mineral resources
- Infrastructure (recreational facilities, transportation and utility corridors)
- Areas of tribal importance
- Cultural and historic resources and uses
- Land status, ownership, use, and access patterns
- Existing designated areas including wilderness and wild and scenic rivers; need and opportunity for new designations

Figure 1. Topics for forest plan assessments (36 CFR 219.6)

are expected to incorporate state-of-the-art scientific knowledge to manage public lands (Lachapelle et al. 2003). However, the role of science in natural resource decision-making has become much more complex (Mills and Clark 2001). Recent literature acknowledges that no important policy issue or decision is purely technical, that established practices are problematic, and that politics are unavoidable (Brunner et al. 2005). In spite of this, numerous policies reflect the scientific management paradigm in their calls for best available science.

In the United States, many policies and statutes contain references to best available science, including the Marine Mammal Protection Act of 1972, the Endangered Species Act of 1973, and the Safe Drinking Water Act of 1974. Despite references to the concept of best available science, these policies do not include specific definitions of its properties, standards, or practical application in the decision-making process (Doremus 2004; Smallwood et al. 1999), leading to different definitions of what it means. Ryder et al. (2010) identify attributes of best available science from published literature that span topics such as endangered species legislation, protection of conservation areas, forest management, water resource management, and ocean fisheries. The paper highlights the diversity of attributes assigned to best available science, and demonstrates that no single attribute is common to all studies, suggesting that best available science is context specific (Ryder et al. 2010). Moreover, as Lowell and Kelly (2016) observe, the ability to use best available science may be inhibited by institutional constraints within particular agencies limited by time or organizational capacity. Other literature has attempted to assign descriptors to the concept. For example, "best" often connotes scientific information with the greatest degree of excellence and authenticity based on sound logic (Moghissi et al. 2010), or that there is no better scientific information, and suggests the use of the most relevant and contemporary data and methods (National Research Council 2004). "Available" connotes scientific information that is accessible and attainable (Moghissi et al. 2010), or that decisions can be consistent with the scientific information that is available even though data gaps exist (National Research Council 2004). "Science or Scientific information" is defined as knowledge that emerges from a process of observation, identification, description, and testing of explanatory hypotheses about fundamental principles that govern cause-and-effect (National Research Council 2004). The National Research Council report includes guidelines for effectively using best available science, including concepts of relevance, inclusiveness, objectivity, transparency and openness, timeliness, and peer review. Finally, Charnley et al. (2017) analyzed a science synthesis for three national forests and suggest criteria for evaluating "best available *social* science," which may be different from the criteria used to evaluate best available biophysical science.

A key aspect of the 2012 planning rule is that it requires the planning process to draw on the best available scientific information (36 CFR 219.3). The preamble to the planning rule notes that there is a range of information that can be considered BASI, stating:

> In some circumstances, the BASI would be that which is developed using the scientific method, which includes clearly stated questions, well-designed investigations and logically analyzed results, documented clearly and subjected to peer review. However, in other circumstances the BASI for the matter under consideration may be information from analyses of data obtained from a local area, or studies to address a specific question in one area. In other circumstances, the BASI also could be the result of expert opinion, panel consensus, or observations, as long as the responsible official has a reasonable basis for relying on that scientific information as the best available. (77 FR 21192 [April 9, 2012])

Planning Directives are agency guidance documents that direct implementation of rules such as the 2012 planning rule, and directives for assessments are in Chapter 10 of the Land Management Planning Handbook (USDA Forest Service 2015a). The definition of BASI is contained in the "zero code" chapter of the handbook and specifies three primary criteria for determining BASI: accuracy, reliability, and relevance (FSH 1909.12.07.12), in addition to referencing the Data Quality Act (PL 106–554) for guidance on evaluating available information (Figure 2). Available is defined as information that currently exists in a form useful for the planning process without further data collection, modification, or validation (FSH 1909.07.01).

The directives also provide guidance regarding sources of scientific information. The sources mentioned in the guidance include peer-reviewed articles, scientific assessments, other scientific information (expert opinion, panel consensus, inventories, or observational data), data prepared and managed by the Forest Service

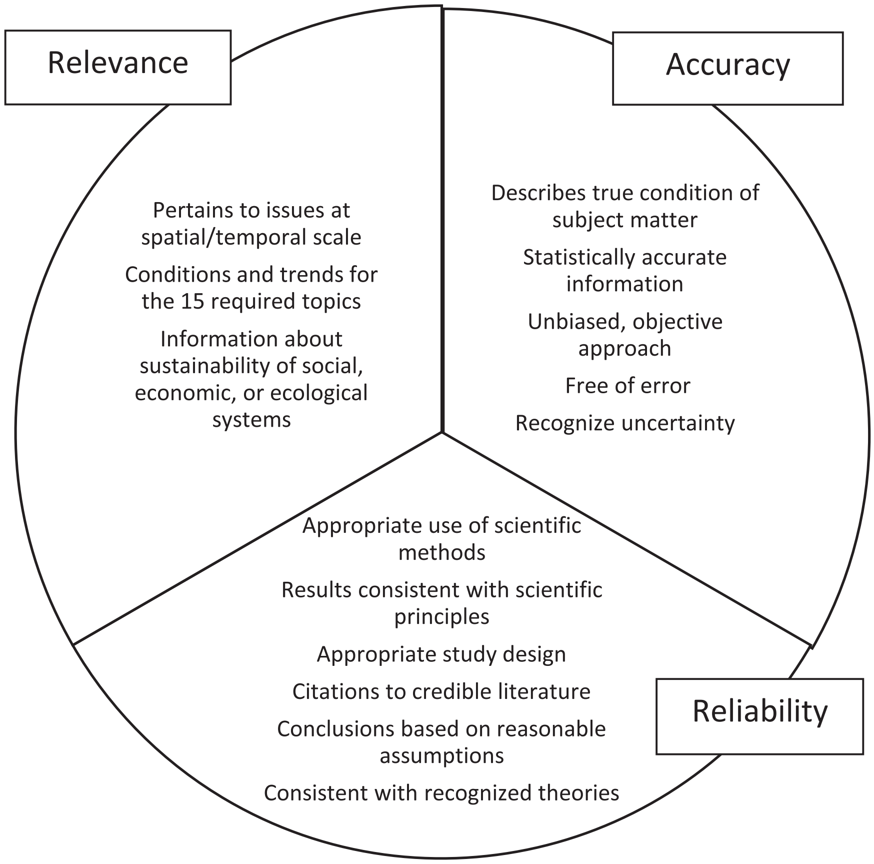

Figure 2. Criteria for determining best available scientific information (BASI). Source: Forest Service Handbook 1909.12.07.12

or other federal agencies, information prepared by universities, national research networks, and other reputable scientific organizations, and data or information from public and governmental participation (FSH 1909.12.07.13).

At the US Forest Service, two regional science synthesis efforts were initiated to assist forest planners in identifying BASI for their assessments. The first synthesis included the Sierra Nevada, southern Cascades, and Modoc plateau areas of California, and informed plan revisions on three national forests (Long et al. 2014). The second synthesis is currently underway as part of the Northwest Forest Plan area planning process, which covers 17 national forests and five Bureau of Land Management units across parts of the Cascade and coastal ranges of Washington, Oregon, and northern California. Once drafted, the synthesis report underwent independent third-party peer review, in addition to public review, and is currently under revision (Spies et al. 2017). Science synthesis efforts represent a noteworthy approach to developing BASI for use in forest assessments, creating a role for public engagement, and for employing a bioregional approach to assembling the latest science for use by multiple forests.

Methods

We used an exploratory case study approach to examine four national forest planning units that were revising their forest plans under the 2012 rule. Information on the USFS website helped us determine the planning status of each national forest as of spring 2015. The primary selection criterion was completion of the assessment process by spring 2015. We also strove to select national forests from different regions. Based on these criteria, we selected the Chugach National Forest (Alaska), Cibola National Forest (New Mexico), Inyo National Forest (California), and the Nantahala and Pisgah National Forests (North Carolina). Table 1 displays characteristics of each national forest planning unit in our sample.

Our research approach relied on content analysis of documents and interview data. We began by conducting a chapter-by-chapter analysis of each forest's assessment report to identify and characterize the information presented. We recorded page counts for each of the 15 assessment topics specified in the 2012 rule. In some cases, the chapters directly aligned with the required topics (Figure 1). In other cases, we had to make a more subjective characterization of the chapter contents. We also noted and analyzed any references to the use of best available science.

Second, as part of the document review, we analyzed data sources used in the assessment. For each assessment report, we identified all of the items cited in the reference section. We then coded each cited item according to the type of publishing entity and the type of document. Every cited item was placed in one category for each coding exercise. For each cited item, we determined the appropriate categories by examining the information in the citation entry and (when necessary) directly reviewing the item or gathering information on the publishing entity. We grouped publishing entities into five types: government; non-government; scientific, scholarly, or peer-reviewed; universities; and unknown or other (Table 2). This categorization approximates the rigor of scientific review, but there is overlap in categories. Most scholarly journals require a double-blind peer-review process, where reviewers and authors are

Table 1. Characteristics of national forests in the study.

Management unit(s)	Geography	Total acreage* (millions of acres)	Notes on use and resources	Designated early adopter?	Most recent previous plan revision	Notes on current plan revision
Chugach National Forest Alaska Region (R10)	Southcentral Alaska: major geographic areas are Cooper River, Prince William Sound, and eastern Kenai Peninsula	6.26	Subsistence, timber, recreation, mining. Human use concentrated in Kenai area. Very limited road coverage and use in other areas. Habitat for all 5 Pacific salmon species	Yes	2002	Managed by a planning team housed within unit
Cibola National Forest Southwest Region (R3)	West-Central New Mexico: Eight noncontiguous parcels organized around distinct mountainous areas known as "sky islands"	2.11	Recreation, timber, cultural heritage, range. Surrounding region experiencing population growth and demographic changes. Pinyon-juniper & ponderosa pine are predominate vegetation types	Yes	1985	Managed by a planning team housed within unit. Does not include 4 associated national grasslands
Inyo National Forest Pacific Southwest Region (R5)	Eastern California & West Nevada: Two noncontiguous parcels at intersection of Sierra Nevada, Great Basin, and Mojave Desert areas	2.07	Water supply, hydroelectricity, recreation, timber, range. Nearly 47% of total area is wilderness. Focus on wildland fire management. Substantial variation in vegetation type, habitat, and elevation	Yes	1988	One of three early adopters in R5. Coordination through a regional planning team, with separate planning teams for each unit. Each unit releases its own assessment & forest plan. Joint EIS for 3 units
Nantahala & Pisgah National Forests Southern Region (R8)	Western North Carolina: Blue Ridge region of Appalachian Mountains	2.48	Timber, recreation, cultural/historical heritage, water development. Located in Blue Ridge National Heritage Area. Hardwood forest with high species diversity	No	1987	Both units will use same revised plan. Managed by planning team housed at NF in NC headquarters

*Total acreage includes NFS-owned land and acreage under other ownership within each unit. Source: USDA Forest Service 2015b.

Table 2. Categories for coding type of publishing entity.

Publishing entity	Description of coding criteria
Government	Federal, tribal, state, or local governments in the United States; foreign governments; international intergovernmental groups such as the United Nations and affiliates. Includes peer-reviewed and non-peer-reviewed materials
Non-government	Materials not published by a government agency, university, or peer-reviewed entity. Includes businesses, consulting firms, and advocacy groups
Scientific scholarly or peer reviewed	Associations, societies, journal publishers, university presses, or other entities that produce peer-reviewed scientific or scholarly material
Universities	Materials from universities that may or may not be subject to rigorous academic peer review. Includes university or college departments, programs, laboratories, and centers, and theses and dissertations from universities
Unknown or other	News organizations or other undefined groups; disposition of publisher could not be determined

unknown to each other. University and government agency scientific documents often require peer review, but the level of rigor of the review may be variable. It was not possible to discern the level or type of peer review or scientific rigor for each category.

For the type of document, we sorted the references into 12 categories: academic book; non-academic book; conference proceeding; correspondence; database; scientific journal; news; technical report; statute or regulation; thesis or dissertation; website; and unknown (Table 3).

Our final data collection activity was qualitative interviewing with members of the planning teams at three of the forests in our study. We conducted nine semi-structured interviews (nine people in total; three interviews each from three forests). Unfortunately, we were not able to recruit interview participants from the Cibola planning effort. Potential interview participants were identified through the list of preparers included in each assessment document. Interviewees were subject matter experts who had contributed material to the assessment reports, along with planning staff officers or coordinators. Interview questions explored the overall structure of the assessment process, the role of the planning directives, the overall organization of the forests' plan revision efforts, and approaches to identification and use of best available science. Interviews were audio-recorded, transcribed, and analyzed using content analysis with a coding framework developed by the study team. Content analysis is a method that uses codes, or labels that assign meaning to descriptive or inferential data collected during a study (Miles et al. 2014). The codes are used to retrieve and organize similar data and aid the researcher in relating data to research questions, theoretical concepts, and themes (Araujo 1995; Miles et al. 2014).

Results

We present results of our analysis in three sections: 1) required topics; 2) sources and types of information; and 3) identifying and using BASI.

Required topics in the forest assessment

The number and percent of pages devoted to each required topic is presented in Table 4. We did not include introductory front matter in the page counts. A 0* entry means that the assessment report did not

Table 3. Categories for coding type of document.

Document type	Description of coding criteria
Academic book	An item printed, bound, distributed as a book, or released as an e-book by a peer-reviewed/scholarly entity
Non-academic book	An item printed, bound, distributed as a book, or released as an e-book by an entity whose primary orientation is not peer reviewed/scholarly
Conference proceeding	Papers, abstracts, and talks presented at a conference and published in a conference proceeding collection
Correspondence	Letters or emails written by individuals of any affiliation
Database	Raw data or data analysis tools/software; online databases
Scientific journal	A peer-reviewed article in a scholarly journal
News	Articles in newspapers (print or online) and news magazines
Technical report	Technical and research reports, white papers, policy papers, fact sheets, briefings
Statute, regulation, and planning documents	Federal, state, or local laws and rules; EISs; management plans; strategic plans
Thesis or dissertation	Advanced degree projects and papers
Website	One or more webpages on a non-database website, including encyclopedias with narrative entries
Unknown	The type of document could not be discerned

Table 4. Page counts and percentages of total pages for 15 required assessment topics.

		Number of pages (pct. of total pages in report)				Pct.
Topic #	Assessment topics (per 36 CFR 219.6)	Chugach	Cibola	Inyo	N&P	Avg.
1	Terrestrial ecosystems, aquatic ecosystems, and watersheds	66 (22.9%)	51.5 (11.2%)	38.5 (21.0%)	29 (15.7%)	**17.7**
2	Air, soil and water resources and quality	17 (5.9%)	88 (19.2%)	9 (4.9%)	19 (10.3%)	**10.1**

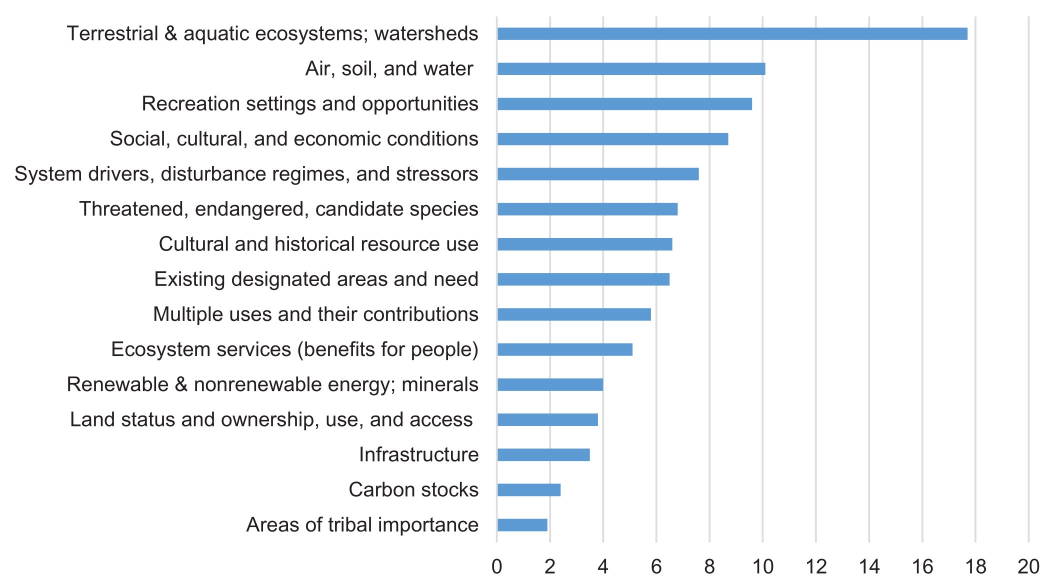

Figure 3. Average percentage of pages devoted to each topic in each forest assessment for all forests combined

have any pages that were specifically devoted to the topic, but references to the topic were instead interspersed throughout the report and it was too difficult to separate them from other topic page counts.

Two of the national forests (Inyo and Nantahala-Pisgah) published assessment reports that consisted of 15 chapters that directly reflected each of the required topics. Meanwhile, the Chugach and Cibola took a different approach; some of the chapter topics aligned with the topic requirements in the 2012 rule, but other required topics were broken up and distributed among multiple chapters. For example, the Chugach had one chapter for areas of tribal importance and one chapter for land status and ownership, but divided the terrestrial and aquatic ecosystems and watersheds

Table 5. Percent allocation of predominant topics among four forest assessments.

Rank	Chugach topics	Pct.	Cibola topics	Pct.	Inyo topics	Pct.	N&P topics	Pct.
1	Terrestrial and aquatic ecosystems	23%	Air, soil, and water	19%	Terrestrial and aquatic ecosystems	21%	Terrestrial and aquatic ecosystems	16%
2	Benefits obtained by people (ecosystem services)	17%	Social, cultural, and economic conditions	16%	Threatened and endangered species	13%	Cultural and historic resources	12%
3	System drivers, disturbance regimes, and stressors	14%	Terrestrial and aquatic ecosystems	11%	Recreation settings and opportunities	9%	Recreation settings and opportunities	11%
4	Recreation settings and opportunities	10%	Cultural and historic resources	9%	System drivers, disturbance regimes, and stressors	8%	Air, soil and water	10%
5	Social, cultural, and economic conditions	7%	Recreation settings and opportunities	9%	Multiple uses	8%	Multiple uses	9%
Total		71%		63%		59%		59%

into five chapters, one each for watersheds, fish, wetlands, vegetation, and wildlife, and these chapters were integrated with material discussing soils and carbon stocks. Two forests did not have any pages specifically devoted to one required topic each (benefits obtained by people for the Cibola, and multiple uses for the Chugach), but these subjects were still referenced in the context of the other topics.

For all four assessments combined, the required topic with the largest average percentage of pages was terrestrial and aquatic ecosystems and watersheds (17.7%), followed by air, soil, and water resources (10.1%) and recreation opportunities (9.6%) (Figure 3).

Terrestrial and aquatic ecosystems and watersheds comprised the largest section of the assessment for three of the four forests. Air, soil, and water was especially prominent for the Cibola National Forest, and all of the forest assessments covered recreation evenly. In contrast, the three required topics with the smallest page counts, on average, were areas of tribal importance (1.9%), carbon stocks (2.4%), and infrastructure (3.4%). Benefits obtained by people (ecosystem services) had the most variable coverage, with one of the shortest sections for three of the four forest assessments, but the second longest topic for the Chugach National Forest. In all four assessment documents, benefits obtained by people were mentioned throughout the document in sentences or paragraphs at too fine a scale for this analysis to count.

We found some variation among the forest assessments in terms of the extent to which a forest focused on a particular topic (Table 5).

For the Chugach National Forest, the top five topics comprised more than 70% of the assessment, with the bulk emphasizing terrestrial and aquatic ecosystems, which reflects the importance of salmon habitat. The Chugach was the only forest to emphasize ecosystem services as a predominant framework to capture benefits obtained by people. However, other forests may have captured this topic under the category of multiple uses. Disturbance regimes (fire and invasive species) were also important for the Chugach. The Cibola National Forest was unique in their emphasis on air, soil, and water as well as social, cultural, and economic conditions and cultural and historic sites. Because water access is very important in the southwest, the predominance of this topic is not surprising. For the Inyo National Forest, the topic of threatened and endangered species was prominent, while topics related to recreation and disturbance regimes (fire, invasive species, and other ecosystem stressors) were also important. Meanwhile, cultural and historical resources were prominent in the Nantahala and Pisgah National Forests, along with recreation.

Although the 2012 rule provides a list of 15 distinct required topics, these topics overlap and are not discussed in complete isolation from one another. As we found in our analysis, it is difficult to discuss multiple uses without also discussing benefits obtained by people; air, soil, and water resources; recreation; and terrestrial and aquatic ecosystems and watersheds. In our analysis, we often found that an assessment chapter devoted to a required topic also contained information that closely resembled material discussed elsewhere. In particular, we found the chapters on multiple uses and benefits obtained by people to be largely redundant, given the other topics that were also included in the report.

Sources and types of information in the forest assessment

To understand the sources and types of information used in the assessments, we conducted a systematic examination and tally of citations by publication source and type. Overall, government sources were the most commonly cited information source (51.8%), followed by scientific scholarly publications (30.7%) (Table 6).

Table 6. Citations based on information source for forest assessments.

	Count (Percent)				
Publishing entity	Chugach	Cibola	Inyo	Nantahala & Pisgah	TOTAL (Mean)

A large portion of the government sources included US Forest Service publications (average of 28%), which were more commonly cited than other federal government sources (average of 12%) or state and local governments (average of 11%). Some variation exists among the forests in our sample, but the trends were consistent in terms of reliance on government sources and scholarly peer-reviewed publishers for the majority of citations (82.5% combined average for both categories). The Chugach relied to a greater degree on scholarly publications than other forests. The Cibola had the highest proportion from non-governmental organizations and trade groups (12.2%). The Inyo and the Nantahala and Pisgah mirrored the group average.

Next, we explored citations by the type of document referenced. We found that technical reports were the most common type of document cited in the assessments, with an average of 38.5% (Table 7).

The technical report classification is broad and includes technical and scientific reports, policy briefings, white papers, and other types of information (sometimes referred to as gray literature). All four forests were consistent in the ratio of technical reports cited. The second most common document type was the scientific journal article, with an average of 23%, although the Cibola assessment featured far fewer than the other forests. All of the forests cited a wide variety of regulations, statutes, and planning documents, (e.g., water quality regulations, county comprehensive plans, environmental impact statements, state resource management plans, and forest plans). The Cibola assessment featured the greatest variety of document types, relying on websites and academic books more than the other forests. The Nantahala and Pisgah assessment relied more heavily on conference proceedings. The least commonly cited document types, on average, were news articles (0.4%), theses or dissertations (0.9%), and correspondence (1.5%). Although there is a separate category for websites, documents in many of the other categories were readily available online.

Table 8. Approaches to identifying and using BASI from interview data.

BASI approach	Chugach	Nantahala/ Pisgah	Inyo

Meet with scientists		x	
Post draft documents on wiki site for public review/editing			x
Other public review opportunity		x	
Gray ("non-peer-reviewed") literature, traditional knowledge			x

Identifying and using best available scientific information in the forest assessment

In interviews, respondents were asked how they identified and obtained BASI for their assessment. Table 8 displays the different approaches used by three of the four forests.

Literature reviews and searches, Forest Service reports and datasets, and personal scientific expertise were mentioned by all nine respondents as primary ways that they identified and obtained BASI. Literature reviews focused on identifying peer-reviewed journals, conference proceedings, or agency reports. Existing datasets and nearby Forest Service research stations and universities were also relied upon. The Sierra Nevada science synthesis effort, which informed the Inyo National Forest assessment, took nearly 18 months to complete (Long et al. 2014). The Inyo also posted draft documents on a wiki site for public review and editing. All nine interviewees stated that their assessment team used the Draft Planning Directives, but also mentioned that the directives were not clear, save for the focus on organizing around the 15 topics. No respondent mentioned specific guidance beyond the draft directives on how to identify BASI. The final directives do specifically address the definition of BASI, as discussed above (Figure 2). Gray literature and traditional knowledge presented challenges, as it at times conflicted with peer-reviewed information. Two respondents mentioned that they wanted to incorporate this type of information, but were unsure how to do so.

Assessments must document what information was determined to be BASI, explain the basis for that determination, and explain how the information was applied to the issues considered (36 CFR

219.3). Our analysis of the assessment documents reveals that all documents discuss the use of high-quality and valid scientific information, citing criteria such as clearly defined and well-developed methodology; standardized methodology; logical conclusions; and reasonable inferences (Chugach National Forest 2014; Inyo National Forest 2014; Nantahala and Pisgah National Forests 2014; Cibola National Forest and National Grasslands 2015). The assessments for all forests mention their reliance on information relevant to their specific forests and issues. Only the Nantahala-Pisgah assessment presented a hierarchy of information sources, with peer-reviewed journal articles the highest, followed by government documents and reports, monitoring datasets, theses and dissertations from universities, and expert opinion where facts were not known through the other sources.

Discussion

The 2012 forest planning rule requires that each national forest or grassland conduct a scientific assessment to guide plan development. We found that assessment reports were disproportionately heavy in science related to terrestrial and aquatic ecosystems, and more limited in treatment of infrastructure, land ownership and access patterns, cultural heritage, and areas of tribal importance. Recreation was the only topic to receive consistent attention across all four forests, although the topic was overshadowed by terrestrial and aquatic ecosystems. We may only speculate about why terrestrial and aquatic ecosystem information was the most prevalent in all four forests, but it is consistent with agency administrative hiring practices since the 1980s that have emphasized recruitment of ecologists, biologists, and other biophysical scientists, compared to social scientists, for example (Thomas and Mohai 1995). The abundance of agency specialists in these topic areas may reinforce the relative importance of terrestrial and aquatic ecosystems compared to other topic areas, such as recreation, social science, or cultural resource management. This has been confirmed by a national assessment of interdisciplinary planning team composition (Cerveny et al. 2011). Ensuring that assessment teams include broad and diverse disciplinary experts will help address this challenge, recognizing that some forests may not have access to necessary disciplinary specialists. It is also possible that some of the topics (e.g., ecosystem services, tribal and cultural resources, land status and use patterns) simply do not have as much relevant and available information as other topics.

The benefits obtained by people (ecosystem services) topic received little or no explicit coverage in all but one assessment. The limited coverage of ecosystem services may make sense because it was not even considered an area of research until the late 1990s, so there would be less existing information on certain important ecosystem service topics (e.g., pollination, stormwater attenuation, medicinal resources, and spiritual and historical significance) compared to recreation, threatened and endangered species, and other traditional assessment topics (Blahna et al. 2017). Previously, "forest benefits to people" were considered elements of "multiple use" and planners might have addressed these benefits under the "multiple use" topic. Ecosystem services (ES) are often categorized into four classes: provisioning, regulating, cultural, and supporting. Timber, recreation, wildlife, and other traditional forest planning topics all fall into one of these four classes. Another reason for lack of coverage of ecosystem services may be that planners could not differentiate the normal assessment topics from the ecosystem service classes. Efforts to help planning team members understand ecosystem services approaches and how they can be used to inform the planning process may be warranted, and the rule's current requirement for only using existing data in assessments may need to be revisited (Blahna et al. 2017). For example, implementation teams working on ecosystem services may consider the benefits of providing specific tools, frameworks, and guidelines for integrating ecosystem services models into the forest planning process. In addition, critical issues and topics (e.g., newly listed threatened or endangered species, or changing recreation behaviors) that forest plans need to address may change from one planning cycle to the next.

The specific required topics may not be universally appropriate for every planning unit. Planners felt obligated to address all 15 topics, but the lack of coverage for some topics suggests that the topic was not deemed relevant or meaningful for their plan, there was no available data on the topic, or it was unclear how the topics could be covered. Variability in application of the directives, and acknowledgment of local context and conditions, is consistent with the overall Forest Service approach toward decentralized decision-making (Kaufman 1960; Tipple and Wellman 1991; Koontz 2007) and localized interpretation by planning teams, similar to "street-level" bureaucrats who create de facto policy through everyday practice (Sabatier et al. 1995; Lipsky 2010; Trusty and Cerveny 2012). Kaufman (1960) observes the traditional Forest Service practice of maintaining control of heterogeneous and geographically dispersed management units by issuing centralized directives that provide parameters (or "side boards") within which line officers have some leeway to make decisions. This tendency toward uniformity and "pre-formed" decisions may result in some inefficiencies and omissions. The implied obligation to cover all 15 topics may have resulted in some assessments that distract from the most important management issues for the unit. This will be especially important during the next stage of planning—revision or amendment—where the assessment data will be used to analyze different management scenarios. Approaches for identifying and analyzing the most relevant assessment data that address the key environmental problems or social conflicts that confront each planning unit will be needed (Blahna et al. 2017). This is especially important for topics like human benefits (ecosystem services) and multiple uses, which cut across all of the other topical areas and are not as easily categorized in assessments. Recent efforts to engage the public in science synthesis efforts in support of forest planning suggest that there may be an important role for the public to help prioritize forest assessment topics.

The most common sources of information were government sources, followed by scholarly academic sources. Many of the agency sources were peer-reviewed scientific studies, which appear to be especially useful because of the topical specificity or geographic focus (relevance). Although not all technical reports are peer reviewed, they may be more accessible and usable compared to scholarly journal articles, which may require planning team members to interpret the findings and make inferences for relevance to local conditions. This finding is consistent with previous research examining the information needs and sources of Forest Service fire managers (Ryan and Cerveny 2011) and recreation managers (Ryan and Cerveny 2010). Fire managers relied heavily on agency information sources. Although managers in the study noted the availability of high-quality, relevant information, they faced significant barriers in terms of time, funding,

and personnel to access and use that information. Similarly, recreation managers also relied on agency information sources, but indicated strong preferences for enhanced interactions with agency scientists, including collaborative research, conferences, and a desire for agency researchers to reach out more directly to managers to ensure their research was relevant and useful. With regard to forest assessments, engagement with scientists is particularly important for topics where little research is available. Assessment teams may want to consider additional ways to interact with scientists and others to create functioning communities of practice related to science exchange for forest planning. In the same way, agency scientists may consider forging new and enduring relationships with planners and managers that could generate new science that is of immediate relevance.

The 2012 planning rule and its directives provide criteria for BASI, and we found similarities across all forests in the most common approaches to identifying BASI, in addition to other approaches, such as data sharing meetings, a wiki review site, and requests for a science synthesis. Information from non-peer-reviewed sources was more difficult for planners to assess and evaluate, and it is not clear how this information was incorporated into each assessment. Teams may not have the capacity to separately evaluate and assess the many different types and sources of information, and so they rely on hierarchical ranking approaches (peer-reviewed sources being highest rank) to streamline the evaluation. Planning teams clearly value peer-reviewed and agency-generated information, and it may be that they are simply identifying information that is "available" and using the "best" of that based on their judgments. This may result in situations where the science expertise on each team could influence BASI decisions. As discussed above, consideration of the makeup and membership of the assessment team is important here, as well as increased transparency regarding the process for determining science relevance and quality.

Conclusion

Implementation of the US Forest Service 2012 planning rule is still in its early stages. Our study illustrates that forest planners use a variety of approaches to address required topics, and do rely on BASI as they develop their forest assessments. While each national forest assessment included the 15 required topics, we found considerable variation in coverage, which suggests that planners may emphasize topics most relevant to their forest, or that variation exists in terms of what science or planning team expertise is available or deemed desirable. The predominance of science related to terrestrial and aquatic ecosystems in the assessments compared to other topics warrants further inquiry in order to learn whether this asymmetry is based on policy, availability of information, existing expertise, or other factors. Efforts to include the public in the process of prioritizing topics for the assessments could also be evaluated. The reliance on government sources for scientific information suggests that agency-supported science is either more accessible or more relevant to the planning team. It also suggests that there may be benefits to bolstering "communities of practice" for key topical areas covered by forest assessments that bring together university and agency scientists with managers.

The appearance of science in an assessment report is important, but the actual *use* of science in planning may be more important. Although our findings are not generalizable to all national forests, they do provide an understanding of plan assessment activities for those in the early phases of forest planning, whose efforts are likely to inform and influence other national forests. Our goal was to provide an early glimpse of plan revision efforts in order to highlight important lessons learned and create a foundation for future research. For example, do planners find that the required topics provide useful guidance for developing their assessments? How can planners become more confident in knowing what BASI is, and how to identify and use it? Is additional guidance needed for incorporation of traditional knowledge and other information? Of particular interest is whether the "science synthesis" information is useful to forest planners in addressing their forest assessment needs, given the significant agency resources devoted to developing science syntheses. Finally, how is information from the assessment used in forest plan revision (development and selection of management options) and monitoring efforts? While draft environmental impact assessment (EIS) reports are available in various stages, as of this writing only one final Record of Decision (ROD) has been issued for a forest plan undergoing revision under the 2012 rule. Thus, it remains to be seen how scientific information will be incorporated in development of alternatives, impact statements, and final management decisions.

Abstract

Fire regime characteristics in North America are expected to change over the next several decades as a result of anthropogenic climate change. Although some fire regime characteristics (e.g., area burned and fire season length) are relatively well-studied in the context of a changing climate, fire severity has received less attention. In this study, we used observed data from 1984 to 2012 for the western United States (US) to build a statistical model of fire severity as a function of climate. We then applied this model to several ($n = 20$) climate change projections representing mid-century (2040–2069) conditions under the RCP 8.5 scenario. Model predictions suggest widespread reduction in fire severity for large portions of the western US. However, our model implicitly incorporates climate-induced changes in vegetation type, fuel load, and fire frequency. As such, our predictions are best interpreted as a *potential* reduction in fire severity, a potential that may not be realized due human-induced disequilibrium between plant communities and climate. Consequently, to realize the reductions in fire severity predicted in this study, land managers in the western US could facilitate the transition of plant communities towards a state of equilibrium with the emerging climate through means such as active restoration treatments (e.g., mechanical thinning and prescribed fire) and passive restoration strategies like managed natural fire (under suitable weather conditions). Resisting changes in vegetation composition and fuel load via activities such as aggressive fire suppression will amplify disequilibrium conditions and will likely result in increased fire severity in future decades because fuel loads will increase as the climate warms and fire danger becomes more extreme. The results of our study provide insights to the pros and cons of resisting or facilitating change in vegetation composition and fuel load in the context of a changing climate.

Introduction

Fire regimes in North America are expected to change over the next several decades as a result of anthropogenic climate change (Dale *et al* 2001). Fire activity (i.e., annual area burned and fire frequency) is expected to increase in many regions (Krawchuk *et al* 2009, Littell *et al* 2010) and new research shows that fire seasons are now starting earlier and ending later compared to previous decades (Jolly *et al* 2015). However, the effect of climate change on one very important fire regime characteristic—*fire severity*—is not well-studied or understood (Flannigan *et al* 2009, Hessl 2011). In the context of this paper, we define severity as the degree of fire-induced change to vegetation and soils one year post-fire (Key and Benson 2006, Miller and Thode 2007). For example, a stand-replacing fire in upper-elevation conifer forest is considered high severity because the site has drastically changed one year post-fire compared to pre-fire conditions, whereas a surface fire in a grass-dominated ecosystem is considered low severity because the vegetation is nearly fully recovered one-year post fire.

The severity at which a site burns influences vegetation response and successional trajectory (Barrett *et al* 2011), faunal response (Smucker *et al* 2005), carbon emissions (Ghimire *et al* 2012), and erosion rates and sedimentation (Benavides-Solorio and MacDonald 2005). Furthermore, human safety and infrastructure are influenced by the severity at which a site burns (Miller and Ager 2013), and management responses to fire and allocation of firefighting resources are also influenced by the expected fire severity (e.g., Calkin *et al* 2011). As such, there is a need to better understand how fire severity will respond to a changing climate (e.g., Miller *et al* 2009).

At fine temporal scales, fire severity depends on factors that are highly variable over time, such as fire spread rate and direction (e.g., heading versus backing fire) and weather (Finney 2005, Birch *et al* 2015). At broader temporal scales, however, climate (in terms of climatic normals) is a major influence through its interactive effect on productivity (and hence amount of biomass) and moisture availability (i.e., wet versus dry ecosystems) (Parks *et al* 2014b, Whitman *et al* 2015). Consequently, because fire regimes are intrinsically defined by the characteristics of fires that occur over extended periods of time (years to centuries) (Morgan *et al* 2001), evaluations of fire severity over gradients of observed and predicted climatic normals allows for a formal assessment of how fire severity may respond to climate change.

We seek to quantify how fire severity in the contiguous western United States (US) (hereafter the 'western US') may respond to climate change. We use statistical relationships between observed climatic normals and fire severity (Parks *et al* 2014b, Kane *et al* 2015) to conduct a formal evaluation of future fire severity patterns. Because the relationship between climate and fire regimes is known to be weak in areas of high human impact (Parks *et al* 2014b), we used data from areas with low anthropogenic influence to build a statistical model of fire severity as a function of climatic normals over the 1984–2012 time period. We then predicted contemporary (1984–2012) and future (mid-century; 2040–2069) fire severity using climate data from numerous global climate models (GCMs) for the western US. As far as we know, this study is the first to examine how fire severity may respond to a changing climate over such a broad spatial extent. The results of this study will advance our understanding of fire regimes in the western US in the context of a changing climate and will assist policy makers and land managers to better manage for resilient landscapes.

Methods

Consistent with major fire severity mapping efforts (Key and Benson 2006, Eidenshink *et al* 2007), we define fire severity as the degree of fire-induced change to vegetation and soils. We built a statistical model of fire severity as a function of climate by first partitioning our study area (the western US; figures 1(a) and (b)) into 500 km^2 hexagonal polygons (i.e., 'hexels'). Within each hexel, we summarized fire severity using the delta normalized burn ratio (dNBR) (Key and Benson 2006), a satellite index (resolution: 30 m) that differences pre- and post-fire Landsat TM, ETM+, and OLI images and has a high correspondence to field-based measures of severity such as the composite burn index (CBI; $R^2 \geqslant 0.65$) (van Wagtendonk *et al* 2004, Parks *et al* 2014a). The CBI is a post-fire assessment in which individual rating factors in each of several vertically arranged strata (soil and rock, litter and surface fuels, low herbs and shrubs, tall shrubs, and trees) are assessed on a continuous 0–3 scale indicating the magnitude of fire effects. A rating of 0 reflects no change due to fire, whereas 3 reflects the highest degree of change. Factors assessed include soil char, surface fuel consumption, vegetation mortality, and scorching of trees. Ratings are averaged for each stratum and then across all strata to arrive at an overall CBI rating for an entire plot. The CBI indicates that, as dNBR values increase, there is generally an increase in char and scorched/blackened vegetation and a decrease in moisture content and vegetative cover (Key and Benson 2006). Measurements of fire severity (dNBR and CBI) are generally conducted one year after fire, so any regrowth that occurs within one year will result in reduced severity compared to assessments conducted immediately post-fire; this is particularly relevant for species that recover quickly after fire (e.g., resprouting shrubs, grasses).

Fire severity (i.e., dNBR) data were obtained from the Monitoring Trends in Burn Severity project (Eidenshink *et al* 2007) for all fires ⩾400 ha for the 1984–2012 time period. Raw dNBR values obtained from MTBS were adjusted using the 'dNBR offset' (Key 2006), which accounts for differences due to phenology or precipitation between the pre- and post-fire images by subtracting the average dNBR of pixels outside the burn perimeter. This adjustment can be important when comparing severity among fires (Parks *et al* 2014a). A mean dNBR was calculated using all pixels of all fires that intersected each 500 km^2 hexel; pixels classified as nonfuel were excluded in the calculation of the mean. We square-root transformed mean dNBR values to linearize the relationship to the CBI (figure S1).

We summarized climate normals within each hexel using five variables with known links to fire regimes (e.g., Littell and Gwozdz 2011, Abatzoglou and Kolden 2013, Parks *et al* 2015b): actual evapotranspiration (AET), water deficit (WD), annual

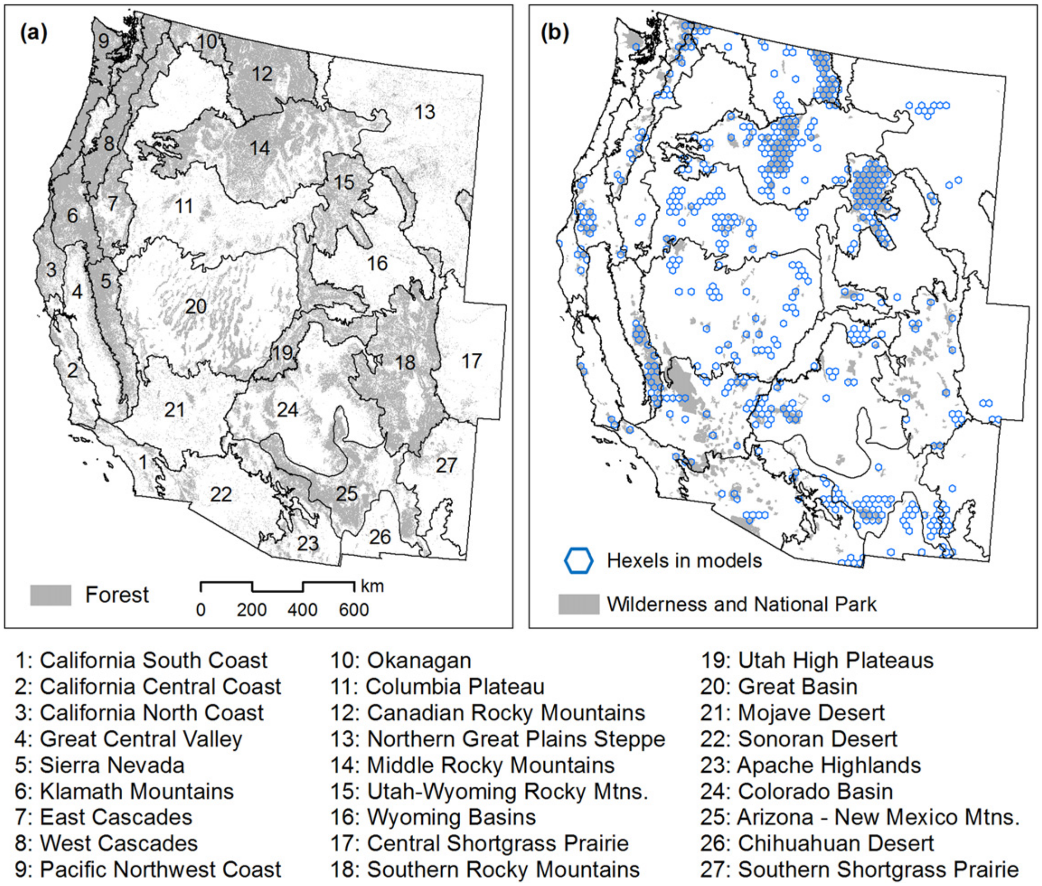

Figure 1. Study area of the western US for which we predicted changes in fire severity under a future climate. Map showing ecoregion boundaries (The Nature Conservancy 2009) and forested areas (in gray) (a) and showing designated wilderness areas and national parks (in gray) as well as the 544 hexels (in blue) used to build the models of fire severity as a function of climate (b). Ecoregion names and boundaries provided for context.

precipitation (PPT), soil moisture (SMO), and snow water equivalent (SWE). Gridded monthly temperature and PPT data were obtained from the parameter-elevation regression on independent slopes model (PRISM; Daly *et al* 2002), which uses weather station data and physiographic factors to map climate at a spatial resolution of ~800 m. In addition, daily and sub-daily surface meteorological variables (~4 km resolution) describing temperature, humidity, winds, solar radiation, and precipitation were produced following Abatzoglou (2013). These data were collectively used to compute climatic water balance following Dobrowski *et al* (2013) to estimate AET, SWE, SMO, and WD. This water balance model operates on a monthly time-step and accounts for atmospheric demand (via the Penman–Monteith equation), soil water storage, and includes the effect of temperature and radiation on snow hydrology via a snow melt model. Each variable was averaged within each hexel for the years 1984–2012, thereby matching the years of the fire severity data. We similarly summarized these five climate variables representing mid-21st century (2040–2069) conditions using 20 global climate models (GCMs) for the RCP8.5 emissions scenario (table S1). These tables were statistically downscaled to the same grid as observed data using the multivariate adapted constructed analogs approach (Abatzoglou and Brown 2012).

Because the relationship between climate and fire is weaker in landscapes that are highly influenced by humans (Parks *et al* 2014b), we built our model using data from a subset of hexels with low human influence (figure 1(b)). We selected only those hexels that were comprised of at least 50% designated wilderness or national park or had an average 'human footprint' (Leu *et al* 2008) $\leqslant$ 2.5 (on a scale of 1–10). We further limited our dataset to include only those hexels with at least 400 ha of total burned area from 1984 to 2012. These selection criteria resulted in 544 hexels that, despite representing a small proportion of our study area (8.7%), are climatically representative of much of the western US, with the notable exception of the wet regions of the Pacific Northwest (figure S2).

Using data from the subset of 544 hexels, we modeled fire severity (dNBR) as a function of contemporary climate (1984–2012) using boosted regression trees (BRT) ('gbm' package) in the R statistical environment (R Development Core Team 2007). BRT is a nonparametric machine-learning approach that does not require *a priori* model specification or test of hypothesis (De'ath 2007). The BRT algorithm fits the best possible model to the data structure, including complex interactions among variables. It does so by building a large number of regression trees, whereby, through a forward stage-wise model-fitting process, each term represents a small tree built on the weighted residuals of the previous tree. The stage-wise procedure reduces bias, whereas variance is decreased through model averaging. The BRT method also employs 'bagging', the use of a random subset of samples, which typically improves model predictions. Comparisons to other modeling techniques indicate that BRT models consistently produce robust predictive estimates (Elith *et al* 2006). We followed the recommendations of Elith *et al* (2008) for selecting BRT options; we set the bagging fraction to 0.5, learning rate to 0.005, and tree complexity to three. We used a custom script from Elith *et al* (2008) to determine the necessary number of trees, thereby reducing the potential for overfitting. We evaluated the model fit using the (a) correlation between predicted and observed fire severity and (b) ten-fold cross-validated correlation between predicted and observed fire severity.

We used the model to predict contemporary (1984–2012) fire severity (dNBR) for all hexels in the western US. However, interpreting dNBR and changes in dNBR under a changing climate is challenging because dNBR units have no direct ecological interpretation. As such, we rescaled these predictions to correspond to the ecologically relevant composite burn index (hereafter 'inferred CBI') that ranges from 0 to 3 (Key and Benson 2006): the lowest predicted severity was given an inferred CBI of 0.1, which is the threshold for 'unchanged' (Miller and Thode 2007), and the highest predicted severity was given an inferred CBI of 3.0. We were then able to infer the CBI of all remaining predictions because the square-root transformation of dNBR linearized the relationship to CBI (figure S1). Consequently, we generated a map representing the inferred CBI for the western US under contemporary climate.

We then predicted fire severity for the mid-21st century (2040–2069) as projected by each GCM using the BRT model. We inferred CBI as previously described using the linear relationship between dNBR and CBI of the observed predictions to make the inferences. Note that the predictions for all hexels in the western US were 'clamped' to avoid predicting outside of the observed range of severity values; all predictions >3 and <0.1 were given values of 3.0 and 0.1, respectively. For each BRT prediction (one for each GCM), we then quantified the predicted change in fire severity by subtracting the inferred CBI of contemporary climate from the inferred CBI of mid-21st century

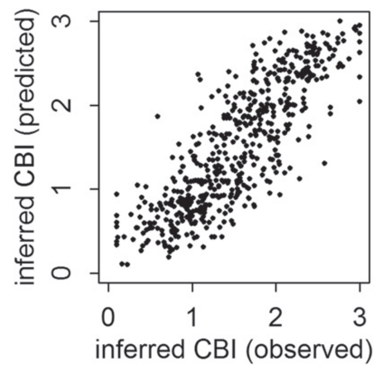

Figure 2. Plot showing predicted versus observed inferred CBI. Inferred CBI of observed data was calculated using similar methods to that of the inferred CBI of predicted data but were bounded by the 0.5 and 99.5 percentile dNBR to ensure extreme values did not overly influence this interpretation. $R^2 = 0.64$.

climate. We summarized the results by generating maps of (1) contemporary fire severity, (2) predicted mid-21st century fire severity (averaged over 20 GCMs) and, (3) the average change (for all 20 GCMs) in fire severity (i.e., inferred CBI) between contemporary and mid-century time periods.

Results

The correlation between predicted and observed dNBR among the 544 hexels was 0.80 and the cross-validated correlation was 0.72. A plot showing predicted versus observed inferred CBI also indicates a good fit ($R^2 = 0.64$; figure 2). Water deficit and PPT were the most influential variables (relative influence = 41.5% and 29.8%, respectively) (figure 3(a)). Fire severity generally decreased with WD and increased with PPT (figures 3(b) and (c)). The map of predicted contemporary (1984–2012) fire severity indicates that cooler and wetter forested ecoregions (e.g., Pacific Northwest, Northern Rocky Mountains, and Southern Rocky Mountains) experience more high severity fire (inferred CBI $\geqslant$ 2.25) compared to warmer and drier forested ecoregions (e.g., Arizona - New Mexico Mountains) (figure 4(a)). Non-forested ecoregions for the most part experience fairly low fire severity (inferred CBI < 1.25). The map of mid-21st century fire severity shows a similar pattern in that the cooler and/or wetter regions generally have higher severity than elsewhere (figure 4(b)), but for the most part, fire severity is predicted to decrease over much of the western US (figure 4(c)). The results of current, future, and predicted changes in fire severity are strikingly similar when we measured fire severity using a relativized metric (the relativized burn ratio; RBR) (Parks *et al* 2014a) instead of dNBR (figure S3).

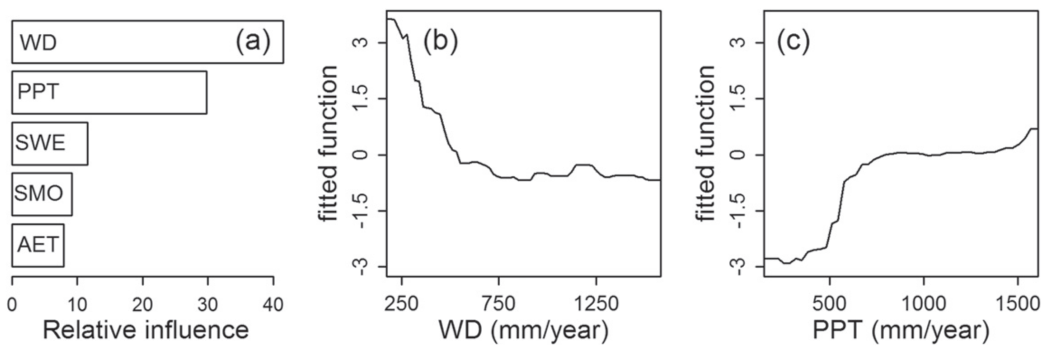

Figure 3. Variable importance in the BRT model (a) and partial dependence plots showing the relationship between dNBR and the two most influential variables (WD and PPT) (b), (c). Note that the partial dependence plots do not reflect interactions between variables and therefore simplify the relationships.

Discussion

Our models based on contemporary fire–climate relationships predict a widespread reduction in fire severity for large portions of the western US by the mid-21st century. Only a very small proportion of the western US is predicted to experience an increase in severity. Our prediction contrasts with those based on the direct influence of climate on fuel moisture and associated fire danger indices that occur at seasonal time scales (Fried *et al* 2004, Nitschke and Innes 2008). Our use of broad-scale climate as a proxy for vegetation composition and fuel load instead emphasizes the indirect influence that climate has on fire regimes (Miller and Urban 1999, Higuera *et al* 2014). Specifically, the predicted decrease in fire severity can be attributed to climatic conditions associated with higher WDs (figures 5(a) and (b)), lower productivity, and less burnable biomass (Zhao and Running 2010, Stegen *et al* 2011).

Our approach and findings are based on an implicit assumption that vegetation composition and fuel load will track changes in climate. Indeed, this is a common assumption that underlies numerous climate change studies, including those that use distribution models to project shifts in habitat ranges (Engler *et al* 2011) and fire activity (Krawchuk *et al* 2009, Moritz *et al* 2012). Specifically, our predictions of overall lower fire severity implicitly assume that vegetation composition and burnable biomass will reflect lower productivity associated with warmer and drier climates (e.g., increased WD; figure 5(b)). As such, our predictions are best interpreted as a *potential* reduction in fire severity, a potential that may not be realized where there is disequilibrium between climate and vegetation. Disequilibrium dynamics are the result of many factors and signals that directional changes in climate may not result in immediate changes in vegetation composition and fuel load (Sprugel 1991, Svenning and Sandel 2013). For example, leading-edge disequilibrium can arise when species are dispersal limited or don't reach reproductive maturity for many years (Svenning and Sandel 2013). Trailing-edge disequilibrium can arise because some species are long-lived and have deep roots, thereby facilitating survival and persistence under substantial inter-annual and decadal fluctuations in climate even though seedlings of the same species are unable to survive (Grubb 1977, Jackson *et al* 2009). To compound this, human-induced disequilibrium has also substantially affected most ecosystems in the western US (and globally) (Parks *et al* 2015b), in that natural disturbances such as fire have been excluded by factors such as livestock grazing, fire suppression, and landscape fragmentation (Marlon *et al* 2008). Both climate- and human-induced disequilibrium underlie present-day concerns about restoration of fire-adapted ecosystems after a century of fire exclusion (Stephens *et al* 2013, Hessburg *et al* 2015).

Consequently, our predictions are more likely to hold up in the presence of an active disturbance regime that catalyzes climatically driven changes in vegetation composition and fuel load (Flannigan *et al* 2000, Turner 2010). Disturbance catalysts are critical components for maintaining a dynamic equilibrium between vegetation and climate and appear to already be occurring with increasing frequency in some regions. For example, many studies have concluded that fire activity has increased in recent years (Westerling *et al* 2006, Kelly *et al* 2013) and widespread tree mortality has been attributed to drought and insect outbreaks (Allen *et al* 2010, Bentz *et al* 2010). In areas recently affected by these disturbances, the post-fire species and vegetation densities may be more tailored to the emerging climate (Overpeck *et al* 1990, Millar *et al* 2007). Although generally considered undesirable, disturbance-facilitated conversions from forest to non-forest vegetation are likely to occur in some situations (Stephens *et al* 2013, Coop *et al* in press), especially when compounded by human-induced disequilibrium.

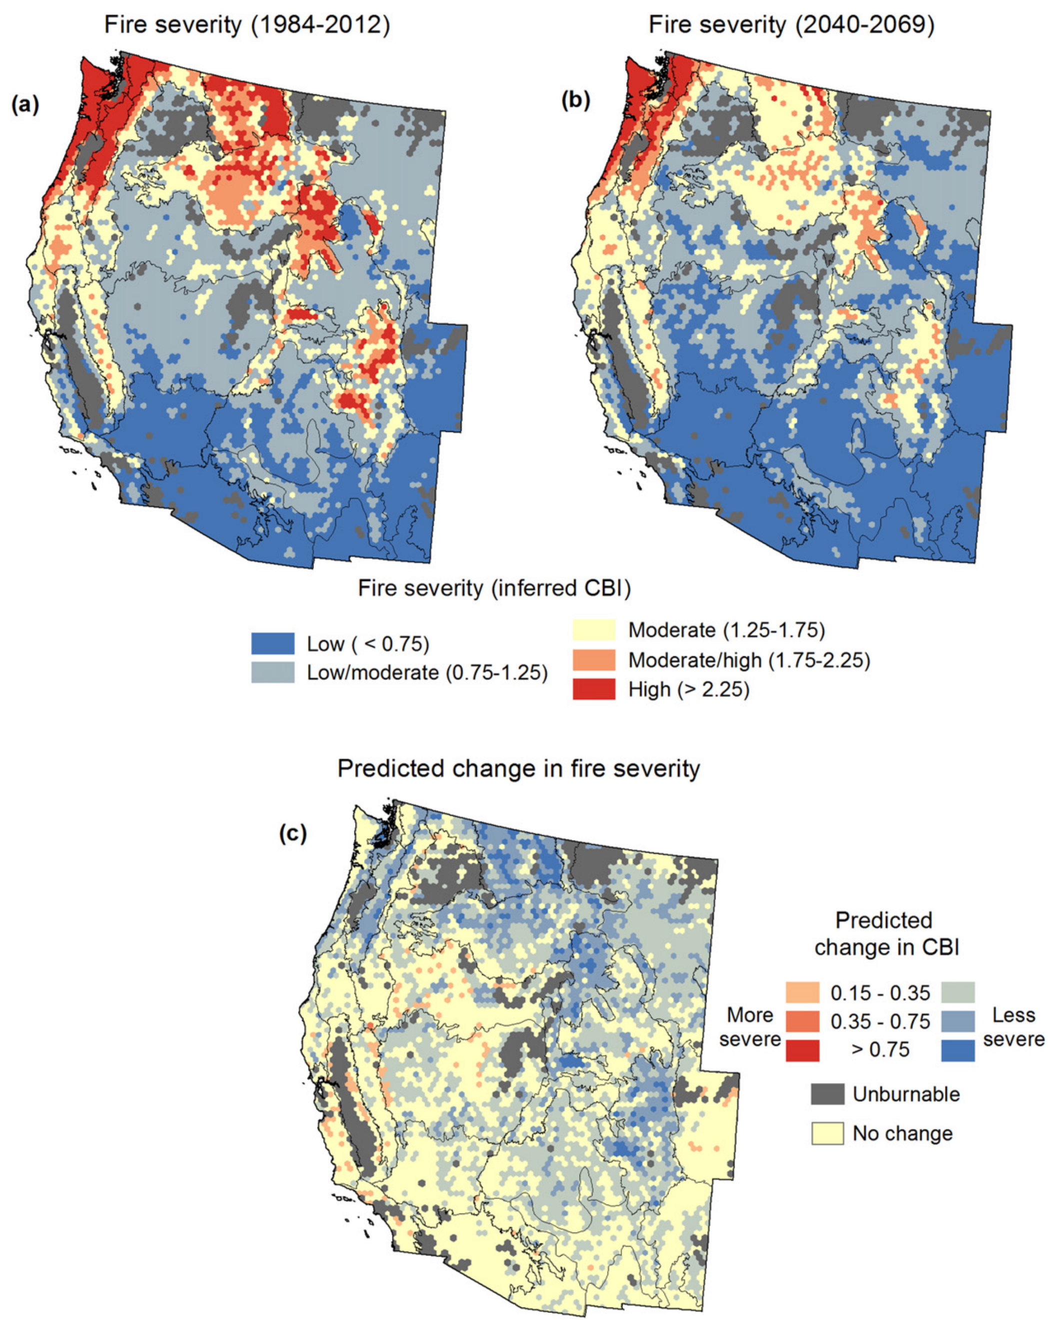

Figure 4. Predicted fire severity under observed (a) and mid-century climate (b). Mean change in fire severity among the 20 predictions (one prediction for each GCM) (c).

Most forested regions in the western US are currently experiencing a 'fire deficit' (Marlon *et al* 2012, Parks *et al* 2015b) because human activities and infrastructure (e.g., fire suppression and roads) exclude fire as an important disturbance agent. Consequently, human-induced disequilibrium between vegetation and climate, coupled with a changing climate, has important implications for future fire severity. We posit that such amplified disequilibrium will likely result in *increased* fire severity in future decades as fuel loads increase, fire seasons lengthen, and fire danger becomes more extreme (Collins 2014, Jolly *et al* 2015). This supposition is consistent with the findings of other studies that found a climate-induced increase in fire severity when assuming static vegetation (Fried *et al* 2004, Nitschke and Innes 2008). Continuing to resist catalysts of vegetation change only increases the probability of undesirable effects given that fire is inevitable (North *et al* 2009, Calkin *et al* 2015). An alternative to this unsustainable cycle is to actively facilitate transition of ecosystems to conditions that are more suited to the future climate by means of managed wildland fire or other restoration treatments (Millar *et al* 2007).

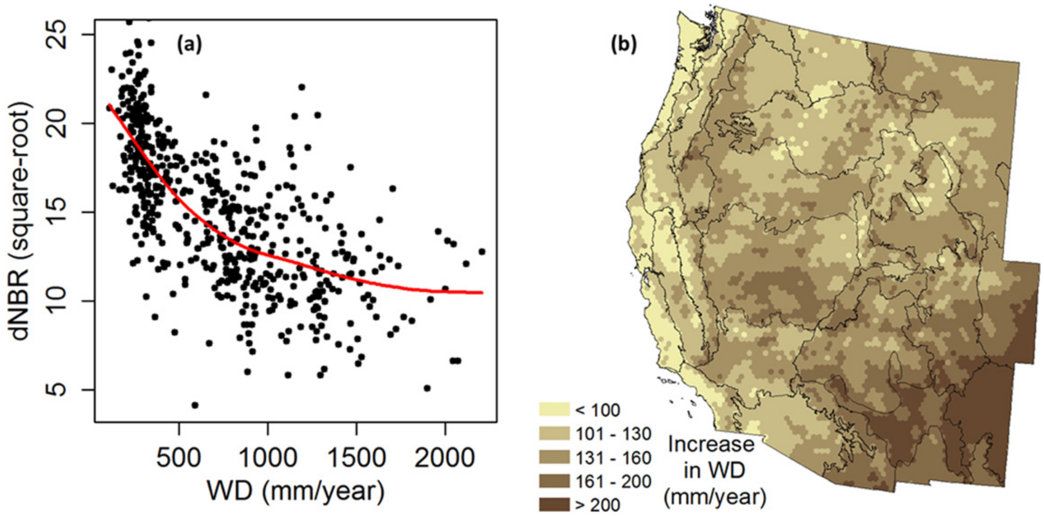

Figure 5. Plot of observed fire severity as a function of observed (1984–2012) water deficit (WD; the most influential variable in the BRT model) for the 544 hexels used to build the model (a). The red line shows the model fit according to a generalized additive model. Map of predicted increase in WD from contemporary to mid-century (2040–2069) climatic conditions (b); values depict the multi-model average change between time periods. According to this simple relationship, increased WD due to climate change will result in decreased fire severity. Note that the relationship flattens out which suggests a weaker response in dry ecosystems.

Our study complements and expands our understanding of controls on fire regimes and how they may respond to a changing climate in the western US. Specifically, predicted increases in fire activity (Littell *et al* 2010, Moritz *et al* 2012) imply that less biomass will be able to accumulate between successive fires, resulting in less biomass available for combustion and a reduction in fire severity. Furthermore, predicted increases in WD (figure 5(b)) are expected to increase water stress and decrease productivity in the generally water-limited western US (Chen *et al* 2010, Williams *et al* 2013), ultimately reducing the amount of biomass available to burn and resultant fire severity. It should be noted, however, that temperature-limited ecosystems (i.e., alpine environments) will likely experience an increase in productivity (and fire severity) under a warmer climate (Grimm *et al* 2013, Goulden and Bales 2014).

Our study relied on observed and predicted climatic normals (i.e., multi-decadal averages) to predict potential changes in fire severity. This is in contrast to other climate change fire studies that used annually or seasonally resolved climate (observed and GCM projections) and fire data to make predictions of potential changes in *fire activity* (i.e., fire frequency or area burned) (Littell *et al* 2010, Stavros *et al* 2014). The latter approach is often used because of the noted importance of climatic extremes on fire regimes (e.g., Westerling *et al* 2006). Although we could have built our model of fire severity using annually resolved data, we posit, for the purpose of predicting future fire severity, using long term averages (e.g., 1984–2012) is more appropriate for at least three reasons. First, although several studies have shown that fire severity responds to annual, seasonal, or daily variability in climate or weather, the relative influence of this variability can be fairly weak (Dillon *et al* 2011, Birch *et al* 2015). This is in contrast to broad temporal scales where the relationship between fire severity and climate has been found to be much stronger (Parks *et al* 2014b, Kane *et al* 2015). Second, because models built at a fine temporal resolution are more focused on the direct influence of climatic variability on fire weather and fuel moisture, they generally fail to incorporate climate- or fire-induced changes in vegetation composition or fuel load (Allen *et al* 2010, Parks *et al* 2015a). We suggest that predictions based on climatic normals implicitly incorporate such changes (Kelly and Goulden 2008, Marlon *et al* 2009). Lastly, GCMs may not adequately simulate annual climatic variability and thus are better suited for predicting long term trends (Stoner *et al* 2009).

Our model used broad scale data and the predictions of widespread reduced fire severity under future climate should be interpreted accordingly. For example, fire severity and climate vary at scales finer than the spatial resolution of the hexel used in this study (Schoennagel *et al* 2004). As such, our analysis does not likely capture finer-scale changes in fire severity that could occur. For example, in alpine environments where localized upward shifts in treeline under a warmer climate are expected to contribute to increases in biomass (Higuera *et al* 2014), fire severity might be expected to increase. Although our model of fire severity (dNBR) as a function of climate performed reasonably well (see section Results), we acknowledge that further error may be introduced due to error in the relationship between CBI and dNBR. However, we posit that the improved ecological interpretation attained by converting dNBR to CBI outweighs any increased error in our predictions.

Our measure of fire severity relied on dNBR (a unitless ratio) and CBI (a composite rating) and, consequently, there is no definable unit of measurement (e.g., grams of carbon consumed m^{-2}). Instead we infer changes in CBI, which integrates several strata (e.g., soil and shrubs) and scales severity from 0 to 3. This is admittedly a somewhat vague framework for assessing potential changes in fire severity, but takes advantage of the widespread availability of satellite-inferred metrics of fire severity and their documented correlation to the CBI. We suggest future research efforts involving fire severity and climate change aim to use more definitive and quantitative units of measurement. On a similar note, fire severity has ecological significance beyond what can be inferred from dNBR and is the result of many complex physical, biological, and ecological factors (Morgan *et al* 2014). For example, in ecosystems that are ill-adapted to fire (e.g., the Mojave Desert), dNBR values may be irrelevant, as any and all fires might be considered 'severe' (Brooks and Matchett 2006). Accordingly, although we used dNBR and CBI as a convenient and standardized way to assess fire severity, predictions for some ecoregions should be carefully interpreted.

Our model does not consider plant physiological responses to a CO_2 enriched atmosphere (e.g., improved water use efficiency and plant productivity) that could lead to increases in fire severity (Drake *et al* 1997, Keenan *et al* 2013). Given that today's atmospheric CO_2 concentration is the highest it's been for at least 650 000 years (Siegenthaler *et al* 2005), this could be a particularly important consideration for extreme water limited ecosystems such as grasslands, where woody plant encroachment could cause changes in biomass amount and structure (Morgan *et al* 2007, Norby and Zak 2011). Consequently, other research approaches using tools such as dynamic global vegetation models may predict different outcomes (Thonicke *et al* 2001).

Although we relied on data from protected areas and other areas of low human influence and thus underrepresented certain climatic environments (see Batllori *et al* 2014), these data represent a surprisingly broad range of ecosystem types in the western US ranging from warm desert (Death Valley National Park (NP) to dry conifer forest (Gila Wilderness) to cold forest (Yellowstone NP) (figure S2). As such, we suggest that under-represented climates have only a marginal effect on our results (see figure S2). Indeed, our analysis (figure S2) indicates that the data we used to build the model adequately represents the climates of most of the western US with the most notable exception being those in the Pacific Northwest where fires were historically and are currently infrequent (Agee 1993).

Conclusions

Our study predicts an overall decrease in fire severity for much of the western US by mid-century (2040–2069) due to changing climatic conditions. These predictions are best interpreted as *potential* decreases in severity that may not be realized unless vegetation composition and fuel load change in parallel with climate. Disequilibrium between plant communities and climate will only escalate, particularly in forested areas, unless natural disturbances and management activities (i.e., prescribed fire and restoration treatments) act as catalysts of vegetation change and push plant communities towards a state of equilibrium with climate. A high degree of disequilibrium between plant communities and climate is generally considered undesirable because the result may be an uncharacteristically severe wildland fire that causes abrupt ecosystem state shifts from, for example, forest to non-forest vegetation (e.g., Coop *et al* 2016).

Our findings support a passive management approach to ecosystem restoration (Arno *et al* 2000), whereby natural disturbance regimes are used to facilitate the transition of plant communities towards a state of equilibrium with the emerging climate. Active restoration treatments may also aid in facilitating these changes in certain situations (Millar *et al* 2007, Stephens *et al* 2010), but the current pace and scale of such treatments is insufficient to make a meaningful impact across the vast forested regions of the western US (North *et al* 2012). In addition, legal (e.g., designated wilderness) and logistical constraints (e.g., steep slopes) make certain activities (mechanical thinning) infeasible across a large proportion of land in the western US (North *et al* 2014). Achieving landscape resilience in a changing climate will likely require increased use of managed wildland fire, especially when weather conditions are not extreme (North *et al* 2015), and in fact, resisting change via activities such as aggressive fire suppression may be counter-productive in the long-run (Calkin *et al* 2015). As such, the results of this study provide insights to policy makers and land managers in the western US as to the pros and cons of resisting or facilitating change in vegetation composition and fuel load in the context of a changing climate.

California Spotted Owl, Songbird, and Small Mammal Responses to Landscape Fuel Treatments

SCOTT L. STEPHENS, SETH W. BIGELOW, RYAN D. BURNETT, BRANDON M. COLLINS, CLAIRE V. GALLAGHER, JOHN KEANE, DOUGLAS A. KELT, MALCOLM P. NORTH, LANCE JAY ROBERTS, PETER A. STINE, AND DIRK H. VAN VUREN

A principal challenge of federal forest management has been maintaining and improving habitat for sensitive species in forests adapted to frequent, low- to moderate-intensity fire regimes that have become increasingly vulnerable to uncharacteristically severe wildfires. To enhance forest resilience, a coordinated landscape fuel network was installed in the northern Sierra Nevada, which reduced the potential for hazardous fire, despite constraints for wildlife protection that limited the extent and intensity of treatments. Small mammal and songbird communities were largely unaffected by this landscape strategy, but the number of California spotted owl territories declined. The effects on owls could have been mitigated by increasing the spatial heterogeneity of fuel treatments and by using more prescribed fire or managed wildfire to better mimic historic vegetation patterns and processes. More landscape-scale experimentation with strategies that conserve key wildlife species while also improving forest resiliency is needed, especially in response to continued warming climates.

Keywords: adaptive management, mixed conifer, restoration, Sierra Nevada, wildlife conservation

The role of wildfire in many of the world's forests that are adapted to frequent, low- to moderate-intensity fire regimes has been altered through fire exclusion, timber harvesting, livestock grazing, and urbanization (Agee and Skinner 2005, Collins et al. 2010). In the western United States, these land-use practices have affected forest structure and species composition, increasing surface fuel loads, tree density, the dominance of shade-tolerant tree species, and forest homogeneity (Hessberg et al. 2005, North et al. 2009, Chiono et al. 2012). As a consequence, many forests in the western United States are experiencing higher-severity burns—in some cases, producing large patches of tree mortality that can severely hinder the reestablishment of conifer forests (Roccaforte et al. 2012, Collins and Roller 2013). Consequently, one of the primary focuses of contemporary forest management is the treatment of fuels and vegetation to reduce fire hazards, especially as climate continues to warm (Stephens et al. 2013).

There is increased recognition that forests adapted to low- to moderate-intensity fire regimes experienced some high-severity fire (Perry et al. 2011, Marlon et al. 2012). Patchy, high-severity fire provides opportunities for early-seral habitat development and the production of large pieces of deadwood resources that are important to many wildlife species (Fontaine and Kennedy 2012). As such, forest fuel treatments should not be used to eliminate all high-severity fire. Rather, treatments should allow for patterns of fire effects that approximate those occurring under more natural forest conditions. What little information we have on fire patterns under these conditions suggests that high-severity fire constitutes fairly low proportions of the overall burned area (5%–15%) in these forest types, which is generally aggregated in relatively small patches (smaller than 4 hectares [ha]), as is the case in the upper mixed-conifer forests in Yosemite National Park (Collins and Stephens 2010, Mallek et al. 2013).

Forest management involving habitat used by wildlife species at risk has been one of the principal challenges to US federal land managers for the last 25 years. In the Sierra Nevada, an ongoing debate is focused on several species that use old-growth forest, including the California spotted owl (CSO; *Strix occidentalis occidentalis*) and the Pacific fisher (*Martes pennanti pacifica*). Forest managers need information on appropriate levels of forest manipulations to create the desired balance between habitat conservation for wildlife populations and modifications of forests to improve their resilience to large high-severity fires that could prove more expensive and detrimental than the short-term effects of restoration treatments.

Fuel-reduction treatments reduce the potential impacts of wildfire by reducing the only aspect of the fire behavior

BioScience 64: 893–906.
doi:10.1093/biosci/biu137
Advance Access publication 3 September 2014

Figure 1. Fuel treatments implemented in the Meadow Valley project area. (a) Pretreatment mixed-conifer forest. (b) Whole-tree harvester cutting small trees (thinning from below). (c) Small trees, tree tops, and limbs being chipped and shipped by truck to a bioenergy plant to produce electricity. triangle (i.e., topography, weather, fuel) that can be modified by managers: the quantity and continuity of fuel. A number of techniques are employed to reduce fire hazards, and each technique has associated effects on forest structure (Agee and Skinner 2005). Mechanical treatments can reduce stand density, basal area, and ladder and canopy fuel. To reduce accumulated surface fuel and to offset the detritus added from harvest operations, prescribed fire is sometimes used following forest thinning to reduce fire hazards, but whole-tree harvesting (i.e., complete tree removal, with the materials chipped and trucked to a processing facility; figure 1) can also effectively keep much of the harvest detritus from being added to the forest floor. Broadcast burning alone is very effective in elevating canopy base height and in reducing surface fuel (Agee and Skinner 2005).

Recent research confirms the ability of fuel treatments to alter potential fire behavior (Fulé et al. 2012) and actual wildfire effects (Safford et al. 2012). Research has also determined that fuel-reduction treatments achieve their objectives with generally positive or neutral ecological effects (Stephens et al. 2012); however, almost all research on the effects of fuel treatments has been performed at the stand scale (10–25 ha). Given the large home ranges of many key wildlife species commonly at the crux of forest management issues in the western United States (e.g., the CSO, the northern spotted owl [*Strix occidentalis caurina*], the Pacific fisher), it is important to understand fuel-treatment impacts at larger spatial scales. This is particularly relevant because many fuel-treatment projects are being proposed—and, in a few instances, implemented—at landscape scales (15,000–40,000 ha; Ager et al. 2007, Collins et al. 2010).

Fuel treatments directly alter wildlife habitat by removing both aerial (trees) and ground (coarse wood, shrubs) cover. These altered conditions can affect both habitat suitability, which influences the number of individuals that an area can support, and habitat quality, which directly affects the fitness

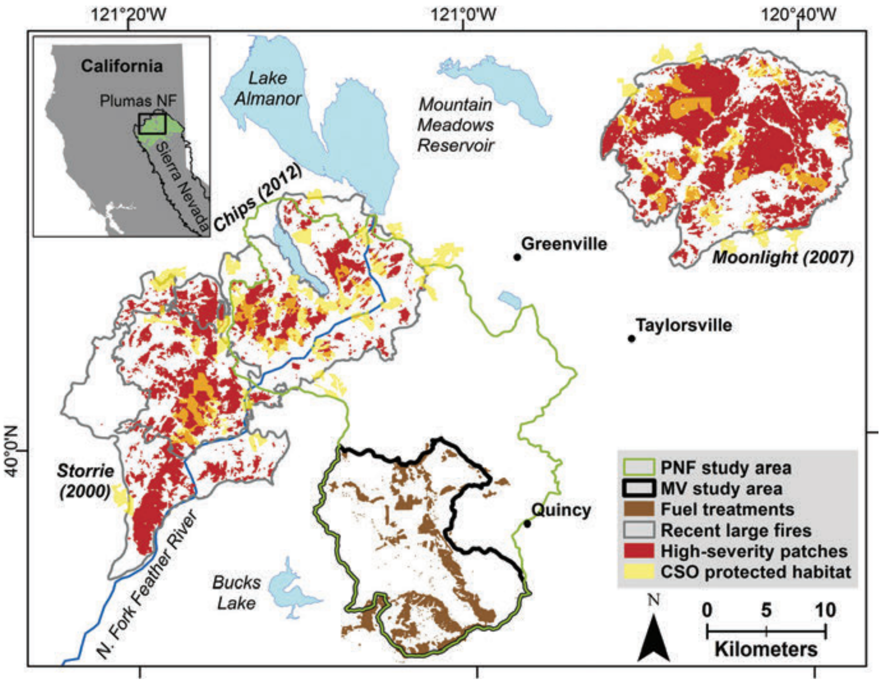

Figure 2. Meadow Valley study area with completed landscape fuel-treatment network. Recent large wildfires and the resulting patches of high-severity fire effects are also indicated. Three wildfires are shown: Storrie (2000), Moonlight (2007), and Chips (2012). These were selected on the basis of the following criteria: proximity to the study area (closer than 25 kilometers), vegetation type (conifer dominated), size (larger than 10,000 hectares), and age (since 2000). Abbreviations: CSO, California spotted owl; MV, Meadow Valley; N, north; NF, national forest; PNF, Plumas National Forest; W, west.

and productivity of individuals. Because more-suitable habitat for certain at-risk wildlife species is associated with greater aerial and ground cover, the effects of fuel treatments are generally perceived as negative. However, large patches of wildfire-caused tree mortality can also negatively affect both habitat suitability and quality (Tempel et al. in press). To the extent that fuel treatments reduce the potential for large patches of tree mortality in wildfire, there may also be an indirect benefit of fuel treatments to certain species' habitat. Finding a balance between these influences is a crucial management need.

Over the past decade, we have studied the ecological effects of one of the few completed landscape-level fuel-treatment networks in western US forests. Here, we distill the results of these efforts. We quantify change in vegetation structure and modeled fire behavior as a result of fuels treatments and assess treatment effects on the CSO, songbirds, and small mammals. Modeling studies have been published in which the trade-offs in these systems have been conceptually examined (Lee DC and Irwin 2005), but this is one of the first studies in which these questions have been empirically examined at landscape scales.

Study area and design

Our study area is located in the Meadow Valley area of the Plumas National Forest, situated in the northern Sierra Nevada, at 39 degrees (°) 56 minutes (′) north, 121°3′ west (figure 2). The climate is Mediterranean, with warm, dry summers and cool, wet winters, which is when most precipitation (1050 millimeters per year; Ansley and Battles 1998) occurs. The core study area is 19,236 ha, with elevations ranging from 850–2100 meters (m). The vegetation is primarily mixed-conifer forest, consisting of white fir (*Abies concolor*), Douglas-fir (*Pseudotsuga menziesii*), sugar pine (*Pinus lambertiana*), ponderosa pine (*Pinus ponderosa*), Jeffrey pine (*Pinus jeffreyi*), incense-cedar (*Calocedrus decurrens*), California black oak (*Quercus kelloggii*), and other less common hardwood species. White fir is the most abundant tree, although large (e.g., larger than 1 m in diameter) stumps of pines encountered frequently in the forest attest to a change in composition and structure in recent history. Red fir (*Abies magnifica*) is common at higher elevations, where it mixes with white fir. In addition, a number of species are found occasionally in or on the edge of the mixed-conifer forest, including western white pine (*Pinus monticola*) at higher elevations, lodgepole pine (*Pinus contorta* var. *murrayana*) in cold air pockets, and western juniper (*Juniperus occidentalis*) on xeric sites. California hazelnut (*Corylus cornuta*), dogwood (*Cornus* spp.), and willow (*Salix* spp.) are found in moister riparian areas. Montane chaparral and some meadows are interspersed in the landscape. Tree density varies as a result of recent fire- and timber-management history, elevation, slope, aspect, and edaphic conditions. Historical fire occurrence, which can be inferred from fire scars recorded in tree rings, suggests that the fire regime was predominantly frequent, low- to moderate-severity fires, at intervals ranging from 7–19 years, with the last widespread fires occurring 85–125 years ago (Moody et al. 2006).

Fire activity in the last 15–20 years has been notably higher in the northern Sierra Nevada than in the rest of the range (Collins 2014). Since 2000, there have been three megafires (covering more than 10,000 ha; Stephens et al. 2014) within 25 kilometers (km) of our study area, burning a total of 73,000 ha (figure 2). These fires burned predominantly in mixed-conifer forests, encompassing approximately 60 CSO protected activity centers (figure 2). Cumulatively, 34% of the area burned in these three fires suffered high-severity fire (more than 95% dominant tree mortality; figure 3a; Miller et al. 2009). More important than the total proportion of area severely burned is the distribution of high-severity patches over the burned area, because this can limit tree seed

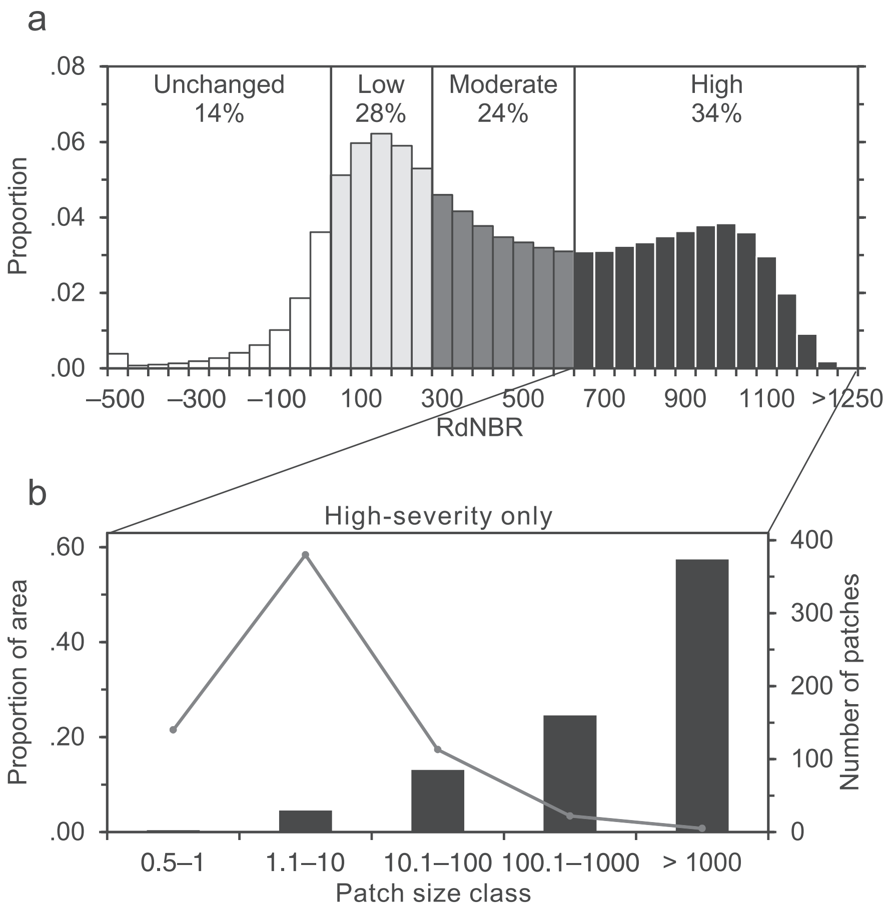

Figure 3. (a) Fire severity distribution for the three recent large fires in the Meadow Valley study area (see figure 2). The fire-severity estimates are based on the relative differenced normalized burn ratio (RdNBR; Miller and Thode 2007). (b) The proportion of total high-severity area (bars) and the number of patches (line) as a function of patch size class.

dispersal from wind and animals (Perry et al. 2011, Collins and Roller 2013). Large patches (defined here as larger than 1000 ha) accounted for a disproportionate amount of the total high-severity-fire area in the recent wildfires near the study area (figure 3b).

The projects that contributed to the fuel-treatment network are part of the larger Herger-Feinstein Quincy Library Group Pilot Project (USHR 1998). This project was directed by the US Congress to involve local communities in forest management. The project objectives included improving forest health, reducing uncharacteristic high-severity fire, conserving wildlife habitats, and stabilizing economic conditions in local communities. The projects in Meadow Valley encompassed a range of treatment types and intensities reflecting changes in regional management directions and differing land-management constraints across a complex landscape (Collins et al. 2010, Moghaddas et al. 2010). The primary fuel treatment used in Meadow Valley was defensible fuel profile zones (DFPZs), which are areas approximately 0.4–0.8 km wide in which surface, ladder, and crown fuel loads are reduced with a combination of moderate thinning from below (Moghaddas et al. 2010) and prescribed fire treatments (figure 1).

The DFPZs were excluded from portions of the landscape set aside as reserves and from designated CSO protected activity centers, which are 121-ha areas of high-suitability nesting habitat designated by forest biologists. In addition, the project predominantly excluded all riparian habitat conservation areas or stream buffers intended to protect riparian and aquatic resources (figure 4). The activities conducted in the DFPZs were chainsaw thinning and pile burning of trees up to 30 centimeters (cm) in diameter at breast height (dbh); mastication: primarily shrubs and small trees were shredded and chipped in place, with the material left on site; prescription burning: stands were burned under conditions of moderate relative humidity and fuel moisture; and a combination of mechanical thinning and prescription burning of trees up to 51 or 76 cm dbh, depending on whether the stands were in the wildland–urban interface, using a whole-tree harvest system (figure 1) to achieve a residual canopy cover of approximately 40%, and some were underburned (Moghaddas et al. 2010). In addition to the DFPZs, group-selection treatments were implemented as part of the project. The group-selection treatments included the removal of all conifers up to 76 cm dbh within an area of 0.8 ha, followed by residue piling and burning, then either natural regeneration or replanting to a density of 270 trees per ha with a mix of sugar pine, ponderosa pine, and Douglas-fir. These treatments collectively covered 3688 ha (3448 ha in the DFPZs, 240 ha in the group-selection treatment), or 19% of our study area, and were implemented between 2003 and 2008.

Forest structure and microclimate

Although they are designed to reduce fire hazards, forest treatments alter stand conditions directly by reducing tree density and canopy cover, and indirectly by altering microclimate conditions affecting the understory community. To assess these changes we measured stand structure, light, understory plant cover, micro-meteorological variables, soil moisture, and fuel moisture in replicated control, thinning, and group-selection treatments plots embedded within the landscape-level treatments (see Bigelow al. 2009, 2011, Bigelow and North 2012 for detailed methods).

The mean forest canopy cover was 69% (standard deviation [SD] = 7%) before treatment; after treatment it was 53%

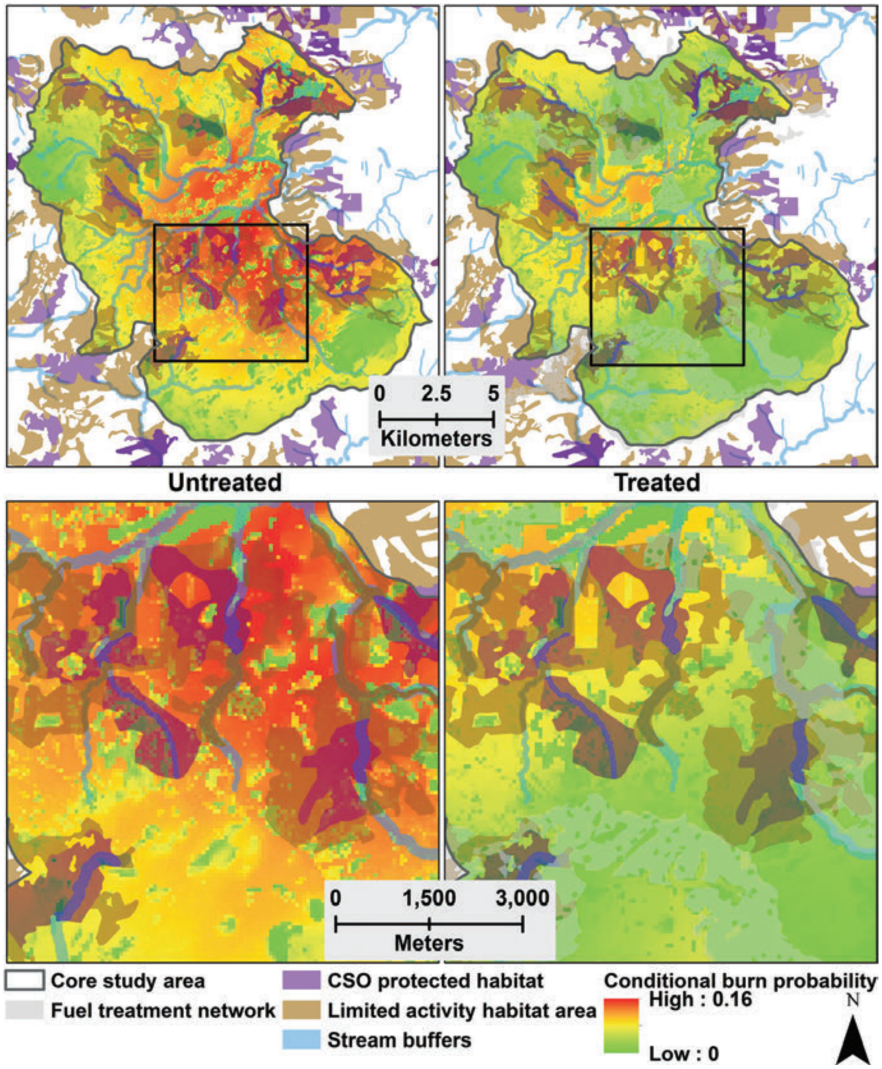

Figure 4. Hazardous fire potential across the Meadow Valley study area for the untreated and treated landscape conditions. This fire potential is based on the conditional burn probability of fire occurring with flame lengths greater than 2 meters, which is consistent with tree torching (see Collins et al. 2013 for specific details). Land designations that often limit or exclude active forest management (e.g., California spotted owl [CSO] protected habitat, stream buffers) are also shown to illustrate off-site effects of the landscape fuel-treatment network. The black square in the upper panels indicates the focal area shown in the bottom panels.

(SD = 7%) in thinned stands and 12% (SD = 6%) in the group-selection openings (Bigelow et al. 2011). These differences were reflected in growing-season understory light, which averaged 17% of full sun before treatment and increased to 26% in thinned stands and 67% in group-selection openings. Models of regenerating tree growth and light availability demonstrated that the height growth rates of shade-intolerant yellow pines (ponderosa and Jeffrey pines) and shade-tolerant white fir were equal at 41% of full sun. Light levels greater than this correlated exponentially with the height growth of the pines. The group-selection treatments provided ample light to recruit shade-intolerant species to the canopy, but only 8% of the sample locations in the thinning treatments had light levels exceeding the 41% crossover point, which suggests that these treatments would not substantially contribute to pine restoration across the landscape. An analysis of hemispherical photographs showed that the treatments decreased canopy closure following thinning. At the plot (1-ha) scale 3 years after treatment, cover of understory plant life-forms only changed under group selection ($p < .05$). Shade-tolerant conifers decreased, and graminoids, forbs, and broad-leaved trees (mainly California black oak and dogwood) increased (figure 5). There was no increase in exotic plant species cover with any of the treatments (Chiono 2012).

Changes in abiotic conditions followed differences in canopy cover for only some of the variables measured (Bigelow and North 2012). Soil moisture increased and duff moisture decreased in the group-selection treatments relative to the thinned and pretreatment conditions. Wind gust speeds (measured 2.5 m above ground) averaged 31% higher in the thinned stands than in the controls, but this was far less than the 128% increase in the group-selection openings. However, there was no difference in air temperature or relative humidity among the treatments, possibly because the increase in understory wind increased air mixing and eliminated any gradients in air temperature and humidity that might have resulted from increased irradiance.

Treatment increased within-stand variability for some vegetation and microclimate conditions but, in general, did not create the landscape-level heterogeneity characteristic of historic forest conditions in the Sierra Nevada (North et al. 2009). Mixed-conifer forests support the highest vertebrate diversity of California forests (Verner and Boss 1980), and studies suggest that this may result from habitat variability associated with the observed range of tree species diversity, canopy cover, microclimate, and deadwood conditions (Rambo and North 2009, Ma et al. 2010, White et al. 2013). This historic forest heterogeneity appears to reflect differences in fire intensity and site productivity associated with local and large-scale changes in slope, aspect, soil, and slope position (North et al. 2009, Lydersen and North 2012). On average, more mesic sites (e.g., drainage bottoms and north-facing slopes) historically supported greater stem density, canopy cover, and tree basal area, whereas drier and

Figure 5. steeper areas burned more frequently and intensely, creating more-open, pine-dominated forests (North et al. 2009). Although the Meadow Valley treatments did increase within-stand heterogeneity, they were not explicitly designed to vary with site topography or local productivity to produce this historic landscape variability.

Potential fire behavior

We employed a spatially explicit fire behavior model (Finney et al. 2007) to simulate fire spread across the Meadow Valley area. We simulated 10,000 individual fire events, with random ignition locations, and compared patterns of burn probability based on the number of times a particular area burned with the given ignition locations and simulated flame lengths for the study area prior to and following the implementation of landscape fuel treatments. Each fire event simulated burning for 240 minutes (one 4-hour burn period) under 97th percentile fuel moisture and wind conditions. These are the conditions associated with large-fire growth in this region (Collins et al. 2013). The burn period duration was selected such that the simulated fire sizes (for one burn period) approximated large-spread events observed (daily) in nearby recent wildfires (Collins et al. 2013). One of the primary assumptions with this approach is that, during these large-spread events (burn periods), fire suppression operations have limited impact, which is consistent with observed large-fire occurrence throughout the western United States (Finney et al. 2007). We summarized the burn probabilities across the Meadow Valley area into land allocations determined by the US Forest Service (USFS; Moghaddas et al. 2010).

The simulated fire behavior indicated that the landscape-scale network of DFPZs and prior fuel treatments were effective at reducing conditional burn probabilities across all land-allocation types, except the small area of off-base lands (figure 4; Moghaddas et al. 2010). Because burn probabilities are correlated directly and positively to fire size (Finney et al. 2007), it is clear that the pretreatment landscape was more conducive to large-fire growth than the posttreatment landscape was (Moghaddas et al. 2010, Collins et al. 2013). Although the influence of the treatments on the modeled burn probabilities of each land allocation varied, the untreated stands (e.g., those designated for protected CSO habitat, riparian and aquatic resources, and reserve lands) and the remaining private and unclassified lands all experienced reduced burn probabilities from the application of fuel treatments at the landscape scale (figure 4; Moghaddas et al. 2010). A similar reduced burn severity immediately adjacent to treated areas has been reported for actual fires across the western United States (Finney et al. 2005).

The substantial reduction in both the total area and the area burned at higher flame lengths under a posttreatment wildfire scenario was notable, given that only 19% of the study area had been treated (Moghaddas et al. 2010, Collins et al. 2013). Both the orientation of the treatments (approximately orthogonal to the predominant wind direction throughout the duration of the simulated fire), and the long, continuous shape of the DFPZs resulted in potential wildfires' intersecting fuel treatments in multiple places. In addition, the treatments were somewhat concentrated in the southwestern portion of the study area (figure 2), which is the dominant direction of strong winds during the fire season (Collins et al. 2013). In combination, these factors limited the ability of the simulated fire to both circumvent the treated areas and to regain spread and intensity after encountering the treatments. These results are important to managers, because similar installations of fuel and restoration treatments are needed in many Sierra Nevada

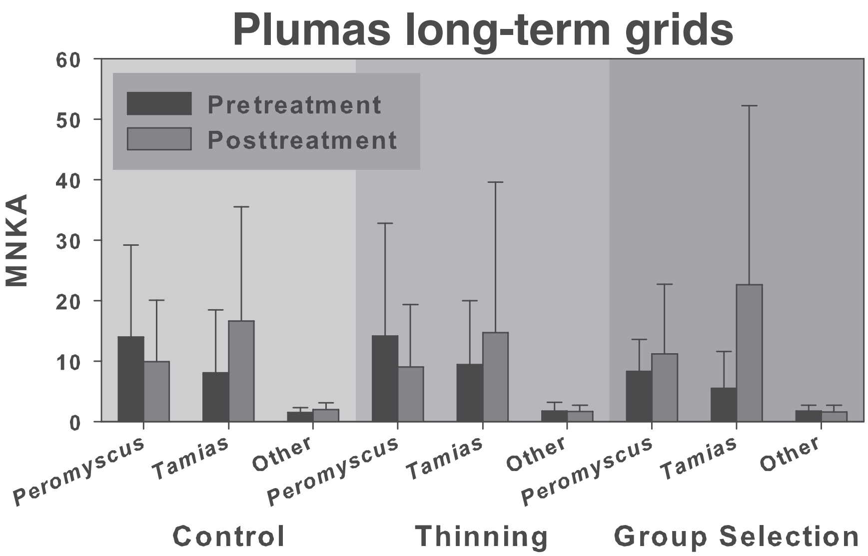

Figure 6. The mean minimum number of small animals known alive (MNKA), recorded before and after fuel treatments in the Plumas National Forest study area. mixed-conifer forests, where the present treatment rates are very low (North et al. 2012).

Small mammals

The northern Sierra Nevada supports a diverse fauna of small mammals that play key ecological roles as consumers, seed and fungal dispersers, and prey for both terrestrial and aerial predators (Hallett et al. 2003, Kelt et al. 2013). We studied small mammals in the Meadow Valley study area and the greater Plumas National Forest study area (PNFSA; figure 2), with a particular focus on two species that are key prey of the CSO (Gutiérrez et al. 1995): the dusky-footed woodrat (*Neotoma fuscipes*) and the northern flying squirrel (*Glaucomys sabrinus*). Results on focal species efforts have been reported elsewhere (Innes et al. 2007, Smith et al. 2011), but one finding merits emphasis here. California black oak, the primary hardwood in mixed-conifer forests, is an important habitat element for both the woodrat and the flying squirrel. Woodrat density was positively correlated with black oak density (Innes et al. 2007), and both species strongly preferred black oaks for nest sites (Innes et al. 2008, Smith et al. 2011). California black oak may be important for other wildlife species as well (Zielinski et al. 2004), but its persistence in our study landscape is in doubt. California black oak is shade intolerant, and across our study area, there were few thriving seedlings and many mature trees in decline as adjacent conifers overtopped them. California black oak trees were present in only 133 of 602 plots placed randomly in the PNFSA and were in a codominant canopy position in less than 10% of the plots in which it was present (see supplement S1).

Our broader studies on the management needs of entire small mammal assemblages included two complementary efforts. We sampled small mammals annually for 8 years on replicate trapping grids in treated and untreated mixed-conifer forests dominated by white fir in order to evaluate the responses of the small mammal community to canopy thinning (Kelt et al. 2013). To determine whether the habitat associations of the mammals in these forests were similar to those of mammals in other forest types, we expanded our efforts to include stratified random sampling of the PNFSA that encompassed the Meadow Valley study area (figure 2).

Whereas canopy thinning in white-fir-dominated mixed-conifer forests caused some significant changes in forest structure, small mammal assemblages were similar before and after canopy thinning and group selection (Kelt et al. 2013), which suggests a minimal response in the short-term to these treatments (*contra* Suzuki and Hayes 2003, Gitzen et al. 2007, but see Carey and Wilson 2001). Although each treatment may have elicited somewhat different responses (figure 6), the variance across replicate plots eroded any such differences even in the face of the substantial variation in canopy cover. The lack of a short-term response may not be surprising in a system characterized by high interannual variation in weather and in a system dominated by generalist species; we look forward to resampling these sites after 10–15 years to assess potential longer-term responses. Because our manipulative experiment was focused on white-fir-dominated mixed-conifer forests, we pursued a more general assessment of mammalian responses to habitat and environmental variation across the entire PNFSA, capitalizing on a series of point-count transects established throughout the forest in a stratified (by forest type) random manner (see the "Songbirds" section below). We sampled eight randomly selected points on each of 74 transects to characterize how small mammals respond to broader variation in forest structure.

We assessed assemblage-wide responses to this variation with ordination (canonical correspondence and canonical correlation) and species-specific responses with multiple stepwise regression. All data were standardized (both rows and columns) by centering and normalizing, and the mammal data were log-transformed to prevent domination of the axes by common species. The results from all of the analyses were qualitatively identical to those of the Meadow Valley experimental grids, which indicates minimal responses of small mammal assemblages to variation in forest structure or composition. Although the spatial arrangement of the

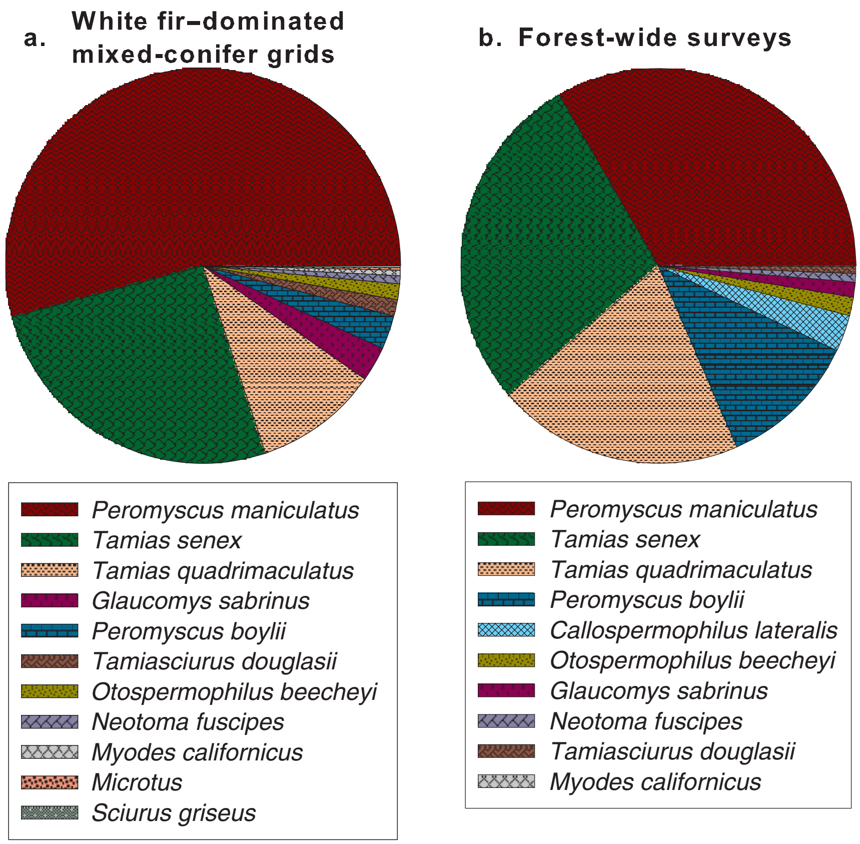

Figure 7. Small mammal composition at two spatial scales in the Plumas National Forest study area. At both scales, captures were dominated by three species. At the forest scale, only one other species was highly represented. All other species at both scales were only minor elements.

small mammal species in the ordination space was ecologically reasonable (e.g., woodrats and brush mice [*Peromyscus boylii*] associated with oaks, and chipmunks [*Tamias*] and Douglas squirrels [*Tamiasciurus douglasii*] associated with conifers and with a high basal area of trees and snags), ordination explained only a small proportion of variance in the distribution of small mammals. Similarly, regression failed to produce compelling associations for any species (or for community metrics such as species richness or diversity). The coefficients for both sets of analyses were universally low (Kelt et al. 2013).

In trapping efforts on the Meadow Valley experimental grids and in the larger PNFSA (figure 2), our captures were overwhelmingly dominated by 3–5 species (figure 7). Deer mice (*Peromyscus maniculatus*) dominated the captures at both spatial scales, comprising a full 55% of the captures on the Meadow Valley experimental grids and just over one-third of the captures in the PNFSA. Two species of chipmunk (*Tamias quadrimaculatus*, *Tamias senex*) represented an additional 40%–44%, and brush mice were an additional 8% in the PNFSA. Therefore, our samples were dominated by ecological generalists known to be tolerant of diverse habitats. What appears to be missing is a reasonable representation of species with more restricted niche requirements. Our sampling was not designed to sample shrews (*Sorex*), but California red-backed voles (*Myodes* [formerly *Clethrionomys*] *californicus*) may have been more common in this region in the 1940s and 1950s (Kelt et al. 2013) and should have been present in our study. This species forages on fungi, however, and requires large downed woody debris and a closed-canopy forest to allow sufficient moisture retention to promote fungal growth (Alexander and Verts 1992). In 177,216 trap nights of effort, we captured only 11 *Myodes* (all but one on Meadow Valley experimental grids). Other species that are mesic habitat specialists were not sampled (e.g., *Zapus trinotatus, Sorex palustris*).

It is not clear whether the taxonomically depauperate assemblage structure documented in our study represents a relatively recent reduction or is more historic for this region. No data on mammal assemblages exist prior to European settlement and the beginning of widespread changes to the Sierra Nevada forest ecosystems (Merchant 2012). However, one implication of this research is that, in spite of nearly a kilometer of vertical elevation relief and diverse forest types from ponderosa pine to red fir, the current forest conditions support a relatively homogeneous small mammal community dominated by ruderal species. It is unclear whether this reflects a legacy of fire exclusion and the resulting accumulation of fine woody debris or, perhaps, a response to a history of logging and fire suppression in this region. In contrast, other recent work in Yosemite (Roberts et al. 2008) confirms that small mammals respond strongly to variation in burn history. Taken together, these results support the fundamental ecological role of fire and broadscale forest heterogeneity in managing mixed-conifer forests in the Sierra Nevada (North et al. 2009).

Songbirds

To evaluate the effects of the Meadow Valley fuel-treatment network on songbirds, we compared avian community diversity before and after treatment. From 2004 to 2011, we surveyed the breeding community in and adjacent to Meadow Valley, using standardized point-count surveys with a 50-m radius (Ralph et al. 1995). Surveys were conducted at 51 stations where DFPZs were implemented (treated) and 201 stations where no treatments were implemented (untreated), proportional to the 19% of the study area treated. An additional 180 stations were surveyed in adjacent untreated PNFSA (figure 2) watersheds (the reference group). We used geographic information systems to establish locations

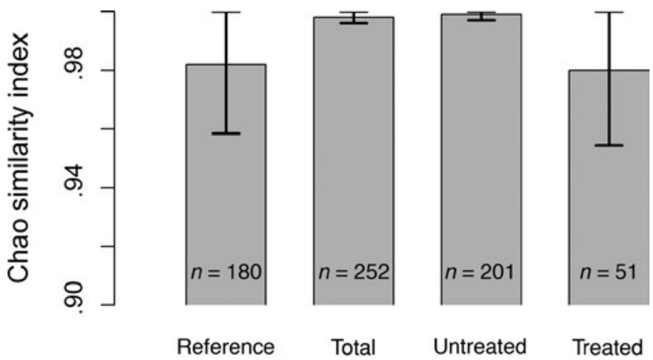

Figure 8. Chao similarity index for the avian community (60 species) before and after treatment at treated and untreated locations in the Meadow Valley study area and reference locations in the adjacent Plumas National Forest study area that also received no treatment. This metric ranges from 0–1, with 1 representing perfect similarity (all species and relative abundances shared among both samples). The error bars are 95% confidence intervals.

for the untreated and reference stations from a randomly selected origin (constrained by slopes lower than 35% and on USFS land) along a random compass bearing in a linear array of 4–12 points. The treated stations were placed within proposed DFPZ treatments across the breadth of treatment types and geography described above. All of the stations were a minimum of 250 m apart.

We surveyed all of the stations in both 2004 and 2005, prior to treatment, and for 2 years after all treatments were implemented (2010–2011). In each year, we surveyed every station twice during the peak of the breeding season (15 May–10 July), with a minimum of 10 days between visits. We limited our analyses to the 60 species breeding in upland habitats that were reliably recorded with point counts (Hutto et al. 1986). The results were summarized at the level of the three treatment groups described above (treated, untreated, reference) and for treated and untreated locations in Meadow Valley combined. For all of the analyses, we summed detections across four surveys (two visits per year over 2 years) for the pre- and posttreatment periods. We compared avian assemblages before and after the treatment with Chao–Jaccard's similarity index (Chao et al. 2005), calculated using EstimateS (version 9.1, University of Connecticut, Storrs). Chao–Jaccard similarity is sensitive to changes in species composition and abundance. Differences in avian diversity were evaluated using the exponent of the Shannon index (Nur et al. 1999). For both analyses, 95% confidence intervals were derived from estimated standard errors from 1000 bootstrap samples.

Our results indicate little change in the Meadow Valley avian communities in response to treatment. The communities were similar across the treated, untreated, and reference samples (figure 8). There was some evidence that the treated areas were less similar to each other than were the untreated areas, but this was not statistically significant ($p > .05$). Avian diversity (the Shannon index) was lowest for the treated sample prior to treatment but increased more in the posttreatment period, such that the Shannon index after treatment was equivalent in the treated and untreated samples (figure 9).

Evaluating the effects of fuel treatments with coarse metrics such as similarity and diversity can cause one to overlook large effects on select species (Hurteau et al. 2008). Numerous studies in seasonally dry fire-prone US forests have shown that fuel treatments can result in at least modest changes in the abundance of a broad range of avian species (Fontaine and Kennedy 2012). We recently reported that mechanical fuel-reduction treatments in the northern Sierra Nevada (including Meadow Valley) resulted in modest decreases in the abundance of a few closed-canopy associates and increases in some edge and open forest associates (Burnett et al. 2013). None of the 15 species evaluated in that study showed a significant decline following the construction of shaded fuel break DFPZ treatments—the primary treatment used in the Meadow Valley study area. With the moderate portion of the landscape treated, small differences in avian community similarity and diversity resulting from treatment, and the results from our previous evaluation of individual species response, we conclude that the effects of the Meadow Valley fuel-treatment network on the songbird community were minimal.

The fuel treatments implemented in Meadow Valley were typically less intense than those shown to result in large changes in avian communities (for a review, see Vanderwel et al. 2007). The treatments were applied to 19% of the landscape, and the prescriptions left relatively high canopy cover. Fire suppression and silvicultural practices over the last century have reduced forest heterogeneity and increased stand density (Scholl and Taylor 2010, Collins et al. 2011). In the Sierra Nevada, most fuel treatments changed the forest structure moderately from historic forest conditions (North et al. 2007). The Meadow Valley mechanical treatments primarily removed ladder fuels, which reduced crown fire potential but did not substantially alter the existing habitat features associated with songbirds, such as shrub cover or large overstory trees.

Our results should be considered in the context of the conditions that existed in the study area prior to the implementation of the landscape treatments. If an objective of these treatments was to maintain the existing avian assemblage and diversity, they appear to have been successful. However, a frequently stated objective for fuel reduction is to act as a surrogate for the natural fire regime (Stephens et al. 2012). Therefore, the maintenance of the pretreatment wildlife community may not always be the most desirable outcome in landscapes such as Meadow Valley and the larger PNFSA, where fire has been excluded for 85–125 years (Moody et al. 2006). Creating or enhancing

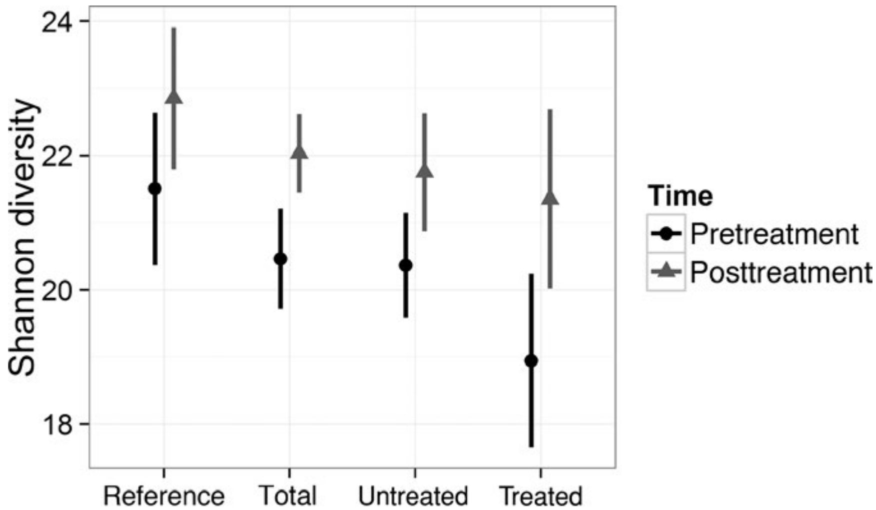

*Figure 9. Shannon diversity index of avian diversity before (*pretreatment*) and after (*posttreatment*) fuel treatments were implemented at treated (*n = 51*) and untreated (*n = 201*) locations and the first two combined (*Total; n = 252*) in the Meadow Valley study area and in reference locations in the adjacent Plumas National Forest study area, which received no treatment (*n = 181*). The error bars are 95% confidence intervals.*

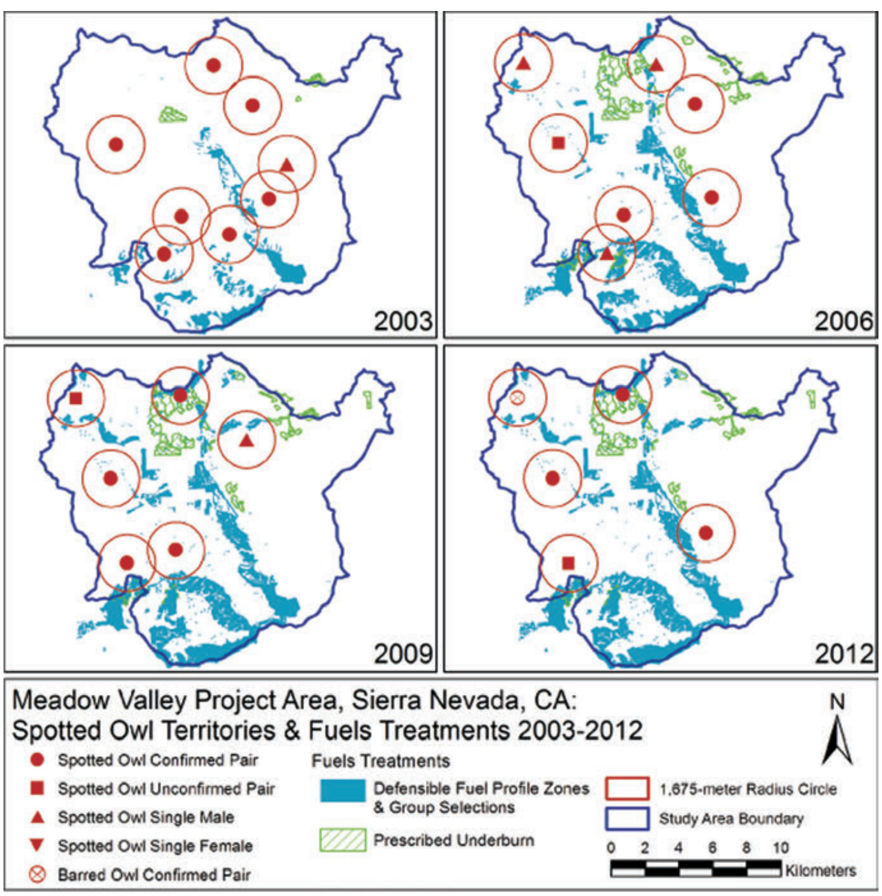

Figure 10. Distribution of territorial California spotted owl sites and landscape forest fuel treatments within the Meadow Valley study area from 2003 to 2012.

conditions for species associated with postdisturbance habitat, some of which have experienced recent declines, may be a prudent approach for achieving some biological diversity objectives (Fontaine and Kennedy 2012). If fuel-reduction treatments are to be a complementary tool to fire in achieving biological objectives, we suggest that they be designed to further increase landscape heterogeneity in fire-excluded forests.

California spotted owls

Modeling studies have projected that fuel treatments on a portion of the landscape (20%–35%) may have minimal effects on owl habitat and that the longer-term benefits of reduced wildfire risk may outweigh the short-term treatment effects on owl habitat (Ager et al. 2007, Roloff et al. 2012). However, no empirical data are available to assess the effects of landscape fuel treatments on the CSO and its habitat.

We used standardized surveys and color banding of individual owls to monitor the distribution, occupancy, survival, and reproduction of CSO sites annually across 1889 square kilometers between 2003 and 2012 in the Plumas and Lassen National Forests. Within this area, four areas were identified for implementation of landscape-scale fuel and restoration treatments. Our initial objectives were to establish baseline values for CSO distribution and abundance and to monitor the owl's response in the treated and untreated landscapes in posttreatment years. However, complete implementation of the fuel-treatment network only occurred on one (Meadow Valley; figure 10) of the four landscapes because of legal challenges to the proposed US Forest Service management strategy.

In the Meadow Valley study area, the number of territorial owl sites declined after treatment. Prior to and throughout the implementation of the treatment, the number of owl sites ranged from seven to nine. Between the final year of the DFPZ and group-selection installations (2008) and 2 years after treatment (2009–2010), the number of owl sites declined by one (six territorial sites), and by 3–4 years after treatment (2011–2012), the number of sites had declined to four—a decline of 43% from the pretreatment numbers (figure 11). These results mirror similar declines of the CSO in the larger Plumas-Lassen CSO study area over the past 20 years (Conner et al. 2013) but suggest a greater magnitude of decline within Meadow Valley (figure 11).

The CSO nests and roosts in dense, multilayered, mature forest patches, and the adult survival and territory occupancy of these owls is positively correlated to the amounts of mature forest in core areas around CSO sites (Dugger et al. 2011). For foraging, however, the CSO uses a broader range of vegetative conditions. Radio-telemetry conducted in Meadow Valley indicates that the CSO avoids foraging in DFPZs in the first 1–2 years after fuel treatments and that the owl's home range size was positively correlated with the amount of treatment within the home range (Gallagher 2010). Barred owls (*Strix varia*) began to colonize the Meadow Valley study area in 2012 and are likely to become a threat to the CSO and a confounding factor to be accounted for in assessments of forest management effects (Keane 2014).

Although inference must be tempered from a single study, the Meadow Valley area is the first large area to receive full the implementation of landscape-scale DFPZ and group-selection treatments in which CSOs were monitored annually both before and after treatment. CSOs are long-lived (up to 20 years) and exhibit high site fidelity as adults, although there is high annual variation in reproduction associated with weather and food (Gutierrez et al. 1995). Given these traits, individual CSOs may exhibit both short- and long-term responses to fuel treatments or wildfire, and understanding both is important to land-use managers. Our results documented a decline in CSO territories as a result of landscape fuel treatments, but the factors driving the decline remain unknown.

Conclusions

This study has shown that coordinated landscape-scale fuel treatments can substantially reduce the potential for hazardous fire across a large montane region, even when a moderate proportion of the area that could not be treated because of management constraints. In many cases, lands with designated management emphasis, such as wildlife habitat reserves and stream buffers, are distributed throughout the landscape. Creating fuel treatments that exclude these lands can result in a patchwork of treated areas heavily dissected by, for example, untreated stream buffers. Hazardous fire potential decreased in untreated areas, but that effect is not stable over time. Even if the existing network was maintained in a "treated" condition (i.e., periodic prescribed fire to keep surface and ladder fuels low) hazards will continue to increase in untreated areas because of stand development (Collins et al. 2013).

Our results indicate negative CSO responses to treatments, supported by the avoidance of DFPZs by foraging owls, larger owl home ranges associated with increasing amounts of treatment within the home ranges, and a 43% decline in the number of territorial CSO sites across the Meadow Valley study area within 3–4 years of the implementation of landscape treatments. In addition to changes in the number of owls, we also observed spatial redistribution of owl sites over time across the landscape (figure 10). The specific mechanisms driving these observations are unclear, but given the region-wide decline in the CSO population (Conner et al. 2013) and the increasing barred owl populations, it is difficult to disentangle fuel treatment effects from background or external pressures. Despite the challenges of working at landscape scales, studies such as this provide opportunities for addressing scale-dependent ecological phenomena, such as population-level species responses and responses to management strategies that cannot be addressed at smaller spatial scales.

To date, little discussion has been focused on what may constitute sustainable, viable CSO populations under various landscape conditions designed to address projected fire and climate scenarios. Furthermore, there is not a clear understanding of the balance between the potential short-term impacts from treatments and the longer-term benefits provided by introducing landscape heterogeneity (North et al. 2009), reducing potential for severe fire (Ager et al. 2007, Collins et al. 2013), increasing the potential for more desirable fire effects (North et al. 2012), and increasing resilience to climate change (Stephens et al. 2010). The Meadow Valley study is an important step in learning about the responses of wildlife species to fuel-reduction treatments.

Recent research in Yosemite National Park suggests that CSOs are not adversely affected by low- to moderate-severity fire (Roberts et al. 2011, Lee et al. 2013). Studies of the CSO both in Yosemite and in Sequoia and Kings Canyon National Parks have not shown population declines that have been found in several national forests in California. There are many differences between the two ownerships: National forest lands generally contain younger forests and lack the large tree structures associated with preferred owl habitat. With continued fire suppression, national forest lands continue to develop dense, small-tree stand conditions, reducing the habitat heterogeneity associated with a variety of small mammals that constitute the CSO's prey base. Because of these differences, it is difficult to determine whether more recent mechanical treatments or existing fire-suppressed conditions might be associated with declining CSO populations. Uncertainty also persists regarding the potential thresholds at which the amounts and patch sizes of high-severity fire reduce the postfire probabilities of CSO occupancy, survival, and reproduction. This is a significant information gap, given the trend for increasing amounts and patch sizes of high-severity fire in many Sierra Nevada forests (Miller et al. 2009). Unfortunately, only one CSO pair in Meadow Valley used an area that received prescribed burn treatments, but unlike those in some of the mechanically treated areas, these owls continued to occupy the burned area through the duration of the study and foraged within the burn-treatment areas (Gallagher 2010). The introduction of barred owls to Meadow Valley adds another important factor that may

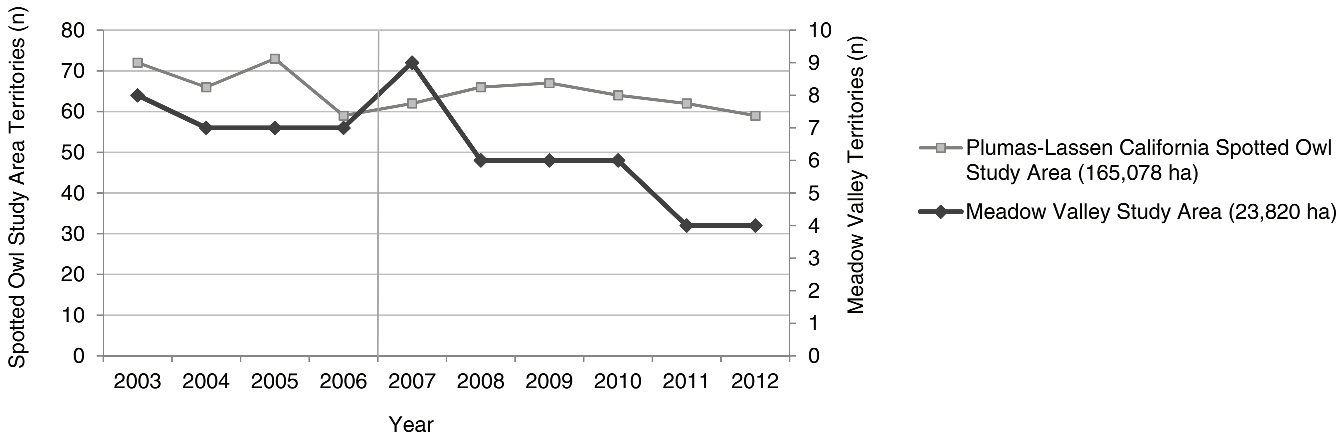

Figure 11. The annual number of territorial California spotted owl sites from 2003 to 2012 within the Meadow Valley study compared with the rest of the Plumas-Lassen study area (in the Plumas and Lassen National Forests). Vertical line represents completion of >80% of treatments.

reduce the population and viability of the CSO, possibly independent of forest structure.

Mechanical treatments can reduce fuels, but, in this study, they also left the largest trees and retained more than 40% canopy cover, two structural characteristics associated with CSO habitat use (Verner et al. 1992). However, although mechanical treatments retain these live features, they often remove snags for operator safety and fuel objectives; reduce tree density and canopy layering; reduce canopy cover to the minimum level (around 40%) considered to function as owl foraging habitat; and simplify the ground structure through a reduction of logs and small trees. Furthermore, DFPZ treatments are often uniformly implemented over large areas along roads, which results in extensive patches of simplified stand structure with regularly spaced trees. Another concern is that treatment size and placement are determined by land-use constraints (gentle slopes, access to roads) and opportunities to affect fire behavior. We have little information about how the location of treatments may affect CSOs' use of areas outside their core nesting locations. Several small mammals appeared to favor sites with steeper slopes (Kelt et al. 2013), possibly reflecting the spatial allocation of treatments in this landscape.

The importance of increasing heterogeneity within stands and across the landscape in mixed-conifer forests is well documented to meet restoration objectives (North et al. 2009, Stephens et al. 2010). Our ability to optimize heterogeneity at large scales may be more effectively achieved with prescribed and managed fires that are allowed to burn under moderate weather conditions. This type of burn often produces variable forest conditions that mimic historic patterns (Collins et al. 2011) to which this fauna, including the CSO, has adapted. Alternatively, mechanical treatments that produce the complex forest structure and composition that more closely mimic the patterns generated under a more active fire regime (North et al. 2009) may provide habitat conditions to support CSOs and a diverse fauna superior to those of the DFPZ and group-selection treatments implemented in Meadow Valley. Although mean stand conditions (e.g., canopy cover) have often been used to infer management impacts on preferred habitat (Tempel et al. in press), the historic heterogeneity of frequent-fire forests suggests we have yet to identify the optimal scales at which to create variable forest conditions.

We encourage further work to examine landscape-level treatments that are intended to emulate the influence of fire in creating spatial heterogeneity in vegetation and fuel conditions. A working hypothesis is that increased habitat heterogeneity, including the retention and development of currently limited but ecologically important forest conditions (areas of large, old trees) and more-open, patchy, early-seral stage conditions, would promote a diverse wildlife community while providing a more fire-resilient landscape. The results from the Meadow Valley study area illustrate the benefits and challenges of working at the landscape scale. Rigorous and controlled experiments are difficult because of the inherent variability across landscapes, sociopolitical constraints, and competing management objectives that can influence planned treatments. However, inferences from these studies can be strengthened by careful replication of management strategies across multiple landscapes.

Acknowledgments

We thank the staff of the Plumas and Lassen National Forests for designing and overseeing the implementation of this project. We also thank the many technicians and other people that did the majority of the fieldwork. Members of the Quincy Library Group provided feedback and support for this project. The USFS Region 5 and the Pacific Southwest Research Station funded this project.

The forgotten stage of forest succession: early-successional ecosystems on forest sites

Mark E Swanson[1*], Jerry F Franklin[2], Robert L Beschta[3], Charles M Crisafulli[4], Dominick A DellaSala[5], Richard L Hutto[6], David B Lindenmayer[7], and Frederick J Swanson[8]

Early-successional forest ecosystems that develop after stand-replacing or partial disturbances are diverse in species, processes, and structure. Post-disturbance ecosystems are also often rich in biological legacies, including surviving organisms and organically derived structures, such as woody debris. These legacies and post-disturbance plant communities provide resources that attract and sustain high species diversity, including numerous early-successional obligates, such as certain woodpeckers and arthropods. Early succession is the only period when tree canopies do not dominate the forest site, and so this stage can be characterized by high productivity of plant species (including herbs and shrubs), complex food webs, large nutrient fluxes, and high structural and spatial complexity. Different disturbances contrast markedly in terms of biological legacies, and this will influence the resultant physical and biological conditions, thus affecting successional pathways. Management activities, such as post-disturbance logging and dense tree planting, can reduce the richness within and the duration of early-successional ecosystems. Where maintenance of biodiversity is an objective, the importance and value of these natural early-successional ecosystems are underappreciated.

Front Ecol Environ 2010; doi:10.1890/090157

Severe natural disturbances – such as wildfires, windstorms, and insect epidemics – are characteristic of many forest ecosystems and can produce a "stand-replacement" event, by killing all or most of the dominant trees therein (Figure 1). Typically, limited biomass is actually consumed or removed in such events, but many trees and other organisms experience mortality, leaving behind important biological legacies (structures inherited from the pre-disturbance ecosystem; Franklin *et al.* 2000), including standing dead trees and downed boles (tree trunks; Franklin *et al.* 2000). Such legacies provide diverse physical/biological properties and suitable microclimatic conditions for many species. Thereafter, species-diverse plant communities develop because substantial amounts of previously limited resources (light, moisture, and nutrients) become available. These emerging plant communities create additional habitat complexity and provide various energetic resources for terrestrial and aquatic organisms.

In a nutshell:

- Naturally occurring, early-successional ecosystems on forest sites have distinctive characteristics, including high species diversity, as well as complex food webs and ecosystem processes
- This high species diversity is made up of survivors, opportunists, and habitat specialists that require the distinctive conditions present there
- Organic structures, such as live and dead trees, create habitat for surviving and colonizing organisms on many types of recently disturbed sites
- Traditional forestry activities (eg clearcutting or post-disturbance logging) reduce the species richness and key ecological processes associated with early-successional ecosystems; other activities, such as tree planting, can limit the duration (eg by plantation establishment) of this important successional stage

[1]*Washington State University, Pullman, WA* [*]*(markswanson@wsu.edu);* [2]*University of Washington, Seattle, WA;* [3]*Oregon State University, Corvallis, OR;* [4]*USFS Pacific Northwest Research Station, Amboy, WA;* [5]*National Center for Conservation Science and Policy, Ashland, OR;* [6]*University of Montana, Missoula, MT;* [7]*Australian National University, Canberra, Australia;* [8]*USDA Forest Service, Corvallis, OR*

The ecological importance of early-successional forest ecosystems (ESFEs) has received little attention, except as a transitional phase, before resumption of tree dominance. In forestry, this period is often called the "cohort re-establishment" or "stand initiation" stage, with attention obviously focused on tree regeneration and the re-establishment of closed forest canopies (Franklin *et al.* 2002). Ecological studies have focused primarily on plant-community development and the needs of selected animal (mostly game) species, and not on the diverse ecological roles of ESFEs.

Here, we highlight important features of ESFEs, including their role in sustaining ecosystem processes and biodiversity, so that they may be appropriately considered by resource managers and scientists, and included within management/research programs dedicated to maintaining these functions, particularly at larger spatio-temporal scales. Most published examples focus on sites in western North America, but ESFEs are important elsewhere (Angelstam 1998; DeGraaf *et al.* 2003). We also discuss how traditional forestry practices, such as clearcutting, tree planting, and post-disturbance logging, can affect early-successional communities.

Figure 1. *Stand-replacement disturbance events in forests create large areas free of tree dominance and rich in physical and biological resources, including legacies of the pre-disturbance ecosystem.*

(Franklin *et al.* 2002). Consequently, the duration of ESFEs varies inversely with rapidity of tree regeneration and growth, which, in turn, depend on such variables as tree propagule availability, conditions affecting seedling or sprout establishment, and site productivity. ESFE longevity after natural disturbances is therefore highly variable.

Development of a closed forest canopy may require a century or more in areas with limited seed sources, harsh environmental conditions, severe shrub competition (in some instances), or combinations thereof (Hemstrom and Franklin 1982). For example, tree canopy closure after wildfire in the Douglas fir region of western North America often requires several decades (Poage *et al.* 2009), but can occur much more rapidly when canopy seedbanks are abundant (eg Larson and Franklin 2005). Closed forest canopies may develop quickly in forests dominated by trees with strong sprouting ability (eg many angiosperms) or when windstorms "release" understories of shade-tolerant tree seedling banks by removing all or most of the overstory (Foster *et al.* 1997).

■ Early-successional ecosystems on forest sites

Initial conditions after stand-replacing forest disturbances vary generically, depending on the type of disturbance; this includes the types of physical and biological legacies available. For example, aboveground vegetation may be limited immediately after the disturbance, as in the case of severe wildfires or volcanic eruptions. Conversely, intact understory communities may persist where forests have been blown down by severe windstorms. Spatial heterogeneity in conditions is characteristic, given that disturbances vary greatly in the amount of damage they cause (Turner *et al.* 1998). For instance, severe wildfires frequently include substantial areas of unburned as well as low to medium levels of mortality, creating variability in shade, litterfall, soil moisture, seed distribution, and other factors.

We define ESFEs as those ecosystems that occupy potentially forested sites in time and space between a stand-replacement disturbance and re-establishment of a closed forest canopy. These ecosystems undergo compositional and structural changes (succession) during their occupancy of a site. Changes begin immediately post-disturbance, as a result of the activities of surviving organisms (eg plants, animals, and fungi), including plant growth and seed production. Developmental processes are enriched by colonization of flora and fauna from outside the disturbed area. Successional change is often characterized by progressive dominance of annual and perennial herbs, shrubs, and trees, although all of these species are typically represented throughout the entire sequence of forest stand development (or sere; Halpern 1988).

The ESFE developmental stage ends with re-establishment of tree cover that is sufficiently dense to suppress and often eliminate many smaller shade-intolerant plants

■ Attributes of early-successional ecosystems

After severe disturbances, forest sites are characterized by open, non-tree-dominated environments, but have high levels of structural complexity and spatial heterogeneity and retain legacy materials.

Environmental conditions

Removal of the overstory forest canopy during disturbances dramatically alters the site's microclimate, including light regimes. These changes lead to increased exposure to sunlight, more extreme temperatures (ground and air), higher wind velocities, and lower levels of relative humidity and moisture in litter and surface soil. Shifts in these environmental metrics favor some species, while creating suboptimal or intolerable conditions for others. For example, post-disturbance plant community composition, cover, and physiognomy are altered as shade-tolerant understory herbs are largely displaced by shade-intolerant and drought-tolerant species. New substrates deposited by floods or volcanic eruptions may lack nutrients, provide additional water-holding capacity, or have high albedo, all of which favor shifts in plant communities.

Survivors

Organisms (in a variety of forms) that survive severe disturbances are extremely important for repopulating and

restoring ecosystem functions in the post-disturbance landscape. Even in severely disturbed areas, organisms may survive as individuals (mature or immature) or as reproductive structures (eg spores, seeds, rootstocks, and eggs), which become in situ propagule sources. For example, after the 1980 volcanic eruption of Mount St Helens (Washington State), most pre-eruption flora and many fauna (especially aquatic and burrowing terrestrial species) survived within the blast zone through several different mechanisms (Dale *et al*. 2005).

Surviving organisms are also often vital for the prompt re-establishment of important ecosystem functions, such as conservation of nutrients and stabilization of substrates. For instance, the important role of resprouting vegetation in curbing massive losses of nitrogen was demonstrated by experimentally clearcutting and applying herbicides in a watershed at Hubbard Brook Experimental Forest (Bormann and Likens 1979).

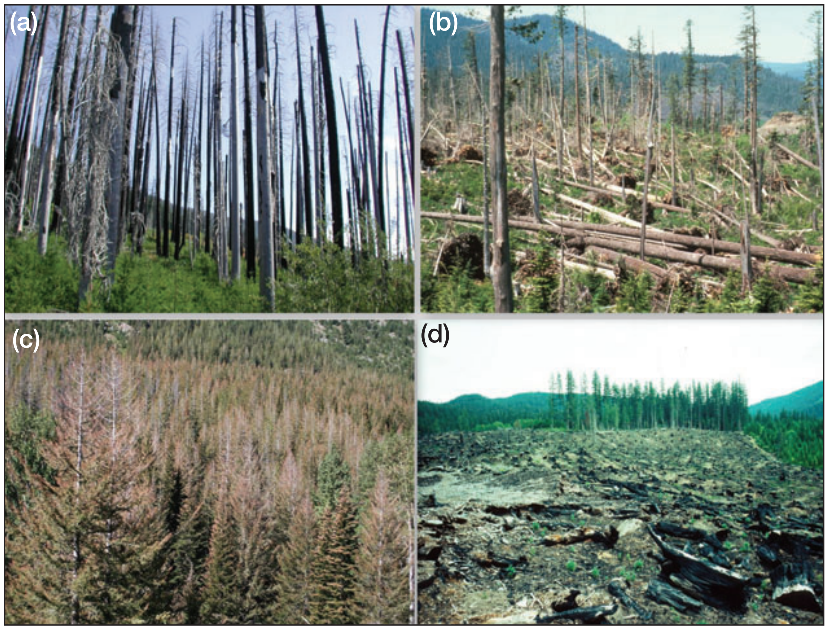

Figure 2. *Different types of disturbances produce different types of biological legacies, including living organisms and structures: (a) standing dead trees (snags) are dominant structural legacies after severe wildfires; (b) downed tree trunks and nearly intact understory communities are characteristic legacies after major windstorms; (c) standing dead trees are also dominant structural legacies after heavy insect infestations; and (d) clearcuts typically eliminate most aboveground structural legacies. Values for each metric are shown in Table 1 and are described in detail in the text.*

Structural complexity

The structural complexity of ESFEs depends initially on legacies, the general nature of which varies with the type of disturbance (Table 1; Figure 2); for example, snags and shrubs originating from belowground perennating (ie resprouting) parts or seeds are dominant legacies after wildfires, whereas downed boles and largely intact understories are typical post-disturbance characteristics of windstorms.

Woody legacies, such as snags and downed boles, play numerous roles in structuring and facilitating the development of the recovering ecosystem – providing habitat for survivors and colonists, moderating the physical environment, enriching aquatic systems in the disturbed area (Jones and Daniels 2008), and providing long-term sources of energy and nutrients (Harmon *et al*. 1986). Although subject to decomposition, these legacies can persist for many decades and sometimes even centuries.

Table 1. Different types of intense disturbances generate different types of biological legacies

	Disturbance				
Biological legacies	*Wildfire*	*Wind*	*Insect*	*Volcano*	*Clearcut*
Live trees	Infrequent	Variable	Variable (depends on stand composition)	Infrequent – confined to margins	Infrequent or absent
Snags	Abundant	Variable	Abundant	Abundant (spatially variable)	Infrequent or absent
Downed woody debris	Variable, but typically abundant	Abundant	Variable, but eventually abundant	Abundant (spatially variable)	Infrequent
Undisturbed understory	Infrequent	Abundant	Abundant	Infrequent – confined to disturbance margins	Infrequent
Spatial heterogeneity of recovery	High	Variable	High	High	Variable – usually low
Time in early-successional condition	Variable	Variable	Long	Variable – usually long	Variable – usually short

Figure 3. *Plant communities with well-developed shrub and perennial herb species are characteristic of early-successional communities on forest sites and provide diverse food resources. Twenty-five years after the Mount St Helens eruption in 1980, this community, which was within the blast zone, includes well-developed shrubs (eg* Sorbus *and* Vaccinium *spp), trees, and perennial herbs (eg* Epilobium angustifolium*).*

Structural complexity is further enhanced by the establishment and development of a variety of plant species, which often include perennial herbs and shrubs characteristic of open environments, as well as individual trees (Figure 3). The diversity of plant morphologies (maximum height, crown width, etc) increases structural richness, so that this associated flora contributes to both horizontal and vertical heterogeneity.

Spatial heterogeneity

Spatial heterogeneity is evident in early-successional ecosystems and has multiple causes: (1) natural variability in the geophysical template (topography and lithology) of the affected landscape; (2) variability in conditions in the pre-disturbance forest ecosystem; (3) variability in the intensity of the disturbance event; and (4) variability in rates and patterns of subsequent developmental processes in the ESFE. The first two sources relate to existing geophysical and biological patterns within the disturbed area. Land formations and patterns of geomorphic processes are certainly key geophysical elements (Swanson *et al.* 1988). The presence of surface water, such as streams and ponds, can be particularly influential in facilitating survival and re-establishment of biota.

Natural disturbances create heterogeneous environments at multiple spatial scales (Heinselmann 1973), because disturbances do not cause damage uniformly. Disturbances such as wildfires and windstorms are variable in intensity (eg "spotting", or initiation of new flame fronts by wind-thrown firebrands, during fire events). Alternatively, geographic variation in environmental conditions and topography (Swanson *et al.* 1988) influences the intensity of the disturbance and results in heterogeneity at multiple scales. Variability in the structure and composition of the pre-disturbance forest also creates spatial and temporal variability (Wardell-Johnson and Horowitz 1996). Some of these patterns may be transient, such as residual snowbanks protecting tree regeneration after the aforementioned Mount St Helens eruption (Dale *et al.* 2005).

Post-disturbance developmental processes also lead to spatial heterogeneity. For example, varying distances to sources of tree seed result in different rates and densities of tree re-establishment (Turner *et al.* 1998). Structural legacies can greatly influence the rates at which wind- or waterborne organic (including propagules) and inorganic materials are deposited. Finally, animal activity can strongly influence patterns of revegetation, as illustrated by the multiple effects that gophers (*Thomomys* spp) can have on post-disturbance landscapes (Crisafulli *et al.* 2005b) or the way ungulate browsing may impede tree regeneration (Hessl and Graumlich 2002).

■ Biological diversity

ESFEs in temperate forest seres show great diversity in the abundance of plant and animal species (Fontaine *et al.* 2009). Species composition may consist of a mix of forest survivors, opportunists, or ruderals (plants that grow on disturbed or poor-quality lands), and habitat specialists that co-exist in the resource-rich ESFE environment (Figure 3). Most forest understory flora can survive disturbances as established plants, perennating rootstocks, or seeds. In one study, in western North America, over 95% of understory species survived the combined disturbance of logging and burning of an old-growth Douglas-fir–western hemlock stand (Halpern 1988). Some important early-successional species (eg *Rubus* spp [blackberry; raspberry], *Ribes* spp [gooseberry], and *Ceanothus* spp [buckbrush]) may persist as long-lived seedbanks.

Opportunistic herbaceous species are often conspicuous dominants early in the development of ESFEs (Figure 4). Many of these weedy species (particularly annuals) decline quickly, although other opportunists will persist as part of the plant community until overtopped by slower growing shrubs or trees. Consequently, diverse plant communities of herbs, shrubs, and young trees emerge in ESFEs; this, combined with the structural legacies from the pre-disturbance ecosystem, often results in high levels of structural richness (Figure 3).

Many animals, including habitat specialists and species typically absent from the eventual tree-dominated com-

munities, thrive under the conditions found in ESFEs. For some species, this is the only successional stage that can provide suitable foraging or nesting habitat. As an example, many butterflies and moths (Lepidoptera) found in forested regions depend on the high diversity and quality of plant forage in ESFEs (eg Miller and Hammond 2007), whereas jewel beetles (Coleoptera: Buprestideae) depend on abundant coarse woody debris. Also, a number of ground-dwelling beetle species occur as habitat specialists in early-successional communities (Heyborne *et al.* 2003).

Figure 4. *Early-successional communities are often dominated by annual herbaceous species for the first few years after disturbance; these are quickly displaced by perennial herbaceous species and shrubs.*

Many vertebrates also respond positively to ESFEs, which may provide the only suitable habitat at a regional scale for some species. Ectothermic animals, such as reptiles (eg Rittenhouse *et al.* 2007), generally respond favorably to sunnier and drier conditions, colonizing early-successional habitat or increasing in abundance if present as survivors. Many amphibians also thrive in ESFEs, provided resources such as water bodies and key structures (eg logs) are available. The diversity and abundance of amphibians in the area affected by the 1980 Mount St Helens eruption is illustrative (Crisafulli *et al.* 2005a); eleven of 15 amphibian species survived the event, and some (eg western toad, *Bufo boreas*) have since had exceptional breeding success.

The broad array of birds using the abundant and varied food sources (eg fruits, nectar, herbivorous insects) and nesting habitat in ESFEs includes many raptors and neotropical migrants, often making bird diversity highest during the ESFE stage of succession (Klaus *et al.* in press). Some species are habitat specialists that directly utilize the legacy of recently killed trees; for instance, black-backed woodpeckers (*Picoides arcticus*) are almost completely restricted to early post-fire conditions (Hutto 2008). Mountain bluebirds (*Sialia currucoides*) and several other woodpecker species also favor structurally rich, early-successional habitats (Figure 5). Observed population declines of many avian species in eastern North America – which, in some cases, have proceeded to a point of conservation concern – are linked to conversion of early-successional habitat to closed forest (Litvaitis 1993).

Small mammal communities in ESFEs typically show high levels of diversity as well, including some obvious habitat specialists. The eastern chestnut mouse (*Pseudomys gracilicaudatus*), for example, inhabits early-successional environments in coastal eastern Australia for 2–5 years after a wildfire, and then declines dramatically until these environments are burned again (Fox 1990). Populations of mesopredators (medium-sized predators, such as raccoons [*Procyon lotor*] and fox species) benefit from the abundance of small vertebrate prey items characteristic of ESFEs. Likewise, some species of large mammals are well known to favor ESFEs (Nyberg and Janz 1990). Utilizing the diverse and luxuriant forage characteristically present in these ecosystems, ungulates, such as members of the Cervidae, in turn serve to benefit large predators (eg wolves [*Canis lupus*]) as well as scavengers, making ESFEs important elements within those species' typically extensive home ranges. Omnivores, such as bears (*Ursus* spp), also rely on the diversity of food sources often present in ESFEs.

Food web diversity

ESFEs are exceptional in the diversity and complexity of food webs they support. Simply stated, a diverse plant community produces many food sources. Food resources for herbivores (grasses, shrubs, forbs) – as well as nectar, seeds, and shrub-borne fruit (eg produced by *Rubus* and *Vaccinium* spp [huckleberry]) – can reach high levels before site dominance by trees. In the temperate Northern Hemisphere, biologically important berry production is maximized in slowly reforesting ESFEs. Resource production in early-successional patches may even augment the richness of adjacent undisturbed forests, as in the case of fluxes of key prey species (Sakai and Noon 1997).

Aquatic biologists have, perhaps, best appreciated the greater complexity of food chains in early-successional versus closed forest environments (Bisson *et al.* 2003). In established forest stands, trees strongly dominate the physical and biological conditions in nearby small streams by controlling light and temperature, stabilizing channels, providing woody debris, and, importantly, offering allochthonous inputs (organic matter originating outside the aquatic ecosystem) – the primary energy and nutrient source for such ecosystems (Vannote *et al.* 1980).

Stand-replacement disturbances remove forest constraints on conditions and processes, and shift streams to an early-

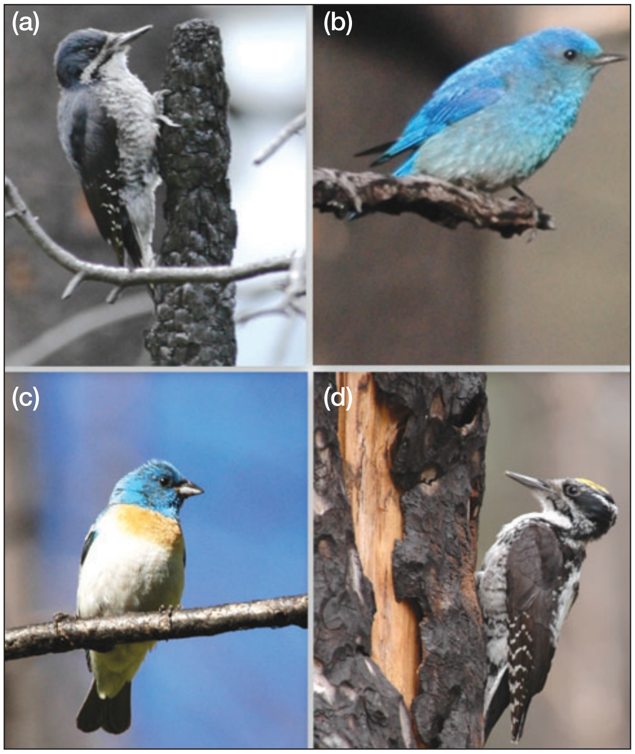

Figure 5. *Bird diversity is typically high in early-successional communities on forest sites and includes many habitat specialists: (a) black-backed woodpeckers (*Picoides arcticus*) are almost entirely restricted to early post-fire habitat; (b) mountain bluebirds (*Sialia currucoides*) favor early-successional ecosystems; (c) lazuli buntings (*Passerina amoena*) and (d) three-toed woodpeckers (*Picoides tridactylus*) have similar requirements.*

successional context (Minshall 2003; Figure 6). This greatly diversifies the types and timing of allochthonous inputs, as well as increases primary productivity. Allochthonous inputs are shifted from primarily tree-derived litter (coniferous-based in many systems) to material from a range of flowering herbs, shrubs, and trees, as well as from conifers. Consequently, litter inputs are highly variable in quality (eg decomposability) and delivery time, as compared with litterfall contributed primarily by evergreen conifer species. Also, inputs to post-disturbance streams often include material with a high nitrogen content, such as litter from the early-successional genera *Alnus* and *Ceanothus* (Hibbs *et al.* 1994).

Greater algal production may increase the diversity and abundance of aquatic invertebrate populations, which, in turn, become prey for fish and other organisms. However, increases in sediment production associated with disturbances can negate some benefits to aquatic processes and organisms (Gregory *et al.* 1987).

■ Processes in ESFEs

Ecosystem processes in ESFEs can be more diverse than those in closed forest systems, where the primary productivity of trees is dominant and organic matter is processed primarily through detrital food webs. Development of more diverse, and perhaps more "balanced", trophic pathways is possible when a disturbance opens a previously closed forest canopy. The contrast is probably greatest in forests dominated by a single tree type, such as evergreen conifers, as opposed to more diverse forests, such as mixed evergreen associations.

Recharging nutrient pools

ESFEs provide major opportunities for recharge of nutrient pools, such as additions to the nitrogen pool by leguminous (eg *Lupinus*) and some non-leguminous early-successional (eg *Alnus* and *Ceanothus*) plant species. These genera are commonly absent from late-successional forests, but are well represented in ESFEs. Nitrogenous additions from these sources are particularly important where the disturbance – eg a wildfire – has volatilized a substantial amount of the existing nitrogen pool.

Mineralization rates of organic material are typically accelerated (sometimes profoundly) after disturbances, as a result of warmer growing season temperatures. Diversified litter inputs in ESFEs, including a greater proportion of easily decomposed litter from herbs and deciduous shrubs, also result in more rapid mineralization. Finally, successional changes in the fungal and microbial communities can also hasten decomposition processes. As noted, these changes will be most profound in forest ecosystems dominated by a single species, including evergreen conifers or hard-leaved, evergreen hardwoods (such as the ash-type eucalypt forests of southeastern Australia).

In aquatic ecosystems that experience fire in adjacent forests, greater post-disturbance light and nutrient availability enhance primary productivity within the water body, causing shifts in food webs from the level of primary producers up through high-level consumers, such as fish (Spencer *et al.* 2003).

Modifying hydrologic and geomorphic regimes

Hydrologic regimes associated with ESFEs contrast greatly with those characterizing closed forest cover. For example, transpiration and interception are dramatically reduced and recover only gradually as forest canopies redevelop. Increases in normally low summer flows and annual water yields may occur immediately after a disturbance, as compared with levels in the dense young forests that may subsequently develop (Jones and Post 2004). The opposite may be true in systems where condensation of cloud or fog on tree crowns is an important component of the hydrologic cycle. ESFEs may also contribute to increased discharge peak runoff flows in hydrologic events of smaller magnitude (Harr 1986), but appear to have little effect on the magnitude of peak flows during large runoff events (Grant *et al.* 2008). From an ecological perspective, this may have a positive outcome, however, because floods restructure and rejuvenate many riparian communities (Gregory *et al.* 1991).

Rates and patterns of geomorphic processes, such as erosion and nutrient leaching losses, are also different between ESFEs and later successional stages. Tree death results in a loss of root strength that is critical for stabilizing soils and deeper rock layers on mountain slopes (Perry *et al.* 2008). Erosion and landslides may occur at higher rates in ESFEs, contributing to the variability of sediment budgets in watersheds (Reeves *et al.* 1995) and creating long-lasting substrates for ruderals. While enhancing erosion processes, ESFEs also provide materials and processes that counteract this effect, such as woody debris, which retain sediments and organic materials, and surviving vegetation, which stabilizes slopes and nutrient stores (eg Bormann and Likens 1979).

Figure 6. *Streams within early-successional forest ecosystems contrast with forest-dominated reaches in many ecosystem attributes, including physical parameters (temperature and insolation), structure, plant and animal composition, and ecosystem processes, such as primary productivity.*

Land management implications

Incorporating ESFE attributes into forest policy and management is highly desirable, given the numerous advantages provided by these ecosystems. Many species and ecological processes are strongly favored by conditions that develop after stand-replacement disturbances. Rapid, artificially accelerated "recovery" of disturbed forest areas (eg via dense planting) to closed forest conditions has serious implications for many species. Clearly the term "recovery" has a different meaning for such early-successional specialists or obligates.

To fulfill their full ecological potential, ESFEs require their full complement of biological legacies (eg dead trees and logs) and sufficient time for early-successional vegetation to mature. Where land managers are interested in conservation of the biota and maintenance of ecological processes associated with such communities, forest policy and practices need to support the maintenance of structurally rich ESFEs in managed landscapes. Natural disturbance events will provide major opportunities for these ecosystems, and managers can build on those opportunities by avoiding actions that (1) eliminate biological legacies, (2) shorten the duration of the ESFEs, and (3) interfere with stand-development processes. Such activities include intensive post-disturbance logging, aggressive reforestation, and elimination of native plants with herbicides.

In particular, post-disturbance logging removes key structural legacies, and damages recolonizing vegetation, soils, and aquatic elements of disturbed areas (Foster and Orwig 2006; Lindenmayer *et al.* 2008). Where socioeconomic considerations necessitate post-disturbance logging, variable retention harvesting (retention of snags, logs, live trees, and other structures through harvest) can maintain structural complexity in logged areas (Eklund *et al.* 2009).

Prompt, dense reforestation can have negative consequences for biodiversity and processes associated with ESFEs, by dramatically shortening their duration. Such efforts reduce spatial and compositional variability characteristic of natural tree-regeneration processes, promote structural uniformity, and initiate intense competitive processes that eliminate elements of biodiversity that might otherwise persist. Artificial reforestation can also reduce genetic diversity by favoring dominance by fewer tree species/genotypes, and may make the system more prone to subsequent, high-severity disturbances (Thompson *et al.* 2007). The elimination of shrubs and broad-leaved trees through herbicide application can alter synergistic relationships, such as the belowground mycorrhizal processes provided by certain shrub species (eg *Arctostaphylos* spp).

Naturally regenerated ESFEs are likely to be better adapted to the present-day climate and may be more adaptable to future climate change. The diverse genotypes in naturally regenerated ESFEs are likely to provide greater resilience to environmental stresses than nursery-grown, planted trees of the same species. Given that climate change is also resulting in altered behavior of pests and pathogens (Dale *et al.* 2001), encouraging greater tree species diversity may also increase ecosystem resilience.

Clearcutting has been proposed as a technique to create ESFEs, but this can provide only highly abridged and simplified ESFE conditions. First, traditional clearcuts leave few biological legacies (eg Lindenmayer and McCarthy 2002), limiting habitat and biodiversity potential. Second, clearcuts are often quickly and densely reforested, and often involve the use of herbicides to limit competition with desired tree species. Clearcuts can provide some early-successional functionality (eg serving as nurseries or post-breeding habitat for many bird species in the southern US; Faaborg 2002), but this service is often truncated by prompt reforestation.

Management plans should provide for the maintenance of areas of naturally developing ESFEs as part of a diverse landscape. This should be in reasonable proportion to *historical* occurrences of different successional stages, as based on region-specific historical ecology. Major disturbance events provide managers with opportunities to incorporate a greater diversity of species and processes in forest landscapes and to enhance landscape heterogeneity. Some aspects of ESFEs can be incorporated into areas managed for production forestry as well, such as through variable retention harvest methods, the incorporation of natural tree regeneration, and extending the duration of herb/shrub communities in some portions of a stand by deliberately maintaining low tree stocking levels.

Finally, we suggest that adjustments in language are needed. Ecologists and managers often refer to "recovery" when discussing post-disturbance ecosystems, inferring that early seral conditions are undesirable and need to be restored to closed canopy conditions as quickly as possible. Emphasizing recovery as the management goal fails to acknowledge the essential ecological roles played by early-successional ecosystems on forest sites. It should also be considered that climate change and other factors may not permit "recovery" to pre-disturbance conditions.

Conclusions

Twentieth-century forest management objectives were centered on wood production and, later, on conservation and development of late-successional forests. Rapid regeneration of dense timber stands was frequently seen as a way to address both of these divergent objectives. Recognizing the ecological value of early-successional ecosystems on forest sites extends the ecological concerns associated with old growth to another "rich" period in a forest sere. This represents an important development in the evolution of holistic management of forest ecosystems, whereby large landscapes are managed for diverse seral stages.

ESFEs provide a distinctive mix of physical, chemical, and biological conditions, are diverse in species and processes, and are poorly represented and undervalued in traditional forest management. Forest policy and practice must give serious attention to sustaining substantial areas of ESFEs and their biological legacies. Similarly, scientists need to initiate research on the structure, composition, and function of ESFEs in different regions and under different disturbance regimes, as well as on the historical extent of these systems, to serve as a reference for conservation planning.

Abstract. Fire Regime Condition Class (FRCC) has been developed as a nationally consistent interagency method in the US to assess degree of departure between historical and current fire regimes and vegetation structural conditions across differing vegetation types. Historical and existing vegetation map data also are being developed for the nationwide LANDFIRE project to aid in FRCC assessments. Here, we compare selected FRCC and LANDFIRE vegetation characteristics derived from simulation modeling with similar characteristics reconstructed from tree-ring data collected from 11 forested sites in Utah. Reconstructed reference conditions based on trees present in 1880 compared with reference conditions modeled by the Vegetation Dynamics Development Tool for individual Biophysical Settings (BpS) used in FRCC and LANDFIRE assessments showed significance relationships for ponderosa pine, aspen, and mixed-conifer BpS but not for spruce–fir, piñon–juniper, or lodgepole pine BpS. LANDFIRE map data were found to be ~58% accurate for BpS and ~60% accurate for existing vegetation types. Results suggest that limited sampling of age-to-size relationships by different species may be needed to help refine reference condition definitions used in FRCC assessments, and that more empirical data are needed to better parameterize FRCC vegetation models in especially low-frequency fire types.

Additional keywords: reference conditions, successional classes, Vegetation Dynamics Development Tool (VDDT).

Introduction

Altered fire regimes and associated changes in vegetation structure, composition, and fuels pose risks to biodiversity, sustainable ecosystems, and economic and community interests across the United States (USDA/USDI 2000). However, the magnitude of these risks varies between ecosystems as a result of differences in their fire and vegetation histories, successional, compositional, and structural dynamics, and the influence of invasive species (Morgan *et al*. 2001; Schoennagel *et al*. 2004). Fire exclusion over the 20th century has not affected all ecosystems uniformly, and accurate characterization of historical fire regimes and recent vegetation changes is critical to inform management decisions about the need for fuel treatments or ecological restoration across differing plant communities.

Use of historical fire regimes and vegetation conditions to inform fire and fuel management decisions in the US has been refined into the Fire Regime Condition Class (FRCC) concept (Hann and Bunnell 2001; Schmidt *et al*. 2002; Hann and Strohm 2003; Hann *et al*. 2003; Shlisky and Hann 2003). FRCC is an index that compares current with historical fire regimes and vegetation composition and structure to assess degree of departure on a scale from one (least departed) to three (most departed). FRCC is based on an assumption that historical processes and patterns (those present before widespread Euro-American settlement in the mid- to late-1800s) represent longer-term sustainable ecosystem conditions, and that greater departure in current conditions represents a greater risk for uncharacteristic fire behavior and associated ecosystem impacts. Initial coarse-level (1-km^2 resolution) FRCC maps described the degree of departure at a national scale (Schmidt *et al*. 2002). After this initial effort, a set of standard guidebook methods was developed to assess FRCC at landscape to stand scales for local management and planning needs (at time of writing, FRCC Guidebook v1.3; Hann *et al*. 2004). FRCC maps of 30-m^2 resolution are also being developed as part the LANDFIRE project, an effort to provide consistent vegetation, fuels, and fire regime data for the entire US (Rollins and Frame 2006; www.landfire.gov, accessed 19 October 2007). FRCC is now a key variable for defining wildfire risk to ecosystems as a result of its explicit incorporation into the Healthy Forests Restoration Act of 2003 (HFRA 2003). FRCC represents a significant advance in the integration of fire and forest histories and landscape and vegetation ecology to provide an ecologically based method for setting fire-management priorities and objectives across the US (Shlisky and Hann 2003).

Definition of departure indices in FRCC assessments begins with simulation modeling of historical vegetation composition and structure using the Vegetation Dynamics Development Tool (VDDT; Beukema and Kurz 2003). VDDT is used to develop non-spatially defined reference conditions within Biophysical Settings (BpS; formerly referred to as Potential Natural Vegetation Groups (PNVG); Küchler 1964; NRCS 2003). For LANDFIRE, BpS are derived from Nature Serve's ecological

 10.1071/WF08001 1049-8001/10/010001

classification system (Comers *et al*. 2003) and are not directly comparable with those used in FRCC assessments. However, both systems use BpS in a similar manner to represent the vegetation communities that would likely exist under given environmental conditions (climate, soils, and landscape physiography) and historical disturbance regimes. BpS in LANDFIRE are assigned to specific locations in their nationwide mapping efforts, whereas BpS in FRCC assessments are non-spatial and assigned based on individual user needs for specific projects or management requirements. Reference conditions are the proportions of vegetation successional stages (community structure and composition) as affected by varying fire frequencies, severities, and successional pathways within each BpS (Hann *et al*. 2004).

FRCC and LANDFIRE vegetation models (also known as Vegetation Dynamics Models) were defined during regional professional workshops conducted between 2002 and 2009 (2005–09 for LANDFIRE). VDDT model inputs for individual BpS are based on historical fire regime characteristics (frequency and severity) and vegetation data derived from published and unpublished studies and expert opinion developed both at the regional workshops and through subsequent peer reviews (Hann *et al*. 2004). The amount and quality of available historical data for each BpS vary, which can affect the quality and accuracy of the resulting modeled reference conditions. In an FRCC assessment, a field evaluation is conducted of existing vegetation structure, which, in forests, is based on cover type, density of tree stands, tree size, and current successional status. Successional status is determined by visually estimating stand composition, tree density, and average tree age, the latter of which is based on tree diameters. Proportions of current successional classes in a project or management area are estimated during the field assessment and then compared with the proportions of reference conditions derived from VDDT model output. The FRCC departure index (1 to 3) is assigned based at least partially on differences in proportions of successional classes present in the current forest relative to modeled reference conditions in the historical forest.

There is a need to test the process of development of reference conditions by comparing VDDT model output with known fire and vegetation histories. This comparison is critical for assessing consistency and accuracy in the modeling process. Here, we compare VDDT-modeled reference conditions with tree-ring-based reconstructions of reference conditions from 11 forested sites in Utah and eastern Nevada (tree-ring data reported in Heyerdahl *et al*. 2005, and Brown *et al*. 2008*a*). The tree-ring reconstructions span transects aligned along elevation gradients that include multiple forest types. We ask the following questions with this comparison: (1) do FRCC methods of evaluating stand structure based on diameter estimates accurately represent ages of forest vegetation and is there variation based on species and site? (2) Do FRCC and LANDFIRE BpS models adequately capture the range of variation in proportions of reference conditions reconstructed by the tree-ring data? (3) Do LANDFIRE mapped data layers for BpS and Existing Vegetation Types (EVT) match the tree-ring plot data? (4) Can further empirical fire history and tree recruitment data be used to strengthen FRCC evaluation and reference condition modeling outputs? We consider this study to be only an initial test of FRCC and LANDFIRE vegetation modeling methods, but one that may provide an example for future testing needs.

Methods

Study area

Tree-ring sites used for this study extend from the Colorado Plateau of southern Utah, west to the Wah Wah Mountains in the eastern Great Basin of western Utah, and north to the Uinta and Bear River Mountains in northern Utah (Fig. 1, Table 1; Heyerdahl *et al*. 2005; Brown *et al*. 2008*a*). The region is a complex of valleys, mesas, canyons, plateaus, and mountains that range in elevation from ~900 to >3600 m. Forest types vary generally across elevation gradients. Piñon (*Pinus edulis* (PIED; four-letter codes are used in tables) and *P. monophylla* (PIMO)) and juniper (*Juniperus scopulorum* (JUSC) and *J. osteosperma* (JUOS)) savannas and woodlands occur at the lowest forest margins above desert shrublands or grasslands. Ponderosa pine (*Pinus ponderosa* (PIPO)) forests occur in montane zones in pure and mixed stands. Douglas-fir (*Pseudotsuga menziesii* (PSME)) often occurs in association with ponderosa pine on north-facing aspects and in relatively mesic sites. Mixed-conifer forests occur at intermediate elevations and include combinations of ponderosa pine, Douglas-fir, piñons, junipers, and firs (*Abies lasiocarpa* (ABLA) or *A. concolor* (ABCO)). Mixed-conifer forests also often occur in association with aspen (*Populus tremuloides* (POTR)). Aspen forms large (>100 ha) pure stands throughout the upper montane and lower subalpine zones across the study area except in the Great Basin. Lodgepole pine (*Pinus contorta* (PICO)) often forms pure stands at mid-elevations (1900 to 2800 m) or occurs in the mixed-conifer zone in northern Utah. Subalpine forests dominated by Engelmann spruce (*Picea engelmannii* (PIEN)) and firs occur at upper elevations (2350 to 3500 m). At the highest forested elevations (generally above 3000 m), pure Engelmann spruce forests occur in mesic sites whereas bristlecone pine (*Pinus longaeva* (PILO)) or limber pine (*P. flexilis* (PIFL)) are typically found in dry or rocky sites.

There was, in general, a gradient in fire frequency across the elevational gradient before fire exclusion that began at all sites in the late 1800s (Heyerdahl *et al*. 2005; Brown *et al*. 2008*a*). Fire occurrence was highest in the middle of the elevation range in ponderosa pine and drier mixed-conifer sites. Fire frequency progressively declined both above and below this middle-elevation zone. At upper elevations, generally moist conditions led to high fuel biomass, both living and dead, in many stands, but fewer years in which fuels were dry enough to ignite and spread. At lower elevations in the piñon–juniper woodlands, fuels were often dry enough to burn because of hotter and dryer fire seasons, but because of lower productivity, there were in general less continuous both aerial and surface fuels and fires were not able to spread. In the middle zone, both fuel amounts and moistures were just right (what has come to informally be called the ‘Goldilocks effect’), and able to burn often in wide-spreading fires.

Utah forests underwent a period of intensive grazing and land use beginning in the 1850s as a result of Euro-American settlement. Intensive grazing removed understorey species and began alteration of longer-term historical forest dynamics. Logging also affected forest structure in many areas. The tree-ring study found that cessation of historical patterns of fires began in

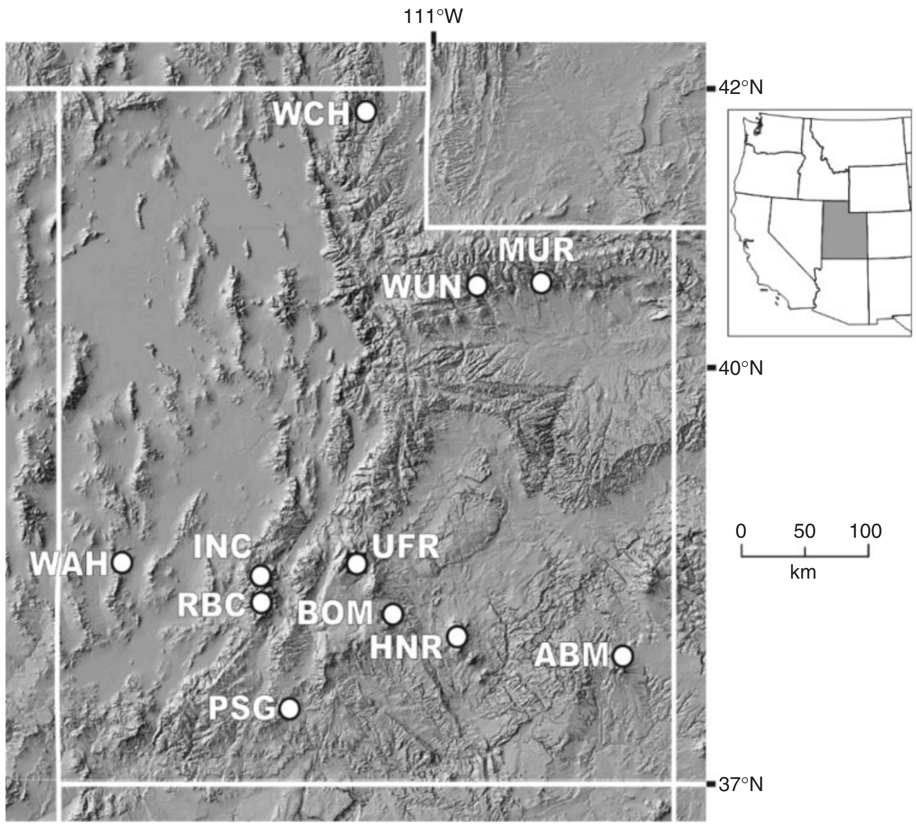

Fig. 1. Locations of tree-ring sites. Three-letter codes correspond to those in Table 1.

the 1860s to 1890s depending on location (Brown *et al*. 2008*a*), similar to patterns seen in forests throughout the western US. Initial reduction in fire frequency was likely the result of grazing that removed grass and herbaceous fuels, followed later by direct fire suppression in the 20th to 21st centuries.

Tree-ring data

The tree-ring study used a systematic sampling design to characterize stand and age structure and fire regimes across forest gradients in each site (Table 1; Heyerdahl *et al*. 2005; Brown *et al*. 2008*a*). Similar methods have been used in multiple studies

around the western US and are described in more detail in Heyerdahl *et al*. (2005, 2006), Brown and Wu (2005), Brown (2006), Brown *et al*. (2008*a*, 2008*b*), and Brown and Schoettle (2008). A 500-m grid was established at each site and plots sampled at grid points. Plot centers were located in the field using hand-held global positioning system (GPS) units. An *n*-tree density-adapted sampling method (Jonsson *et al*. 1992) was used to collect data from the nearest ~30 remnant (logs, snags, or stumps) or living trees >20 cm diameter at breast height (DBH) to each plot center. Maximum plot radius was set at 40 m (~0.5 ha) and most plots were ~<0.2 ha in size. For each plot tree, species was recorded and an increment core (on living trees) or cross-section (from logs, snags, and stumps) was collected from ~10 cm height above ground. Sampled cores had to be no more than a field-estimated 10 years from pith to minimize pith offset when assessing pith date. Diameter at sample height (DSH) and DBH were measured on living trees, and DSH was measured or estimated for remnant trees missing bark, sapwood, or heartwood. Distance from plot center and azimuth were measured on all trees for reconstruction of tree basal areas, density, and spatial patterning. To reconstruct surface fire history, cross-sections were cut from any fire-scarred trees found within plots. Additional fire-scarred trees also were sampled within ~80 m of each grid point and between grid points when discovered. GPS coordinates and species of fire-scarred trees outside of plots were recorded.

Standard dendrochronological methods were used to crossdate all samples using locally developed master chronologies (Heyerdahl *et al*. 2005). Pith dates were estimated on cores that did not intersect pith based on the curvature of the innermost rings sampled. The tree recruitment date is considered to be the date of tree pith at 10-cm height. No corrections were made for time to grow from germination to 10 cm sample heights because of the widely varying species and environmental conditions at the sites that were collected for the study. Once crossdating of ring series was completed on all samples, dates for any fire scars seen within the ring series were assigned. Any trees that were not able to be dated were not used in subsequent analyses.

FRCC and LANDFIRE vegetation models

VDDT modeling estimates the relative proportions of non-spatially defined reference conditions that would have occurred under a historical fire regime and an equilibrium (current) climate regime within each BpS (Beukema and Kurz 2003). VDDT input includes average fire frequencies, severities, and other disturbances defined as probabilistic events, and vegetation structural stage development pathways, including changes in species composition and density through a successional sequence. VDDT runs are commonly made for 500 years to allow vegetation conditions to equilibrate over time. VDDT output is proportions of vegetation successional classes – the reference conditions – across a non-spatially referenced landscape at the end of the 500-year model run. Reference conditions for most forest types are summarized into five seral stages that approximate overall developmental characteristics of community age and structure: early-replacement, mid-open, mid-closed, late-open, and late-closed. Each developmental stage represents a successional class defined by average tree age, species composition, structural characteristics, and response to disturbances. LANDFIRE and FRCC assessments use VDDT in a similar manner, but in LANDFIRE, reference condition proportions are then coupled with the spatial model LANDSUM (Keane *et al*. 2002) to map resulting vegetation conditions for each BpS across actual landscapes at a 30-m^2 spatial resolution.

FRCC and LANDFIRE developed their own BpS models using two different vegetation classification systems (Küchler 1964 *v.* Comers *et al*. 2003). Both systems attempt to describe the same historical vegetation using VDDT; however, their models use different probabilities for disturbance, and have somewhat different species distributions and geographic extents (often based on expert opinion; see http://frcc.gov, accessed 19 October 2007; www.landfire.gov for details).

Comparing tree-ring with FRCC and LANDFIRE data

We performed three tests to compare the tree-ring data with FRCC and LANDFIRE vegetation models. First, we compiled age and DBH data derived from the tree-ring study to assess whether FRCC methods of visual estimates of tree diameters accurately represent the age of forest vegetation for defining mid- and late-development classes of reference conditions. FRCC guidebook methods define >23 cm DBH as a visual indicator of a mature tree when conducting field assessments. For this analysis, we assumed that plots with trees averaging ≤23 cm DBH would be considered to be in a mid-development reference condition, and >23 cm would be in late-development. We conducted least-squares linear regressions to estimate fitness of tree age to DBH by species and site. As many of the regression models did not meet the statistical requirements of homoscedasticity, normality, and constant variance in model residuals, a logarithmic transformation was applied to the tree ages before regression. Models that had significant *P* values ($P < 0.05$) were considered to be representative of species growth estimates. We also conducted an analysis of variance (ANOVA) of age and diameter by species and site to both determine the strength of these relationships and how they varied by species and location across the region. All statistical analyses were conducted using the *Statistica* software (StatSoft Inc. 2008). The tree-ring study sampled a total of ~10 000 remnant and living trees; however, we only used data from the living trees for this part of our assessment. Dead trees (stumps, snags, and logs) often were missing bark, sapwood, or portions of the heartwood that reduced confidence in diameter estimates. The DBH-to-age analysis therefore consisted of 5173 living trees from 13 species from the 11 sites.

Our second test was whether VDDT modeled reference conditions captured the range of variation in reference conditions reconstructed by the tree-ring data as of a date of 1880. Dates of initial Euro-American settlement varied across the study area but all sites showed some Euro-American impact by 1880, including cessation of spreading fires in almost all of the sites (Brown *et al*. 2008*a*). As current vegetation may not be representative of past vegetation type, only species present in 1880 and their corresponding ages were used to assign BpS and reference condition to each of a total of 273 plots that were sampled from the 11 sites (Heyerdahl *et al*. 2005; Brown *et al*. 2008*a*). Both living and remnant trees were used to estimate the 1880 plot compositions. FRCC and LANDFIRE use key species to

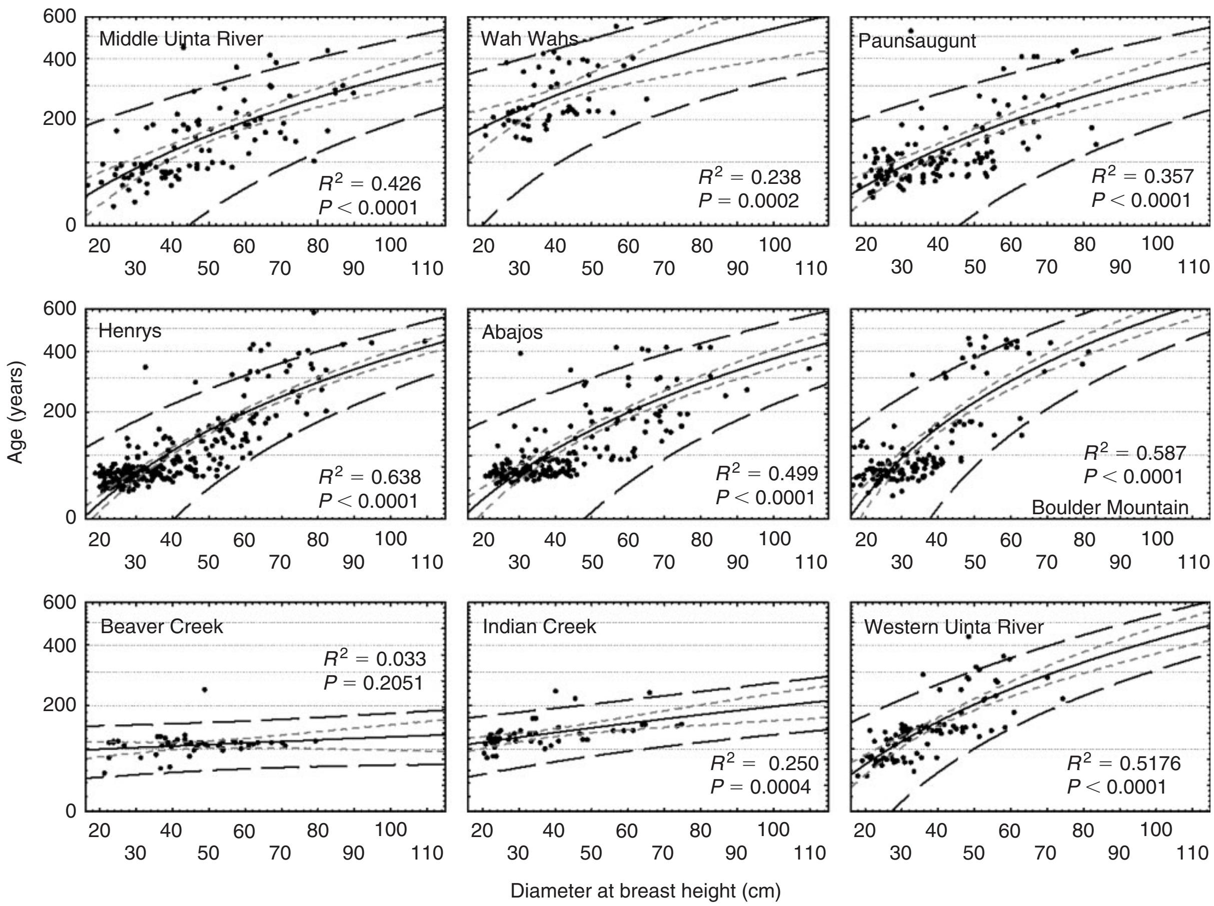

Fig. 2. Diameter at breast height (DBH) and log(age) regressions for ponderosa pine trees by site, with linear fits (solid lines), 95% confidence intervals (gray dashed lines), and 95% prediction intervals (black dashed lines). Overall R^2 for ponderosa pine trees across all sites was 0.44.

define vegetation characteristics when conducting an assessment and we used these species as the basis for assigning BpS and reference condition to each plot.

Historical age class and species composition in 1880 for each plot were compared with FRCC and LANDFIRE reference conditions for selected BpS. FRCC and LANDFIRE BpS descriptions are available on their respective project websites (www.frcc.gov; www.landfire.gov). We did not evaluate the typical five-stage VDDT models because of difficulties in using the tree-ring data to accurately recreate smaller size classes in historical stand densities as a result of probable tree mortality and decay since pre-settlement periods (e.g. Brown and Cook 2006; Brown *et al*. 2008*b*). However, we assume that we are able to define with some confidence mid- and late-development stands based on crossdated ages of trees present in each plot in 1880. The mean age of a 23-cm-DBH live tree varied by species, and we used the tree-ring results to estimate the upper 95% confidence interval for predicted tree size to consider whether a stand was late developmental stage in 1880. We grouped data from open and closed stands together based on age and composition for comparison with succession classes from VDDT output. If any trees in a plot were older than their predicted age-to-size confidence interval, the plot was considered to be in late-development in 1880. If there were no older trees during the historical period, then the plot was considered to have been in mid-development. If there were no trees during the historical period, the plot was considered to have no data and not used in this analysis. Once plots were categorized by BpS and reference condition, they were compared with FRCC and LANDFIRE BpS model proportions of mid- and late-development vegetation based on VDDT output. We used a Chi-square test to determine if the observed tree-ring reference condition proportions were significantly different than the expected based on the VDDT output.

Finally, we compared tree-ring plot data with LANDFIRE BpS and EVT map layers produced by the LANDFIRE project. LANDFIRE data are spatially mapped, which provided a unique opportunity to evaluate vegetation models at a high spatial resolution through comparison with the mapped tree-ring data. Plots were first located through their GPS coordinates relative to LANDFIRE map data. The BpS assignments we made for each plot in 1880 were then compared with LANDFIRE BpS map data. We also compiled the living tree composition in each plot and compared that with the LANDFIRE EVT map data. If key

species were present in the tree-ring data in comparison with the mapped BpS or EVT, then the grid point was considered to have been accurately mapped in LANDFIRE.

Results

Age–diameter relationships

DBH and tree ages exhibited generally broad relationships, both within species and among sites (Figs 2–4; Tables 2, 3). Ponderosa pine was the only species where age and size were strongly correlated using data from all sites ($R^2 = 0.438$, $P < 0.001$) and were strongly correlated over most of the individual sites (Table 2). There were outliers for most species by DBH and age; however, their deviance did not significantly change the results. Median tree age was predicted for trees at 23 cm using an inverse prediction with 95% confidence interval (Table 3). ANOVA results indicate that species associated with infrequent fire regimes (piñon–juniper, spruce–fir, and bristlecone pine; Heyerdahl *et al.* 2005) were found to have greater average ages than frequent fire species (especially ponderosa pine and Douglas-fir; Fig. 5). Variance of diameters relative to ages for species that contained a large sample n, such as Douglas-fir (PSME), ponderosa pine (PIPO), and Engelmann spruce (PIEN) was small. There was greater variance found in species that had fewer sampled trees and plots, such as bristlecone pine (PILO), Rocky Mountain juniper (JUSC), one-seed juniper (JUOS), limber pine (PIFL), and single leaf piñon (PIMO), but this result is likely an artifact of the smaller number of trees used in each regression. ANOVA indicated that DBH and age estimates for all sites were similar with the exception of WAH (Fig. 5). This may be explained by the large presence of fire-infrequent and older species (bristlecone pine, Rocky Mountain juniper, and one-seed juniper) that were sampled in that site.

FRCC and LANDFIRE BpS models

Median ages of trees >23 cm DBH were used to define the proportions of mid- and late-development reference conditions for trees present in plots in 1880 (Table 3). Reference condition proportions reconstructed from the tree-ring data compared favorably with FRCC BpS models for ponderosa pine (PPIN5), mixed-conifer (SPDF), and lodgepole (CHPI) but not for piñon–juniper (JUPI1, JUPI2), south-western mixed-conifer (MCAN) and spruce–fir (SPFI2, SPFI7; Table 4, Fig. 6). Reference condition proportions reconstructed from the tree-ring data

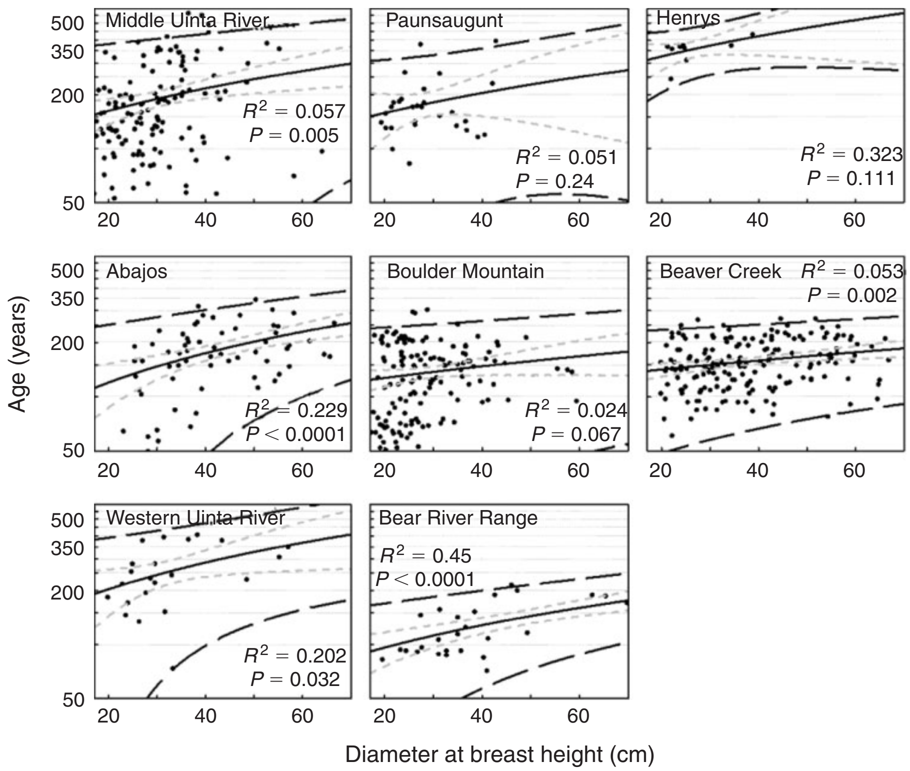

Fig. 4. Diameter at breast height (DBH) and log(age) regressions for Engelmann spruce trees by site, with linear fits (solid lines), 95% confidence intervals (gray dashed lines), and 95% prediction intervals (black dashed lines). Overall R^2 for Engelmann spruce trees across all sites was 0.06.

compared favorably with LANDFIRE BpS models for Rocky Mountain dry–mesic montane mixed-conifer (10510), aspen and aspen–mixed-conifer low- and high-elevation forests (10110, 10611, 10612), but not for piñon–juniper (10160), ponderosa pine (10540), Rocky Mountain mesic montane mixed-conifer (10520), Rocky Mountain subalpine dry–mesic spruce–fir forest and woodland (10550), and Rocky Mountain lodgepole pine (10500; Table 4, Fig. 6). The JUPI1 BpS model (Table 4) was the most different from the tree-ring data, although the JUPI2 model had a similar trend of a larger proportion of late-successional

stands in comparison with the tree-ring data (Fig. 6). Spruce–fir and lodgepole pine data both showed low correspondence with VDDT model results, including opposite trends of more older than younger stands in the tree-ring data in contrast to the VDDT modeled reference conditions (Fig. 6).

LANDFIRE map data

LANDFIRE map layers were found to be overall ~58% accurate for BpS and 60% accurate for EVT when compared with the tree-ring data for each plot (Table 5). LANDFIRE maps were 38% accurate for both BpS and EVT, 28% accurate for at least one type (17% EVT accurate and BpS inaccurate, with 11% BpS accurate and EVT inaccurate), and 34% inaccurate. Mixed-conifer and spruce–fir types had the highest accuracies by BpS for LANDFIRE with accuracies ranging from 64 to 82% for BpS and 67 to 79% for EVT. Piñon–juniper was the least accurately mapped BpS and EVT with 13 and 37% accuracy respectively.

Discussion

FRCC and LANDFIRE BpS models

Current stand conditions are determined through visual estimates of stand structure, including tree diameters, in FRCC assessments (Hann *et al*. 2004). FRCC assessments are designed to be a relatively rapid method of characterizing current vegetation and fire regime departures from historical conditions. The expense of collecting field data, such as canopy closure, canopy base height, tree density, stand age structure, and fire and stand histories, make field sampling impractical for FRCC assessments. However, based on the limited findings of this study, it appears that FRCC methods may result in inaccurate measures of plant community departure based on visually estimated

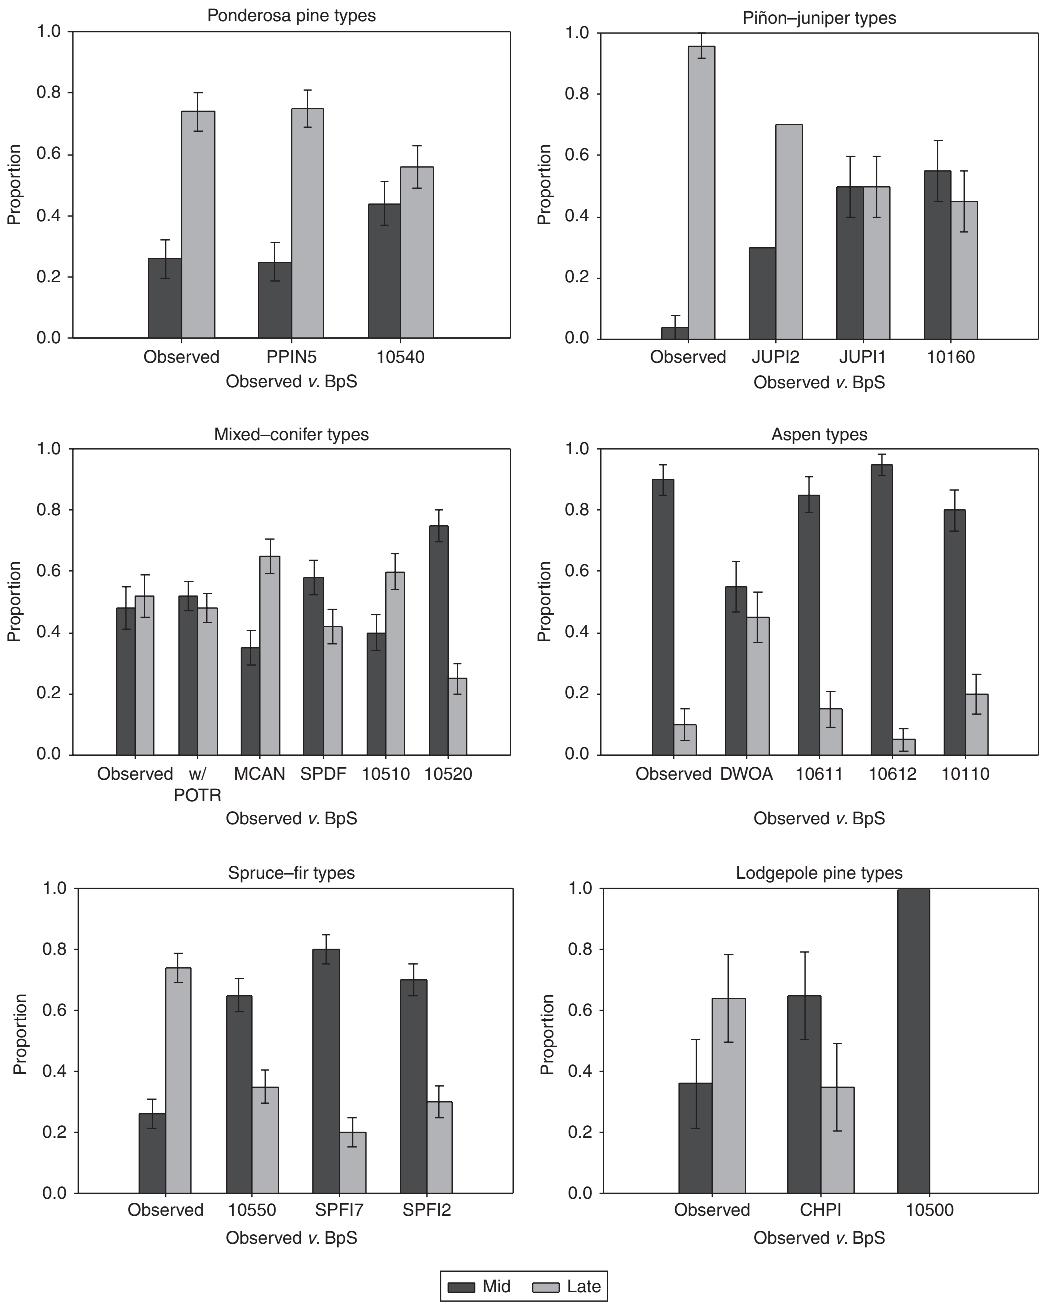

Fig. 6. Proportion of plots observed in the tree-ring data compared to FRCC (Fire Regime Condition Class) and LANDFIRE modeled reference condition proportions. Error bars were generated by calculating the 95% confidence interval from sample variance and standard error of observed points. Tree-ring results are on the left (e.g. observed), FRCC and LANDFIRE models are listed by their four-letter abbreviations on the right (e.g. PPIN5, 10540, etc.).

age–diameter relationships for determining reference condition proportions. Variations in age–size relationships both within species and among sites (Figs 2–5) may limit the ability to accurately gauge departure from estimated historical composition based on VDDT model results. Generally poor relationships between size and age may result in misassignment of current reference condition proportions based only on visual estimates, which may in turn lead to misassignment of the FRCC index.

Better correspondence between the tree-ring data and some BpS models indicates that VDDT models more accurately reflect historical forest structure in frequent-fire forest types such as ponderosa pine, mixed-conifer and aspen, than in

infrequent-fire types such as spruce–fir and piñon–juniper (Fig. 6). BpS reference condition models were determined by managers and scientists familiar with the local ecology of each region during regional workshops. BpS types that are considered to be representative of each region were identified and described based on available historical and ecological data. Some BpS types, such as ponderosa pine and dry mixed-conifer forests, have extensive fire and forest history data with which to parameterize VDDT model runs. Other BpS types are less well studied and their fire and vegetation histories less certain, especially across the range of environmental and community variation within and between regions. The better correspondence between modeled and reconstructed reference conditions in frequent-fire-type models (ponderosa pine and mixed-conifer forest types; Fig. 6) is likely related to the greater amount of fire and forest history research that has been conducted in these forest types. Conversely, fire-infrequent types (spruce, and piñon–juniper woodland types; Fig. 6) have had less fire history research conducted, with the result that their fire regimes and successional patterns are less well documented for input to VDDT modeling. Furthermore, infrequent-fire types generally have fewer observations of historical fires and forest successional changes available for adequate characterization of fire regime parameters for VDDT modeling (e.g. Brown *et al*. 2008*a*).

Another factor that undoubtedly results in varying model and data results is that individual-site fire histories often have experienced contingent historical events that lead to differences from a ‘typical’ or average fire regime of a particular forest type. Stochastic modeling in FRCC and LANDFIRE generalizes vegetation and its fire regimes into generic types and does not take into account site-specific variability or, more importantly, the history of climate variations or other disturbances that may have affected changes in community structure through time. Variations in site histories undoubtedly contribute to variations in ratios of actual from modeled reference conditions. For example, spruce–fir and lodgepole pine FRCC and LANDFIRE BpS models predict more mid- than late-development stands, but the Utah tree-ring data found the opposite (Fig. 6). This may be due to longer fire intervals in this region than in other areas, leading to generally older stands across landscapes. Many spruce trees found in the tree-ring study were >300 years old at the time of sampling and probably resulted from fires that occurred in the late 1600s, most commonly in 1685 (Heyerdahl *et al*. 2005). However, the current presence of older rather than younger stands does not mean that these forests are outside their historical ranges of variability in either their fire regime or forest structure, but rather that they have not had extensive fires in the intervening period that would have resulted in a larger proportion of mid-successional stands as suggested should be present based on VDDT model results. Without taking into account this history of the forest landscapes, the VDDT models suggest that there is current departure in the landscape proportions of reference conditions in Utah spruce–fir and lodgepole pine forests.

Taking into account differences in fire histories, the trend of model results toward older or younger successional classes in each BpS may be more important to consider in FRCC assessments rather than the absolute proportions of stand structures. This may provide a more realistic perspective for assessing whether a particular BpS should be considered as inside or outside of its historical range of variation. For example, the tree-ring fire data for piñon–juniper (P-J) woodlands show the majority of stands are currently in late-development structural stages (Fig. 6). The FRCC BpS model JUPI2 (Table 4) also predicts more late-development trees than younger, but underpredicts what was found in the tree-ring data. The sensitivity of the VDDT model to fire frequency is critical to the setting of reference conditions. The model inaccuracy may be due to the model’s fire

return interval, currently predicted to be ~450 years. If the interval is increased (~1000 years), the model begins to more closely reflect the tree-ring results. A recent assessment of (P-J) ecosystems in the western US concluded that fire was only a minor disturbance in many less productive stands because of lack of both surface and crown fuels with which to carry fire (Romme *et al*. 2009). We believe that many of the Utah stands sampled probably fell into this category of fire regime historically, which means that if the longer intervals had been used in VDDT modeling, the reference conditions would likely be closer to what was found in the tree-ring data. The error may also be due to the definition of a mid-development stand in terms of the age; the mean ages of sampled piñon and juniper were among the highest in the tree-ring study. The mid-definition could be changed for P-J to an older age class by species to define the mid- from late-successional classes in the reference conditions.

Good correspondence between the tree-ring data and models for ponderosa pine (PPIN5), aspen (10110), and mixed-conifer (SPDF, 10510; Fig. 6) suggests that the reference conditions for these BpS were accurately modeled by VDDT parameters, at least in the Utah study sites. However, results of this study suggest that inaccuracy in piñon–juniper and subalpine types makes any decision based on a VDDT output possibly subject to error. For BpS types in which disturbance may not be the major or only factor in tree recruitment, VDDT models may need further evaluation. Additional empirical disturbance and forest history sampling in piñon–juniper, spruce–fir, and lodgepole pine types should increase the available information about these systems to use in VDDT modeling. However, because of generally longer fire intervals in these forests, any departure from historical to present conditions may be less than in frequent-fire BpS such as ponderosa pine and mixed-conifer forests. A possible result of inaccurate estimations of departure and wrong FRCC classification may be the application of incorrect management actions that could lead to even further departure from historical conditions (see also Romme *et al*. 2009).

The only accurate way to establish the age of a stand is to physically sample the trees for ages. We suggest based on the results of our comparison that at least some limited age sampling is needed for FRCC assessments. This sampling probably should include removing cores from the field and crossdating by trained dendrochronologists to most accurately characterize age and successional status of stands. Additional field-sampled fire history and stand establishment data, especially in the less-well-studied ecosystems, should further increase the accuracy of VDDT models through better dynamic estimations of age structures and relationships with fire regimes. However, we also realize that this type of sampling is expensive and – perhaps more critically to the efficient use of FRCC in forest management decisions – more time-consuming than FRCC visual assessment methods as currently practiced. Nevertheless, we suggest that some sort of compromise solution could be found that would provide both the most accurate as well as timely data possible for FRCC assessment needs.

LANDFIRE maps

Zhu *et al*. (2006) used a cross-validation technique to determine that existing vegetation data layer accuracies are between 60 and 89% in LANDFIRE maps. Our study's comparison of LANDFIRE and tree-ring data falls on the lower end of the estimate of Zhu *et al*. (2006) (Table 4). When broken down by BpS and EVT, some types are more accurately represented in LANDFIRE data than others. EVT mapping in LANDFIRE is most accurate for the mixed-conifer and spruce–fir types. These forests generally have the densest and most continuous canopies, and may have been easiest to identify through remote sensing methods because of their continuous canopies and more distinctive NDVI reflectance in Landsat spectral bands (Zhu *et al*. 2006). Conversely, sparser canopy cover may have led to lower accuracy in other types such as piñon–juniper, which is similar to what Zhu *et al*. (2006) found. It should be noted, however, that piñon–juniper plots sampled for the tree-ring study were generally found in ecotonal areas near lower ends of study sites, and may not be wholly representative of piñon–juniper BpS as defined in the LANDFIRE mapping effort.

Conclusion

Historical forest conditions reconstructed from tree-ring data provide opportunities for comparison with FRCC and LANDFIRE modeled vegetation data across multiple forest types. The tree-ring reconstructions we examined suggest that reference conditions are better modeled in frequent-fire forest types but not necessarily in infrequent-fire forest types, at least in Utah forests. Additional studies in fire-infrequent forest types should increase understanding of historical stand compositions, fire histories, and other disturbances with which to better parameterize VDDT reference condition models. The greatest amount of fire history research has been conducted in ponderosa pine and mixed-conifer forests, which likely contributed to the better correspondence between tree-ring data and VDDT model results that we found in this study. We consider this study as only a first step in comparison of empirical vegetation data with vegetation models used in both FRCC assessments and the nationwide LANDFIRE mapping effort. Tree-ring data provide an opportunity to compare site-specific vegetation patterns and fire regime variations that are often not easily accounted for in modeling efforts. Revised methods for assessing FRCC may need to take into greater account both tree ages and stand histories to more accurately compare with model results. We also suggest that ranges of reference conditions be incorporated into the BpS classifications to better take into account fire and forest histories rather than trying to establish average conditions that must be met for a FRCC index to be assigned.

Acknowledgements

We are especially grateful to Emily Heyerdahl, Stan Kitchen, and Marc Weber for sharing data from the tree-ring project in Utah. The Utah project was funded by the Joint Fire Science Program, Fishlake National Forest, Rocky Mountain Research Station, Utah Bureau of Land Management, and Rocky Mountain Tree-Ring Research. We thank Brendan Ward, Kathy Schon, and Jim Menakis with the LANDFIRE project for sharing their expertise and data for this research. Phil Guertin, Steve Yool, Tom Swetnam, Wendel Hann, Steve Barrett, and three anonymous reviewers provided valuable comments on the manuscript. This research was funded by the National Interagency Fuels Technology Transfer Team that is responsible for development and updating of FRCC methods and vegetation models.

Abstract

Increasing numbers of homes are being destroyed by wildfire in the wildland-urban interface. With projections of climate change and housing growth potentially exacerbating the threat of wildfire to homes and property, effective fire-risk reduction alternatives are needed as part of a comprehensive fire management plan. Land use planning represents a shift in traditional thinking from trying to eliminate wildfires, or even increasing resilience to them, toward avoiding exposure to them through the informed placement of new residential structures. For land use planning to be effective, it needs to be based on solid understanding of where and how to locate and arrange new homes. We simulated three scenarios of future residential development and projected landscape-level wildfire risk to residential structures in a rapidly urbanizing, fire-prone region in southern California. We based all future development on an econometric subdivision model, but we varied the emphasis of subdivision decision-making based on three broad and common growth types: infill, expansion, and leapfrog. Simulation results showed that decision-making based on these growth types, when applied locally for subdivision of individual parcels, produced substantial landscape-level differences in pattern, location, and extent of development. These differences in development, in turn, affected the area and proportion of structures at risk from burning in wildfires. Scenarios with lower housing density and larger numbers of small, isolated clusters of development, i.e., resulting from leapfrog development, were generally predicted to have the highest predicted fire risk to the largest proportion of structures in the study area, and infill development was predicted to have the lowest risk. These results suggest that land use planning should be considered an important component to fire risk management and that consistently applied policies based on residential pattern may provide substantial benefits for future risk reduction.

Introduction

The recognition that homes are vulnerable to wildfire in the wildland-urban interface (WUI) has been established for decades [e.g., 1,2]; but with a recent surge in structures burning, this issue is now receiving widespread attention in policy, the media, and the scientific literature. Single fire events, like those in Greece, Australia, southern California, and Colorado have resulted in scores of lost lives, thousands of structures burned, and billions of dollars in expenditures [3–6]. With the potential for increasingly severe fire conditions under climate change [7] and projections of continued housing development [8], it is becoming clear that more effective fire-risk reduction solutions are needed. "Fire risk" here refers to the probability of a structure burning in a wildfire within a given time period.

Traditional fire-risk reduction focuses heavily on fire suppression and manipulation of wildland vegetation to reduce hazardous fuels [9]. Enormous resources are invested in vegetation management [10], but as increasing numbers of homes burn down despite this massive investment, the "business-as-usual" approach to fire management is undergoing reevaluation. One issue is that fuel treatments may not be located in the most strategic positions, i.e., in the wildland-urban interface [11]. Yet, even if treatments surrounded all communities, scattered development patterns are difficult for firefighters to reach [12–14], and fuel treatments do little to protect homes without firefighter access [15–16]. Fuel treatments may also be ineffective against embers or flaming materials that blow ahead of the fire front [17].

One alternative to traditional fire management that is receiving widespread attention is to prepare communities through the use of fire-safe building materials or creating defensible space around structures [17–18]. These actions represent an important shift in emphasis from trying to prevent wildfires in fire-prone areas to better anticipating fires that are ultimately inevitable. Nevertheless, the cost of building and retrofitting homes to be fire-safe can be prohibitive, and these actions do not guarantee immunity from fire [19].

Land use planning is an alternative that represents a further shift in thinking, beyond the preparation of communities to withstand an inevitable fire, to preventing new residential structures from being exposed to fire in the first place. The reason homes are vulnerable to fires at the wildland-urban interface is a function of its very definition: "where homes meet or intermingle with wildland vegetation" [20]. In other words, the location and

pattern of homes influence their fire risk, and past land-use decision-making has allowed homes to be constructed in highly flammable areas [21]. Land use planning for fire safety is beginning to receive some attention in the literature [22–23], and there is growing recognition of the potential benefits of directing development outside of the most hazardous locations [8,19,24].

Despite recent attention in the literature, land use planning for wildfire has yet to gain traction in practice, particularly in the United States. However, fire history has been used to help define land zoning for fire planning in Italy [22], and bushfire hazard maps are integrated into planning policy in Victoria, Australia [25]. Although some inertia inevitably arises from complications with existing policy and plans, a primary impediment to the design and implementation of fire-smart land use planning is lack of guidance about specific locations, patterns of development, or appropriate methodology to direct the placement of new development. Without a solid knowledge base to draw from, planners will be misinformed about which planning decisions may result in the greatest overall reduction of residential landscape risk. Even worse, poor science could result in placement of homes in areas that actually have high fire hazard.

Research on how planning decisions contributed to structures burning in the past provides some guidance about what actions may work in the future. Analysis of hundreds of homes that burned in southern California the last decade showed that housing arrangement and location strongly influence fire risk, particularly through housing density and spacing, location along the perimeter of development, slope, and fire history [26]. Although high-density structure-to-structure loss can occur [27–28], structures in areas with low- to intermediate- housing density were most likely to burn, potentially due to intermingling with wildland vegetation or difficulty of firefighter access. Fire frequency also tends to be highest at low to intermediate housing density, at least in regions where humans are the primary cause of ignitions [29–30].

These results suggest, for example, that placing new residential development within the boundaries of existing high-density developments or in areas of low relief may reduce fire risk. However, it is difficult to know whether broad-scale planning policies would actually result in the intended housing arrangement and pattern at the landscape scale, and whether those patterns would result in lower fire risk. Our objective here was to simulate three scenarios of future residential development, and to project wildfire risk, in a rapidly urbanizing and fire-prone region where we have studied past structure loss [25]. We based all future development on an econometric subdivision model, but we varied the emphasis of subdivision decision-making based on three broad and common growth types.

Although cities vary in extent, fragmentation, and residential density [31–32], urban form typically adheres to a set of common patterns [33–34], and we based our development scenarios on the three primary means by which residential development typically occurs: infill, expansion, or leapfrog [34]. Infill is characterized by development of vacant land surrounded by existing development, typically in built-up areas where public facilities already exist. [35–36], and should result in higher structure density rather than increased urban extent. Expansion growth occurs along the edge of existing development, extends the size of the urban patch to which it is adjacent, and may have variable influence on structure density. Leapfrog growth occurs when development occurs beyond existing urban areas such that the new structure is surrounded by undeveloped land. This type of growth would expand the urban extent and initially result in lower structure density; but these areas may eventually become centers of growth from which infill or expansion can occur. We asked:

1) Do residential development policies reflecting broad growth types affect the resulting pattern and footprint of development across the landscape?
2) Do differences in extent, location, and pattern of residential development translate into differences in wildfire risk, based on the current configuration of structures?
3) Which development process, infill, expansion, or leapfrog, results in the lowest projected fire risk across the landscape?

Methods

Study Area

The study area included all land within the South Coast Ecoregion of San Diego County, California, US, encompassing an area of 8312 km^2. The region is topographically diverse with high levels of biodiversity, and urban development has been the primary cause of natural habitat loss and species extinction [37]. Owing to the Mediterranean climate, with mild, wet winters and long summer droughts, the native shrublands dominating the landscape are extremely fire-prone. San Diego County was the site of major wildfire losses in 2003 and 2007 [38], although large wildfire events have occurred in the county since record-keeping began, and are expected to continue, as fire frequency has steadily increased in recent decades [29,39]. The county is home to more than three million residents, and approximately one million more people are expected by 2030 [40]. Although most residential development has been concentrated along the coast, expansion of housing is expected in the eastern, unincorporated part of the county.

Econometric Subdivision Model

A host of alternative modeling approaches exist to simulate future land use scenarios [41], including a cellular automaton model that we previously applied to the study area [42]. We chose to use an econometric modelling approach for this study because we wanted to capture fine-scale, structure-level patterns and processes that are correlated with housing loss to wildfire [26]; and econometric models may perform better at the scale of individual parcels [43].

Although we based the three development scenarios on generalized planning policies, we also wanted to ensure that the residential projections were realistic and adhered to current planning regulations. The objective of the econometric modeling was to estimate the likelihood that residential parcels will subdivide in the future. Therefore, we used a probit model to estimate the transition probability of each parcel based on a range of potential explanatory variables typically associated with parcel subdivision and housing development [44–45].

To develop the model of subdivision probability, we acquired GIS data of the county's parcel boundaries in years 2005 and 2009 from the San Diego Association of Governments (SANDAG). The dependent variable was equal to 1 if a parcel subdivided between 2005 and 2009, and zero otherwise. Using these data layers we first determined which parcels were legally able to subdivide given current land use regulations. Minimum lot size restrictions are typically considered the most import restriction for determining future land use. We deemed a parcel eligible for subdivision if the current lot size was greater than twice the minimum legal size given the land class. To determine which parcels subdivided between 2005 and 2009, we queried parcel IDs where the total

area was reduced by at least the minimum lot size between the two time periods. Finally, we were able to generate a suite of variables that determine the likelihood of a parcel developing in the future (Table S1).

We overlaid the parcel boundaries over a range of GIS layers representing our explanatory variables. These data are available to download at (http://www.sandag.org/index.asp?subclassid = 100&fuseaction = home.subclasshome). Our explanatory variables included: parcel size, parcel size squared, six dummy variables which capture non-linear effects of parcel size, distance to the coast, distance to the coast squared; distance to city center and its square, current zoning, slope, land use, roads, if the parcel is in a protected area, if the parcel is in a development area, if the parcel is in the redevelopment area (Table 1).

Spatial Model of Future Development under Planning Alternatives

The outcome of the land use change econometric model is the subdivision probability for each parcel for a five-year time step. Based on these probabilities, we developed a GIS spatial simulation model of future land use under three distinct planning scenarios: infill (development in open or low density parcels within already developed areas), expansion (development on the fringe of developed areas), and leapfrog (development in open areas). The model runs in four 5-year time steps from 2010 to 2030, and generates the spatial locations of new housing units in the county.

Although development decisions could feasibly depend on fire risk, we did not model that here. There is no evidence that fire has influenced past regional planning decisions, so it was not used as an explanatory variable in the econometric model. Although we could have evaluated the potential for future development decisions to be based in part on fire risk, this would have required simulation of feedbacks between fires and probability of development. Because our objective in this study was to isolate the effects of the three distinct growth types, we modeled fire risk only as a function of development pattern and not vice versa.

We constructed a complete spatial database of existing residential structures in the study area [26]. These structures and their corresponding parcel boundaries served as the initial conditions for all three scenarios of the spatial simulation model. The current and projected future GIS layers of structures were also subsequently used in the fire risk model (see below). The

dataset of existing housing includes locations of 687,869 structures, of which 4% were located within the perimeter of one of 40 fires that burned since 2001. During these fires, 4315 structures were completely destroyed, and another 935 were damaged.

For future development scenarios, we wanted to allocate an equal number of new structures to the landscape. This was to ensure that any predicted difference in fire risk was a function of the arrangement and location of structures, not the total number of structures. Nevertheless, differences in the total number of structures were simulated with each of the 5-year time steps. We determined the number of housing units to add during the simulations based on projections made by San Diego County [46]. Using factors such as development proposals, general plan densities, and information from jurisdictions, the county estimated that between 331,378 units and 486,336 units could be supported within the developable residential land by 2030. Because the eastern, desert portion of the county was not included in our study area, we used a conservative approach and simulated the addition of 331,378 new dwelling units. We divided this number by four to define the number of new dwelling units to add at each time step, assuming a linear growth rate.

One output of the econometric model was the prediction of the maximum number of new dwelling units that could be added to each parcel. However, dwelling units may consist of apartments as well as single family homes. The mix of single and multifamily units in the region has remained relatively constant over time, and the overall trend has been a mix of roughly 1/3 multifamily and 2/3 single family units. Because the fire risk model is based on points representing structure locations across the landscape, regardless of the number of dwelling units per structure, we needed to generate a conversion factor from dwelling units to structures. We therefore defined a minimum lot size of 0.25 acre on which no more than a single structure could be built, regardless of the number of dwelling units in it (i.e., a single family home or apartment complex). Then, once a parcel was selected for development by the model (see details below), we divided its total area by the maximum number of dwelling units to be added, according to the econometric model. If the result was larger than 0.25, we subdivided parcels according to the result. If not, we quantified how many 0.25 acre parcels fit into the original parcel, and generated the new parcel boundaries accordingly.

Using the initial map of parcels (year 2010), we classified each parcel that was defined as eligible for development (in the previous stage) as suitable for one of the three planning scenarios described above, according to the number of developed parcels in its immediate neighborhood (i.e., those parcels that share a boundary with the focal parcel). We defined 'developed parcels' as ones that had more than one house per 20 acres (8.09 ha). Therefore, according to these density thresholds, we allowed some parcels with nonzero housing density to be considered as 'undeveloped' because these large, rural parcels might contain a single or a handful of houses but they exist within a large open area. In other words, the overall land cover of these parcels was effectively undeveloped, and we therefore assumed that development in adjacent parcels would be akin to development in open areas.

We defined infill parcels as those that were completely surrounded by developed parcels. Expansion parcels had at least one neighboring parcel that was undeveloped; and leapfrog parcels were those with no developed parcels in their immediate surroundings. We reclassified the type of each available parcel in the same manner after each time step, to account for changing dynamics in the development map of the county.

We conducted three simulations, one for each development scenario (infill, expansion, and leapfrog). In each simulation, all parcels were eligible to subdivide, regardless of their class. Therefore, to build a simulation for a specific scenario, we increased the development probability of parcels of the selected scenario by 20%, to favor their development compared to the other types of parcels, without prohibiting development in the other parcel types. This approach was necessary because the projected number of dwelling units was much larger than it would be possible to fit in infill and leapfrog class parcels solely. For example, as the spatial coverage of developed parcel expands, there is less contiguous area that is undevelopable and suitable for leapfrog development. Therefore, the scenarios are not exclusive, but rather a mixture of the three development types. Yet, in each scenario, there is one main type of development, and smaller amounts of development events of the other two types.

Due to the immense computational demand of the simulations, we adopted a deterministic, rather than a stochastic approach to decide on which parcels were subdivided. After enhancing the transition probability according to the corresponding scenario, we ranked and then sorted all parcels according to their probability of subdivision. We then sequentially selected parcels, while simultaneously tallying the number of dwelling units in them, until the development target in that time step (one fourth of the total number of dwelling units to be added: 82,795) was reached. Once the development target was reached, we moved to the next time step. After each time step, the remaining parcels that were still eligible for development were re-classified to development types according to the new spatial configuration of the landscape.

Once a parcel was selected for subdivision, and the number of new parcels to develop in it was calculated (as detailed above), an equal-area spatial splitting model was employed to split the parent parcel to the predefined number of equal-area child parcels. We developed a simple splitting model which is based on iterative splitting of larger parcels into two smaller parcels using a straight line splitting boundary. Once the parcel was fully split into the needed number of sub-parcels, we allocated a new structure inside each new parcel by generating a point at its centroid (center of gravity). The point datasets of all structure locations per time step per scenario were passed over to the fire risk model, which is described below.

Fire Risk Modeling and Analysis

To project the distribution of fire risk under alternative scenarios, we used MaxEnt [47–48], a map-based modeling software used primarily for species distribution modeling [48], but we have used it successfully for ignition modeling [50] and for projecting current fire risk in the study area [26]. For this study, we slightly modified the model from Syphard et al. [26]. The dependent variable was the location of structures destroyed by fire between 2001 and 2010. Although inclusion of damaged structures in the data set does not significantly affect results [26], we only included completely destroyed structures to avoid the introduction of any uncertainty.

The MaxEnt software uses a machine-learning algorithm that iteratively evaluates contrasts among values of predictor values at locations where structures burned versus values distributed across the entire study area. The model assumes that the best approximation of an unknown distribution (i.e., structure destruction) is the one with maximum entropy. The output is an exponential function that assigns a probability to every cell of a map. Thus, the resulting continuous maps of fire risk represented the probability of a structure being destroyed by fire. In these output maps, areas of predicted high fire risk that did not have structures on them represented environmental conditions similar to those in which structures have actually burned.

We based the explanatory variables on those that were significantly related to burned structures in Syphard et al. [26], including maps depicting housing arrangement and pattern, housing location, and biophysical factors. Housing pattern variables reflected individual structure locations as well as the arrangement of structures within housing clusters. We calculated housing clusters, defined as groups of structures located within a maximum of 100 m from each other, by creating 100 m buffers around all structures and dissolving the overlapping boundaries [51].

Because burned structures were significantly related to small housing clusters [26], we calculated the area of every cluster as an attribute, and then created raster grids based on that attribute. Low-to intermediate housing density and distance to the edge of the cluster were also significant explanatory variables relative to housing pattern and location [26], so we also created raster grids for those. GIS buffer measures at 1-km have been found to explain approximately 90% of the variation in rural residential density [52], so we developed density grids using simple density interpolation based on a 1-km search radius, with area determined through square map units. To create grids representing distance to the edge of clusters, we first collapsed the cluster polygons into vector polyline files, and then created grids of interpolated Euclidean Distance to the edge within each cluster.

Because the MaxEnt model randomly selects background samples in the map to compare with locations of destroyed structures, we used a mask to restrict sampling to the developed environment within cluster boundaries; the distance to the edge of the cluster would represent a different relationship inside a cluster boundary versus outside in the wildland. We also modified the grids to ensure that any random sample located within the 100m buffer zone would receive a value of 100m; thus, all points within the buffer were considered "the edge of the development".

After creating the grids representing housing pattern and arrangement of the current configuration of structures, we applied the same algorithms to the maps of simulated future structure locations. We thus generated grids representing future housing pattern and arrangement under alternative development scenarios. The other explanatory variables, including fire history, slope, fuel type, southwest aspect, and distance to coast [26] remained constant through time for current and future scenarios. Although historic fire frequency and fuel type typically change through time, we did not simulate their dynamics here because we wanted to isolate the effect of planning decisions on housing pattern and arrangement while holding everything else constant.

We conditioned the MaxEnt model on present distributions of housing using ten thousand random background points and destroyed structures located no closer than 500-m to minimize any effect of spatial autocorrelation. We used 80% (260 records) of these data for model training, and 20% [66 records) for testing. We repeated the process using cross-validation with five replicates and used the average of these five models for analyses. For smoother functions of the explanatory variables, we used hinge features, linear, and quadratic with an increase in regularization of beta set at 2.5, based on Elith et al. [48]. The smoother response curves minimize over fitting of the model. We conducted jackknife tests of explanatory variable importance.

We first developed the model using mapped explanatory variables derived from the current configuration of structures. To project fire risk under the different time steps of the alternative development scenarios, projected the model conditioned upon current conditions onto maps representing future conditions by substituting the grids representing future housing pattern and arrangement. This is similar to how potential future distributions of species are projected under climate change scenarios [49].

To quantify differences among current and future alternative scenarios, we calculated metrics representing housing density, pattern, and footprint to determine the extent to which the planning policies produced differences in housing pattern and location. We compared the modeled structure fire risk of the scenarios by overlaying all maps of structure locations with their respective mapped output grids from the MaxEnt models and calculating probability of burning for every structure point. We also calculated total area of risk by selecting three threshold criteria [53]. These criteria, at 0.05, 0.25, and 0.5 represented three different degrees of risk, and we calculated the proportion of structures that were located in risk areas for every time step in all scenarios.

Results

The probit econometric model, run on 113 001 observations, showed that larger parcels were most likely to subdivide, although the relationship between parcel size and subdivision probability was non-linear (Table 1). Parcels closer to existing roads, the ocean, those with lower slopes, and those designated as fit for development were all most likely to develop. Parcels designated in redevelopment areas were less likely to develop. Overall, the model had a pseudo r –squared of 0.22.

The land use simulation model, based on a combination of the econometric subdivision model and three different growth policies, resulted in substantial differences in the extent and pattern of housing of the three scenarios. The total area of housing development, or the housing footprint, was largest for simulations where leapfrog growth dominated, followed by expansion-type development, and then infill (Figure 1a). The differences in the housing footprint became larger among the scenarios over time, but the largest difference was between infill and the other two development types. As the housing footprint expanded in the three scenarios, the corresponding housing density declined, so that leapfrog growth resulted in the lowest housing density per 1-km, followed by expansion and then infill (Figure 2b). Despite the near inverse of this relationship, there was generally a larger separation among scenarios with regard to housing density. With larger housing footprints and lower housing density, the number of separate housing clusters increased while their size decreased (Figure 2c).

In the first two time steps of the model (2015 and 2020), the simulated development pattern closely followed the desired pattern in the scenario, although some of the growth in the infill scenario ended up becoming expansion or leapfrog (Table 2). In the last two time steps (2025 and 2030), there were not enough infill parcels left, and thus, the majority of growth in these simulations became expansion, followed by infill, and then leapfrog. In the last time step, there were not enough isolated parcels in the leapfrog scenario and thus, the majority of development became expansion. Thus in general, as more development occurred in the simulations by the year 2030, the majority took the form of expansion.

The area under the curve (AUC) of receiver operating characteristic (ROC) plots, indicating the ability of the MaxEnt model to discriminate between burned and unburned structures, averaged across five cross-validated replicate runs was 0.91. The AUC represents the probability that, for a randomly selected set of observations, the model prediction was higher for a burned structure than for an unburned structure [49].The two most important variables in the model according to the internal jackknife tests in MaxEnt [47] were related to housing pattern:

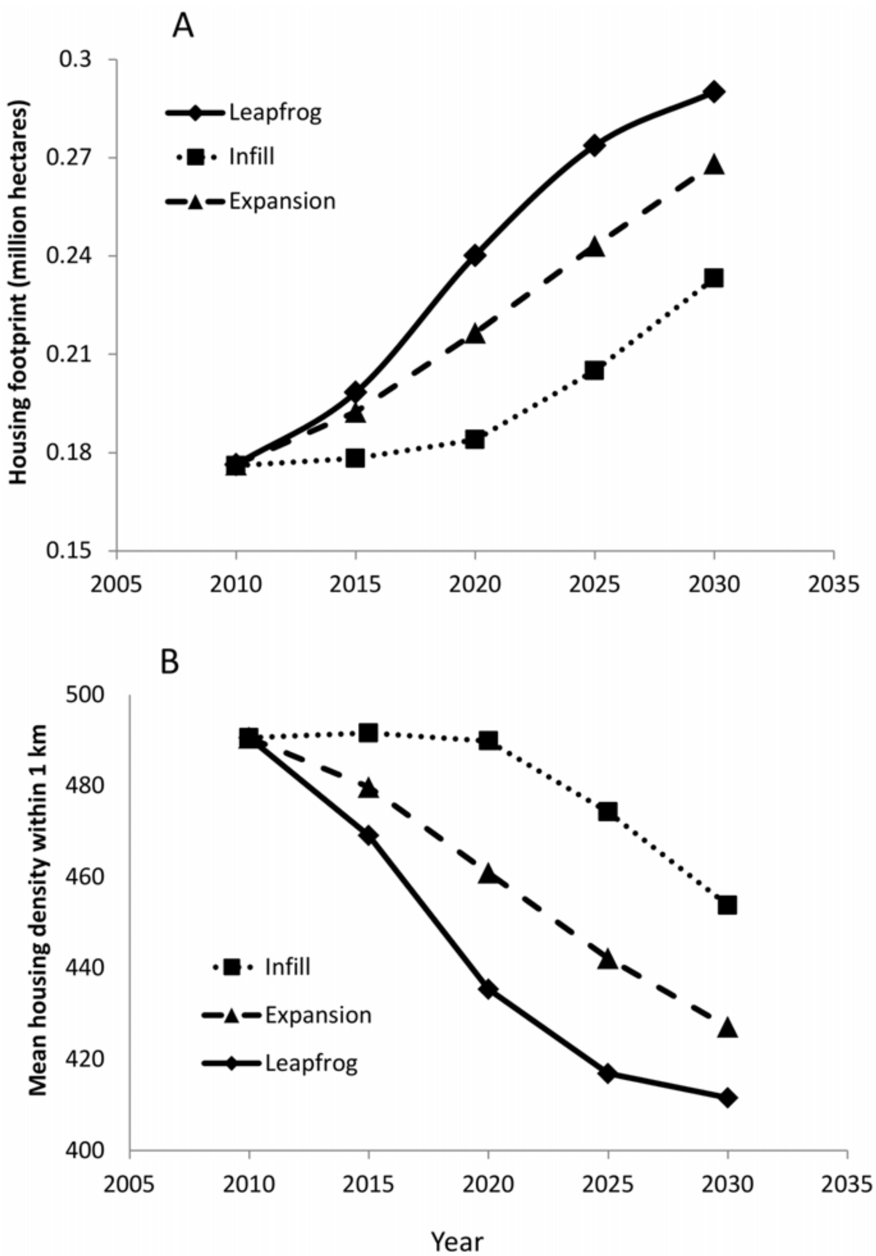

Figure 1. Trends of development extent and pattern for three planning policy simulations from 2010–2030, including A) total housing footprint representing the area of land within all housing clusters, and B) mean housing density averaged across all housing clusters.
doi:10.1371/journal.pone.0071708.g001

low to intermediate housing density and small cluster size and housing density (Figure 3). The distance to the edge of housing cluster was a less important contribution.

Maps showing the probability of a structure being destroyed in a wildfire, displayed as a gradient from low to high risk, show broad agreement relative to the general areas of the landscape that are riskiest, with correlation coefficients ranging from 0.85–0.91 (Figure 4). Nevertheless, subtle differences are apparent in the three development-scenario maps by year 2030, with the highest-risk areas in the expansion scenario located farther east than infill, and the highest-risk areas in leapfrog occupying a wider extent than either of the other two scenarios.

Differences among current housing and the three development scenarios are clearly illustrated through the mean landscape risk, or total probability of all structures burning (Figure 5). All three development scenarios were predicted to experience an increase in mean landscape risk over the duration of the simulations, except for infill at year 2015. The highest landscape risk to structures was predicted for the leapfrog scenario, followed by expansion, and then infill. The increase in risk over time is more gradual for the infill scenario than the other two scenarios.

The ranking of scenarios varied according to the proportion of structures located within different levels of risk defined through binary thresholding (Figure 6). When the continuous risk maps were thresholded at the lowest number of 0.05, a large proportion

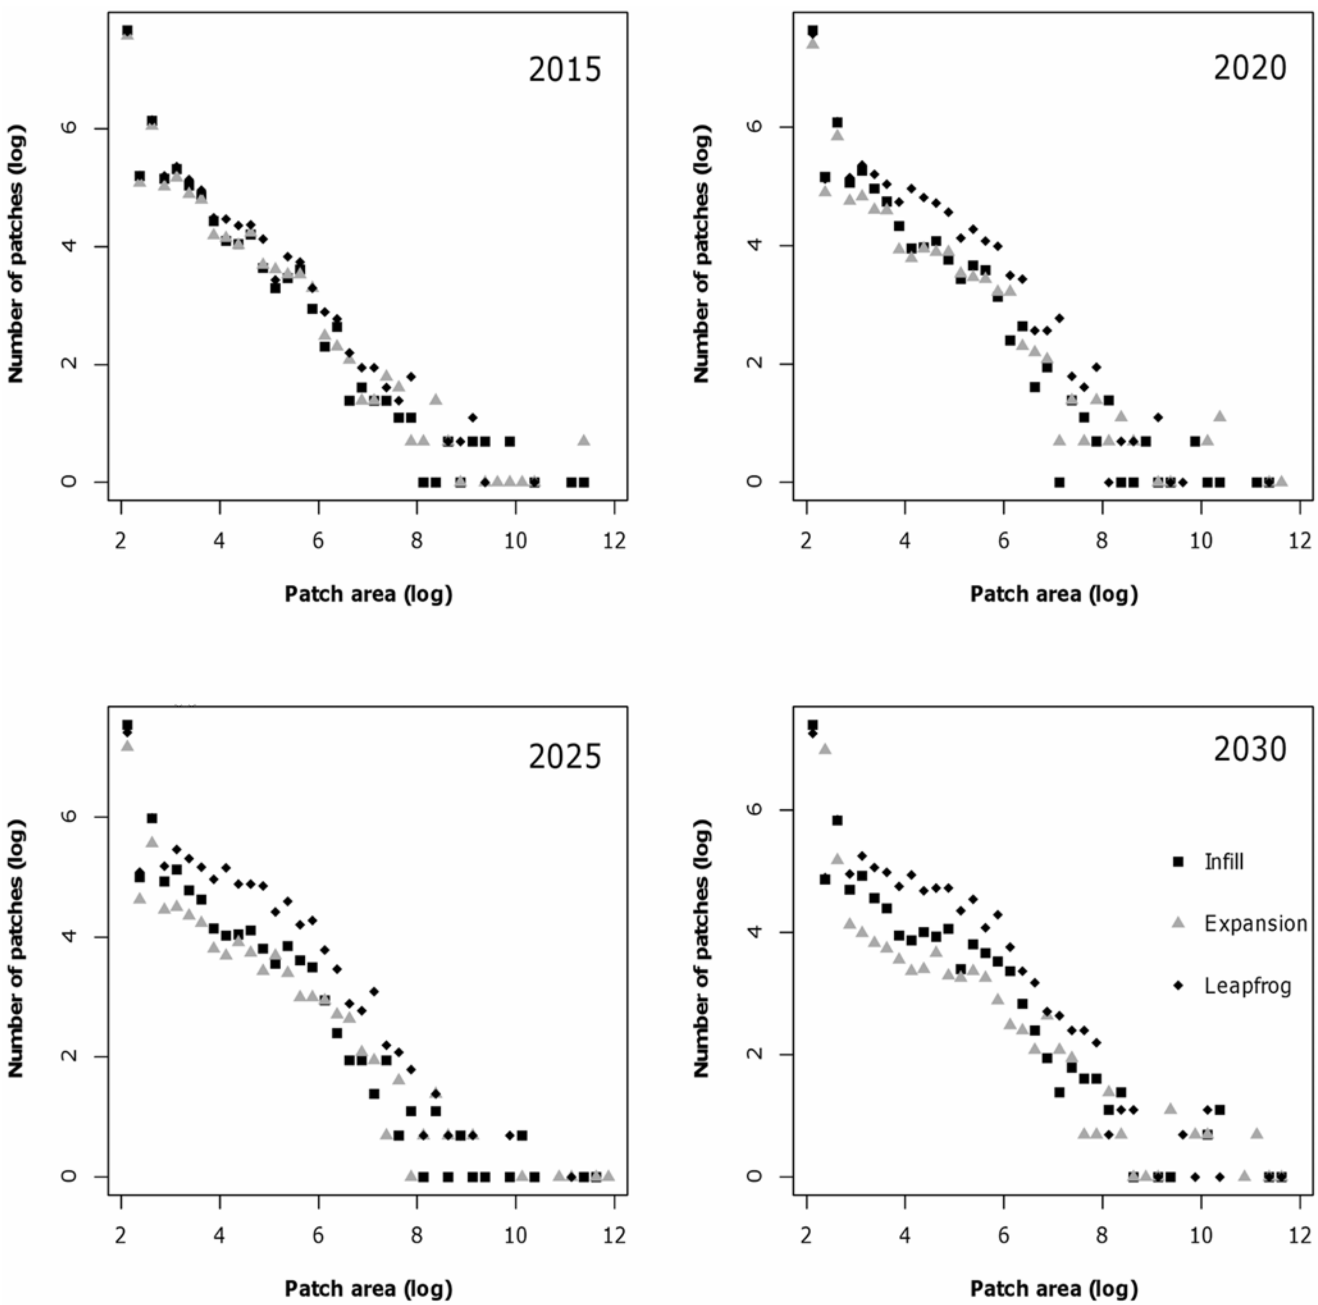

Figure 2. Trends in number of patches and patch area for three planning policy simulations from 2010–2030. Numbers were log-transformed for better visual representation of the scenarios.
doi:10.1371/journal.pone.0071708.g002

of structures in all scenarios fell within areas defined as risky according to this criterion. At this threshold, the proportion of structures in high-risk areas increased linearly for the expansion and leapfrog development scenarios while the proportion of infill homes increased more gradually. When risk was defined more conservatively at 0.25, temporal trends for the leapfrog and infill scenarios were similar to the 0.05 threshold. However, the proportion of structures at risk in the expansion scenario initially increased to 2020, but this proportion leveled off and declined by 2030. When the threshold was highest at 0.50, a very low proportion of structures in any scenario were located in areas at risk. But in these high-risk areas, the expansion scenario switched places with infill to have the lowest proportion of structures at risk in all time steps. Leapfrog had the largest proportion of homes at risk. This proportion of homes located in areas at risk with a threshold at 0.5 declined over time for all three scenarios.

Discussion

Our simulations of residential development showed that planning policies based on different growth types, applied locally for subdivision of individual parcels, will likely produce substantial and cumulative landscape-level differences in pattern, location, and extent of development. These differences in development pattern, in turn, will likely affect the area and proportion of

Table 2. Pattern of simulated development under infill, expansion, and leapfrog growth policies.

		Actual development		
Development scenario	**year**	***Infill***	***Expansion***	***Leapfrog***
Infill	2015	9450	18	6
	2020	11787	153	29
	2025	236	624	144
	2030	325	890	179

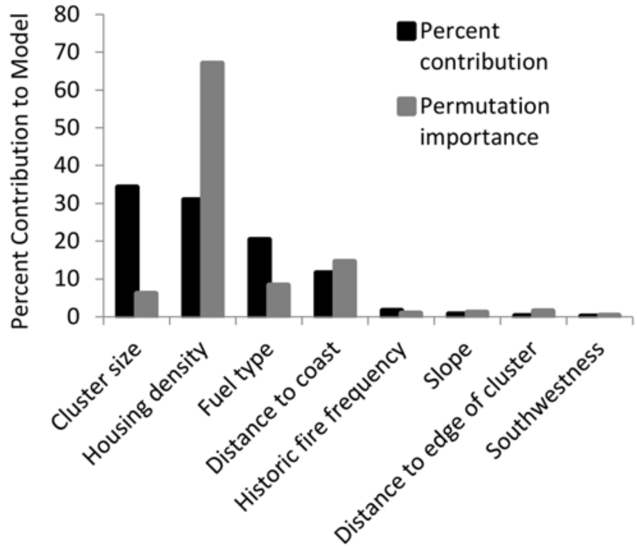

Figure 3. The importance of explanatory variables averaged across five cross-validated replications in the MaxEnt fire risk model. Percent contribution is determined as a function of the information gain from each environmental variable throughout the MaxEnt model iterations. Permutation importance reflects the drop in model accuracy that results from random permutations of each environmental variable, normalized to percentages.
doi:10.1371/journal.pone.0071708.g003

structures at risk from burning in wildfires. In particular, the scenarios with lower housing density and larger numbers of small, isolated clusters of development, i.e., leapfrog followed by expansion and infill, were generally predicted to have the highest predicted fire risk to the largest proportion of structures in the study area. Nevertheless, rankings of scenarios were affected by the definition of risk.

Theoretically, it makes sense that leapfrog development produced fragmented development with larger numbers of small patches, lower housing density, and a larger housing footprint; and that infill resulted in the opposite, with expansion in the middle. By definition, leapfrog development requires open space around all sides of the newly developed parcel, whereas infill requires development on all sides, and expansion requires development on one side and open space on another. Implementing these planning policies on real landscapes, however, can be complex if there are more houses to build than there are parcels that meet the definitions of the three planning rules, and thus not all development conforms strictly to the policy [54]. In our simulations, parcels meeting the definition of each growth type had a higher probability of subdividing; yet, as we were simulating a real landscape, many newly developed parcels did not meet the scenario criteria. That the three scenarios nevertheless produced substantial differences in landscape-level development patterns shows that decision-making at the individual level can lead to meaningful broad-scale effects.

The objective of the econometric model was to provide a baseline probability to predict which parcels were most likely to subdivide; thus, the econometric model itself provides no explanation of how a given policy affects likelihood of subdivision, although it does indicate the correlation between the policy and the outcome. In our setting, which areas are protected, marked for redevelopment, or marked for development may be endogenous to the land owner decision to subdivide. In the case of these variables especially, our results should not be interpreted as causal predictors. Likewise, we use data only from 2005–2009 to predict changes to 2030. If major changes in the land market take place over this time horizon our model will not be able to take this into account.

Although some differences in predicted fire risk among the three scenarios likely stemmed from location of new structures relative to variables such as distance to coast, fuel type, or slope, the most important variables in the fire risk model were housing density and cluster size, with most structure loss historically occurring in areas with low housing density and in small, isolated housing clusters. Thus, leapfrog development was generally the riskiest scenario and infill the least risky. The most surprising result was the variation in predicted risk for the expansion scenario over time and at different thresholds. While leapfrog and infill showed similar trajectories across thresholds, expansion went from being the highest-risk scenario at the low threshold to being the lowest-risk scenario at the highest threshold. Because the threshold is merely a way to group structures into a binary classification, this means that, while the average risk calculated across all homes shows expansion to rank in the middle of infill and leapfrog throughout the simulation (Figure 5), the other two scenarios have a relatively larger proportion of homes that are modeled to be at a very high risk (i.e., 0.25 or 0.5), particularly by the end of the simulations. Because the total number of structures with a risk greater than 0.25 or 0.5 is relatively low in all scenarios, this difference in distribution of homes at the highest risk is not reflected in the mean. Another reason for the shift in rank of expansion over time is that, as more development occupied the landscape, there were fewer parcels remaining to accomplish infill or leapfrog type growth in the other scenarios. Thus, by the end of the simulations in year 2030, the majority of growth in all scenarios was expansion, and there was some convergence between scenarios. Finally, the change in risk of expansion growth over time may reflect that, despite the relatively low importance of distance to edge of cluster as an explanatory variable, expansion growth is characterized as having an initially fragmented landscape pattern that eventually merges into large patches with low edge.

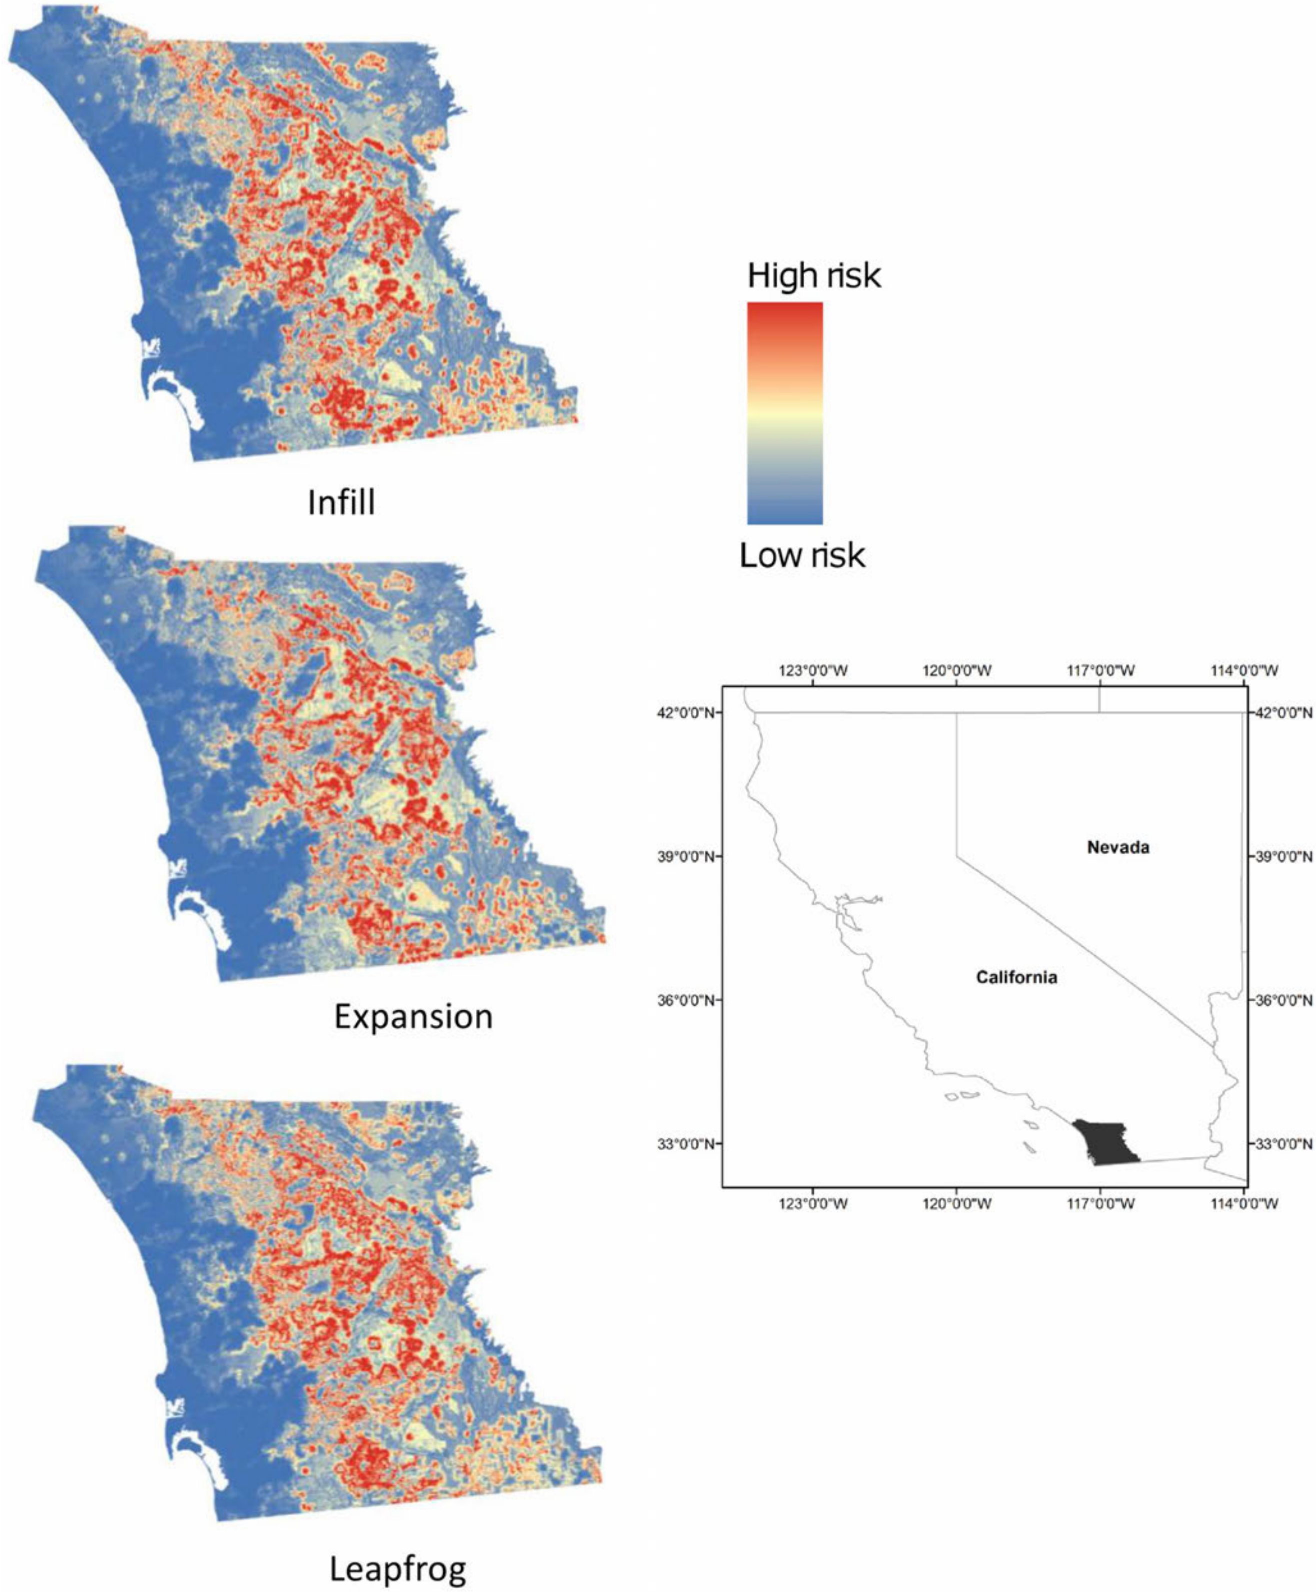

Figure 4. Maps of the study area showing projected wildfire risk at year 2030 for simulations of residential development under policies emphasizing infill, expansion, or leapfrog growth.
doi:10.1371/journal.pone.0071708.g004

Although leapfrog development clearly ranked highest in terms of fire risk, the interpretation of which planning policy is best may depend on fire management objectives and resources, as well as other considerations such as biodiversity or ecological impacts.

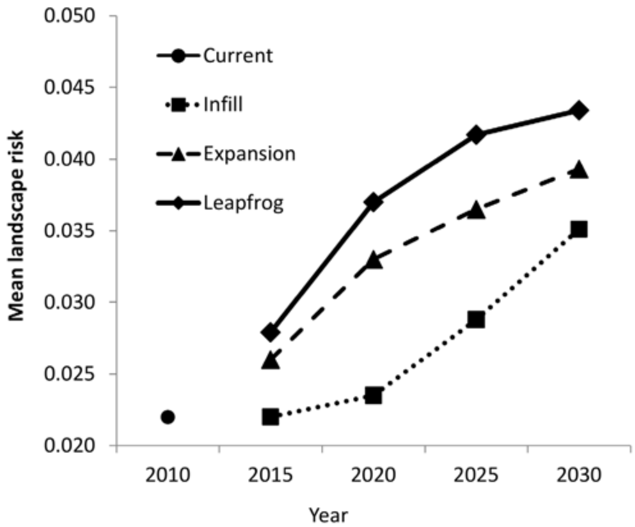

Figure 5. Projected landscape fire risk, reflecting the probability of burning in a wildfire averaged across all residential structures on the current landscape and in three development scenarios of infill, expansion, and leapfrog for year 2030.
doi:10.1371/journal.pone.0071708.g005

The spatial pattern of development affects multiple ecological functions and services [55], with potentially varying conservation implications; both leapfrog and expansion development consumed more land than infill, which would likely lead to more ecological degradation [56]; nevertheless, higher-density clustered development may be dominated by more invasive species [57]. Trade-offs between fire protection and conservation are common, but techniques are available for identifying mutually beneficial solutions [58].

Different perceptions of the fire risk results could also potentially translate into different planning priorities for management. For example, if the priority is to plan for the lowest overall risk to structures, then the mean landscape risk clearly delineates the rankings of options, with infill being the winner. However, if the objective is to reduce the number of structures at the highest risk threshold, i.e., $>=0.5$, then expansion is the best option, at least by 2030. An important consideration for fire management is the total area that needs to be protected, as well as the length of wildland-urban interface [8,13]. Therefore, despite the lower number of structures at the highest risk thresholds, expansion creates more edge than infill and may translate into greater challenges for firefighter protection.

Although we did not create separate scenarios for high or low growth, the results at different time steps can be substituted to envision the potential outcome of developing more or fewer houses. In the short term, the total fire risk is projected to increase proportionately as more land is developed. However, given the inverse relationship between housing density and fire risk, it is possible that this trend could reverse if housing growth eventually resulted in expansive high-density development.

Land use planning is one of a range of options available for reducing fire risk, and the best outcome will likely be achieved through a combination of strategies that include homeowner actions, improvements in fire-safe building codes, and advanced fire suppression tactics. Although we isolated the effect of land use planning policy in the three development scenarios, the fire risk model nevertheless showed that the pattern and location of structures in this study area were the most important out of a suite of factors influencing structure loss. We used a correlative approach that did not incorporate mechanisms or feedbacks, but our models clearly illustrated differences in the cumulative effects of individual planning decisions. The relationship between spatial pattern of development and fire risk is likely related to the intermixing of development and wildland vegetation [29,59]; thus, these results likely apply to a wide range of fire-prone ecosystems with large proportions of human-caused ignitions. Nevertheless, because fire risk is highly variable over space and time, and due to a range of human and biophysical variables [60], we recommend planners develop their own models for the best understanding of where the most fire-prone areas are in their region [19].

With projections of substantial global change in climate and human development, we recommend that land use planning should be considered as an important component to fire risk management, potentially to become as successful as the prevention of building on flood plains [61]. History has shown us that preventing fires is impossible in areas where large wildfires are a natural ecological process [4,9]. As Roger Kennedy put it, "the

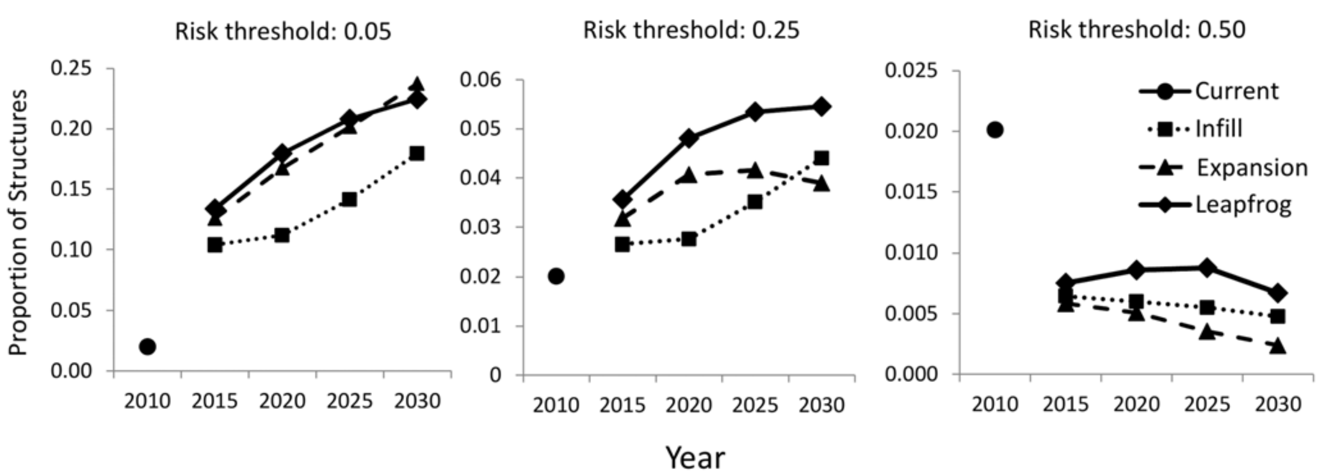

Figure 6. Proportion of residential structures that are located in areas of high fire risk defined using thresholds from the fire risk model of 0.05, 0.25, and 0.5 for current structures and for structures simulated under infill, expansion, and leapfrog growth policies.
doi:10.1371/journal.pone.0071708.g006

problem isn't fires; the problem is people in the wrong places [62]."

Abstract. With the potential for worsening fire conditions, discussion is escalating over how to best reduce effects on urban communities. A widely supported strategy is the creation of defensible space immediately surrounding homes and other structures. Although state and local governments publish specific guidelines and requirements, there is little empirical evidence to suggest how much vegetation modification is needed to provide significant benefits. We analysed the role of defensible space by mapping and measuring a suite of variables on modern pre-fire aerial photography for 1000 destroyed and 1000 surviving structures for all fires where homes burned from 2001 to 2010 in San Diego County, CA, USA. Structures were more likely to survive a fire with defensible space immediately adjacent to them. The most effective treatment distance varied between 5 and 20 m (16–58 ft) from the structure, but distances larger than 30 m (100 ft) did not provide additional protection, even for structures located on steep slopes. The most effective actions were reducing woody cover up to 40% immediately adjacent to structures and ensuring that vegetation does not overhang or touch the structure. Multiple-regression models showed landscape-scale factors, including low housing density and distances to major roads, were more important in explaining structure destruction. The best long-term solution will involve a suite of prevention measures that include defensible space as well as building design approach, community education and proactive land use planning that limits exposure to fire.

Received 16 September 2013, accepted 30 May 2014, published online 14 October 2014

Introduction

Across the globe and over recent decades, homes have been destroyed in wildfires at an unprecedented rate. In the last decade, large wildfires across Australia, southern Europe, Russia, the US and Canada have resulted in tens of thousands of properties destroyed, in addition to lost lives and enormous social, economic and ecological effects (Filmon 2004; Boschetti *et al.* 2008; Keeley *et al.* 2009; Blanchi *et al.* 2010; Vasquez 2011). The potential for climate change to worsen fire conditions (Hessl 2011), and the projection of continued housing growth in fire-prone wildlands (Gude *et al.* 2008) suggest that many more communities will face the threat of catastrophic wildfire in the future.

Concern over increasing fire threat has escalated discussion over how to best prepare for wildfires and reduce their effects. Although ideas such as greater focus on fire hazard in land use planning, using fire-resistant building materials and reducing human-caused ignitions (e.g. Cary *et al.* 2009; Quarles *et al.* 2010; Syphard *et al.* 2012) are gaining traction, the traditional strategy of fuels management continues to receive the most attention. Fuels management in the form of prescribed fires or mechanical treatments has historically occurred in remote, wildland locations (Schoennagel *et al.* 2009), but recent studies suggest that treatments located closer to homes and communities may provide greater protection (Witter and Taylor 2005; Stockmann *et al.* 2010; Gibbons *et al.* 2012). In fact, one of the most commonly recommended strategies in terms of fuels and fire protection is to create defensible space immediately around structures (Cohen 2000; Winter *et al.* 2009). Defensible space is an area around a structure where vegetation has been modified, or 'cleared,' to increase the chance of the structure surviving a wildfire. The idea is to mitigate home loss by minimising direct contact with fire, reducing radiative heating, lowering the probability of ignitions from embers and providing a safer place for fire fighters to defend a structure against fire (Gill and Stephens 2009; Cheney *et al.* 2001). Many jurisdictions provide specific guidelines and practices for creating defensible space, including minimum distances that are required among trees and shrubs as well as minimum total distances from the structure. These distances may be enforced through local ordinances or state-wide laws. In California, for example, a state law in 2005 increased the required total distance from 9 m (30 ft) to 30 m (100 ft).

Despite these specific guidelines on how to create defensible space, there is little scientific evidence to support the amount and location of vegetation modification that is actually effective

at providing significant benefits. Most spacing guidelines and laws are based on 'expert opinion' or recommendations from older publications that lack scientific reference or rationale (e.g. Maire 1979; Smith and Adams 1991; Gilmer 1994). However, one study has provided scientific support for, and forms the basis of, most guidelines, policy and laws requiring a minimum of 30 m (100 ft) of defensible space (Cohen 1999, 2000). The modelling and experimental research in that study showed that flames from forest fires located 10–40 m (33–131 ft) away would not scorch or ignite a wooden home; and case studies showed 90% of homes with non-flammable roofs and vegetation clearance of 10–20 m (33–66 ft) could survive wildfires (Cohen 2000). However, the models and experimental research in that study focussed on crown fires in spruce or jack pine forests, and the primary material of home construction was wood. Therefore, it is unknown how well this guideline applies to regions dominated by other forest types, grasslands, or nonforested woody shrublands and in regions where wooden houses are not the norm.

Some older case studies showed that most homes with non-flammable roofs and 10–18 m (33–ft) of defensible space survived the 1961 Bel Air fire in California (Howard *et al.* 1973); most homes with non-flammable roofs and more than 10 m (33 ft) of defensible space also survived the 1990 Painted Cave fire (Foote and Gilless 1996). Also, several fire-behaviour modelling studies have been conducted in chaparral shrublands. One study showed that reducing vegetative cover to 50% at 9–30 m (30–ft) from structures effectively reduced fireline intensity and flame lengths, and that removal of 80% cover would result in unintended consequences such as exotic grass invasion, loss of habitat and increase in highly flammable flashy fuels (A. Fege and D. Pumphrey, unpubl. data). Another showed that separation distances adequate to protect firefighters varied according to fuel model and that wind speeds greater than 23 km h^{-1} negated the effect of slope, and wind speed above 48 km h^{-1} negated any protective effect of defensible space (F. Bilz, E. McCormick and R. Unkovich, unpubl. data, 2009). Results obtained through modelling equations of thermal radiation also found safety distances to vary as a function of fuel type, type of fire, home construction material and protective garments worn by firefighters (Zárate *et al.* 2008).

Although there is no empirical evidence to support the need for more than 30 m (100 ft) of defensible space, there has been a concerted effort in some areas to increase this distance, particularly on steep slopes. In California, a senate bill was introduced in 2008 (SB 1618) to encourage property owners to clear 91 m (300 ft) through the reduction of environmental regulations and permitting needed at that distance. Although this bill was defeated in committee, many local ordinances do require homeowners to clear 91 m (300 ft) or more, and there are reports that some people are unable to get fire insurance without 91 m (300 ft) of defensible space (F. Sproul, pers. comm.). In contrast, homeowner acceptance of and compliance with defensible space policies can be challenging (Winter *et al.* 2009; Absher and Vaske 2011), and in many cases homeowners do not create any defensible space.

It is critically important to develop empirical research that quantifies the amount, location and distance of defensible space that provides significant fire protection benefits so that guidelines and policies are developed with scientific support. Data that are directly applicable to southern California are especially important, as this region experiences the highest annual rate of wildfire-destroyed homes in the US. Not having sufficient defensible space is obviously undesirable because of the hazard to homeowners. However, there are clear trade-offs involved when vegetation reduction is excessive, as it results in the loss of native habitats, potential for increased erosion and invasive species establishment, and it potentially even increases fire risk because of the high flammability of weedy grasslands (Spittler 1995; Keeley *et al.* 2005; Syphard *et al.* 2006).

It is also important to understand the role of defensible space in residential structure protection relative to other factors that explain why some homes are destroyed in fires and some are not. Recent research shows that landscape-scale factors, such as housing arrangement and location, as well as biophysical variables characterising properties and neighbourhoods such as slope and fuel type, were important in explaining which homes burned in two southern California study areas (Syphard *et al.* 2012; 2013). Understanding the relative importance of different variables at different scales may help to identify which combinations of factors are most critical to consider for fire safety.

Our objective was to provide an empirical analysis of the role of defensible space in protecting structures during wildfires in southern California shrublands. Using recent pre-fire aerial photography, we mapped and measured a suite of variables describing defensible space for burned and unburned structures within the perimeters of major fires from 2001 to 2010 in San Diego County to ask the following questions:

1. How much defensible space is needed to provide significant protection to homes during wildfires, and is it beneficial to have more than the legally required 30 m (100 ft)?
2. Does the amount of defensible space needed for protection depend on slope inclination?
3. What is the role of defensible space relative to other factors that influence structure loss, such as terrain, fuel type and housing density?

Methods

Study area

The properties and structures analysed were located in San Diego County, California, USA (Fig. 1) – a topographically diverse region with a Mediterranean climate characterised by cool, wet winters and long summer droughts. Fire typically is a direct threat to structures adjacent to wildland areas. Native shrublands in southern California are extremely flammable during the late summer and fall (autumn) and when ignited, burn in high-intensity, stand-replacing crown fires. Although 500 homes on average have been lost annually since the mid-1900s (Calfire 2000), that rate has doubled since 2000. Most of these homes have burned during extreme fire weather conditions that accompany the autumn Santa Ana winds. The wildland–urban interface here includes more than 5 million homes, covering more than 28 000 km^2 (Hammer *et al.* 2007).

Property data

The data for properties to analyse came from a complete spatial database of existing residential structures and their

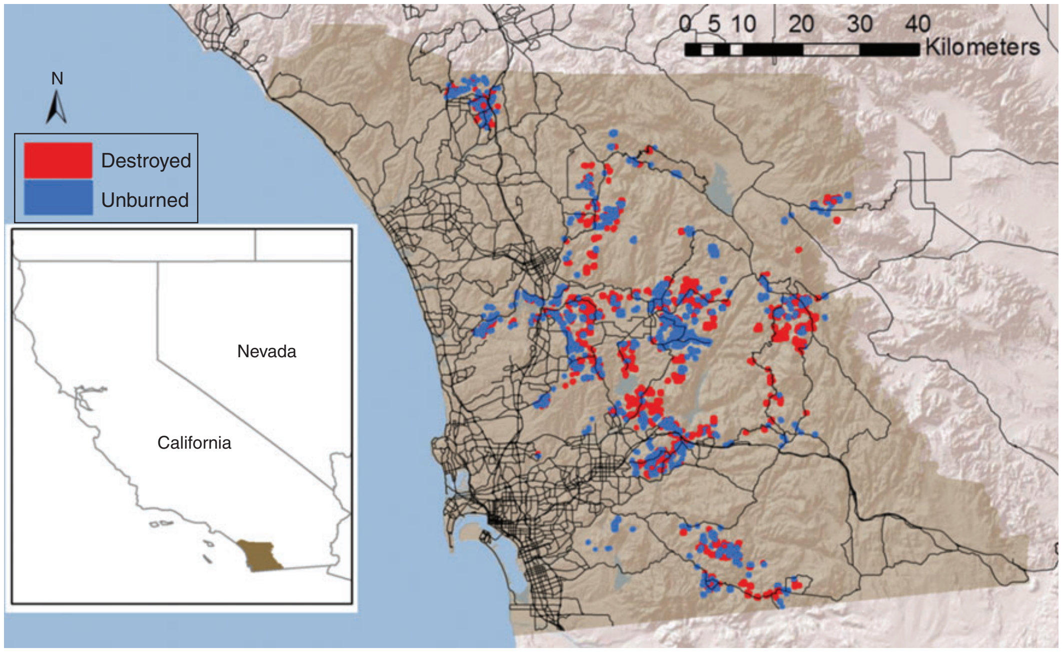

Fig. 1. Location of destroyed and unburned structures within the South Coast ecoregion of San Diego County, California, USA.

corresponding property boundaries developed for San Diego County (Syphard *et al.* 2012). This dataset included 687 869 structures, of which 4315 were completely destroyed by one of 40 major fires that occurred from 2001 to 2010. Our goal was to compare homes that were exposed to wildfire and survived with those that were exposed and destroyed. To determine exposure to fire, we only considered structures located both within a GIS layer of fire perimeters and within areas mapped as having burned at a minimum of low severity through thematic Monitoring Trends in Burn Severity produced by the USA Geological Survey and USDA Forest Service. From these data, we used a random sample algorithm in GIS software to select 1000 destroyed and 1000 unburned homes that were not adjacent to each other, to minimise any potential for spatial autocorrelation. Our final property dataset included structures that burned across eight different fires. More than 97% of these structures burned in Santa Ana wind-driven fire events (Fig. 1).

Calculating defensible space and additional explanatory variables

To estimate defensible space, we developed and explored a suite of variables relative to the distance and amount of defensible space surrounding structures, as well as the proximity of woody vegetation to the structure (Table 1). We measured these variables based on interpretation of Google Earth aerial imagery. We based our measurements on the most recent imagery before the date of the fire. In almost all cases, imagery was available for less than 1 year before the fire.

Our definition of defensible space followed the guidelines published by the California Department of Forestry and Fire Protection (Calfire 2006). 'Clearance' included all areas that were not covered by woody vegetation, including paved areas or grass. Although Google Earth prevents the identification of understorey vegetation, woody trees and shrubs were easily distinguished from grass, and our objective was to measure horizontal distances as required by Calfire rather than assess the relative flammability of different vegetation types. Trees or shrubs were allowed to be within the defensible space zone as long as they were separated by the minimum horizontal required distance, which was 3 m (10 ft) from the edge of one tree canopy to the edge of the next (Fig. 2). Although greater distances between trees or shrubs are recommended on steeper slopes, we followed the same guidelines for all properties. For all structures, we started the distance measurements by drawing lines from the centre of the four orthogonal sides of the structure that ended when they intersected anything that no longer met the requirements in the guidelines. A fair number of structures are not four sided; thus, the start of the centre point was placed at a location that approximated the farthest extent of the structure along each of four orthogonal sides.

We developed two sets of measurements of the distance of defensible space based on what is feasible for homeowners within their properties *v.* the total effective distance of defensible space. We made these two measurements because homeowners are only required to create defensible space within their own property, and this would reflect the effect of individual homeowner compliance. Therefore, even if cleared vegetation extended beyond the property line, the first set of distance measurements ended at the property boundary. The second set of measurements ignored the property boundaries and accounted for the total potential effect of treatment. For all measurements, we recorded the cover types (e.g. structure >3 m (10 ft) long, property boundary, or vegetation type) at which the distance measurements stopped (Table 1). Because property

Table 1. Defensible space variables measured for every structure

Urban veg, landscaping vegetation that was not in compliance with regulations within urban matrix; wildland veg, wildland vegetation that was not in compliance with regulations; orchard, shrub to tree-sized vegetation in rows; urban to wildland, landscaping vegetation that leads into wildland vegetation; structure, any building longer than 3 m (10 ft)

Variable	Definition
Distance defensible space within property	Measure of clearance from side of structure to property boundary calculated for four orthogonal directions from structure and averaged
Total distance defensible space	Measure of clearance from side of structure to end of clearance calculated for four orthogonal directions from structure and averaged
Cover type at end of defensible space	Type of cover encountered at end of measurement (urban veg, wildland veg, orchard, urban to wildland, structure)
Percentage clearance	Percentage of clearance calculated across the entire property
Neighbours' vegetation	Binary indicator of whether neighbours' uncleared vegetation was located within 30 m (100 ft) of the main structure
Vegetation touching structure	Number of sides on which woody vegetation touches main structure (1–4) Structure with more than 4 sides were viewed as a box and given a number between 1 and 4
Vegetation overhanging roof	Was vegetation overhanging the roof? (yes or no)

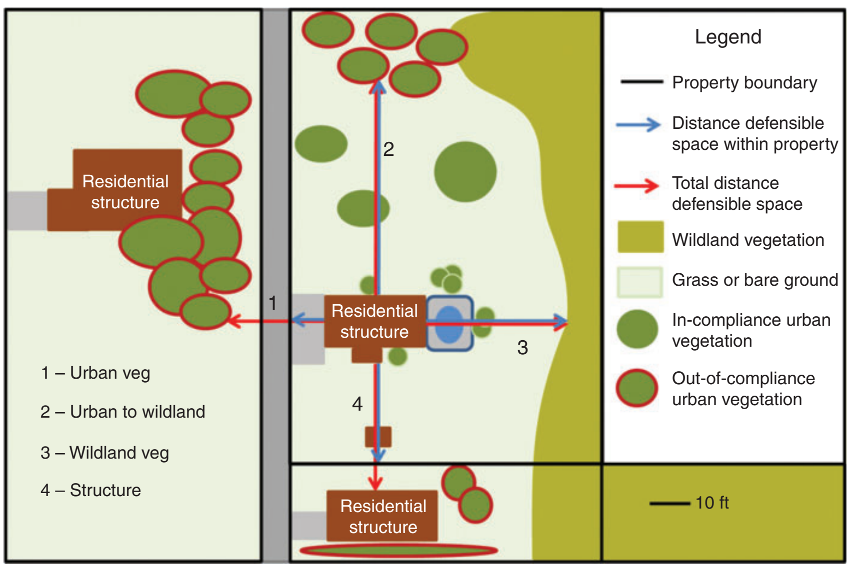

Fig. 2. Illustration of defensible space measurements. See Table 1 for full definition of terms.

owners usually can only clear vegetation on their own land, it is possible that the effectiveness of defensible space partly depends upon the actions of neighbouring homeowners. Therefore, we also recorded whether or not any neighbours' un-cleared vegetation was located within 30 m (100 ft) of the structure.

To assess the total amount of woody vegetation that can safely remain on a property and still receive significant benefits of defensible space, we calculated the total percentage of cleared land, woody vegetation and structure area across every property. This was accomplished by overlaying a grid on each property and determining the proportion of squares falling into each class. Preliminary results showed these three measurements to be highly correlated, so we only retained percentage clearance for further analysis. To evaluate the relative effect of woody vegetation directly adjacent to structures, we also calculated the number of sides of the structure with vegetation touching and recorded whether any trees were overhanging structures' roofs.

In addition to defensible space measurements, we evaluated other factors known to influence the likelihood of housing loss to fire in the region (Syphard *et al.* 2012, 2013). Using the same data as in Syphard *et al.* (2012, 2013), we extracted spatial information from continuous grids of explanatory variables for the locations of all structures in our analysis. Variables included interpolated housing density based on a 1-km search radius; percentage slope derived from a 30-m digital elevation model (DEM); Euclidean distance to nearest major and minor road and fuel type, which was based on a simple classification of US Forest Service data (Syphard *et al.* 2012), including urban, grass, shrubland and forest & woodland.

Analysis

We performed several analyses to determine whether relative differences in home protection are provided by different distances and amounts of defensible space, particularly beyond the legally required 30 m (100 ft), and to identify the effective treatment distance for homes on low and steep slopes.

Categorical analysis

For the first analysis, we divided our data into several groups to identify potential differences among specific categories of defensible space distance around structures located on shallow and steep slopes. We first sorted the full dataset of 2000 structures by slope and then split the data in the middle to create groups of homes with shallow slope and steep slope. We divided the data in half to keep the number of structures even within both groups and to avoid specifying an arbitrary number to define what constitutes shallow or steep slope. The two equal-sized subsets of data ranged from 0 to 9%, with a mean of 8% for shallow slope, and from 9 to 40%, with a mean of 27% for steep slope. Within these data subsets, we next created groups reflecting different mean distances of defensible space around structures. We also performed separate analyses based on whether defensible space measurements were calculated within the property boundary or whether measurements accounted for the total distance of defensible space.

Within all groups, we calculated the proportion of homes that were destroyed by wildfire. We performed Pearson's Chi-square tests of independence to determine whether or not the proportion of destroyed structures within groups was significantly different (Agresti 2007). We based one test on four equal-interval groups within the legally required distance of 30 m (100 ft): 0–7 m (0–25 ft), 8–15 m (26–50 ft), 16–23 m (51–75 ft) and 24–30 m (76–100 ft). A second test was based on three groups (24–30 m (75–100 ft), 31–90 m (101–300 ft) and >90 m (>300 ft) or >60 m (>200 ft)) to evaluate whether groups with mean defensible space distances >30 m (>100 ft) were significantly different from groups with <30 m (<100 ft). When defensible space distances were only measured to the property boundary, few structures had mean defensible space >90 m (>300 ft). Therefore, we used a cut-off of 60 m (200 ft) to increase the sample size in the Chi-square analysis. In addition to the Chi-square analysis, we calculated the relative risk among every successive pair of categories (Sheskin 2004). The relative risk was calculated as the ratio of proportions of burned homes within two groups of homes that had different defensible space distances.

Effective treatment analysis

In addition to comparing the relative effect of defensible space among different groups of mean distances, as described above, we also considered that the protective effect of defensible space for structures exposed to wildfire is conceptually similar to the effect of medication in producing a therapeutic response in people who are sick. In addition to pharmacological applications, treatment–response relationships have been used for radiation, herbicide, drought tolerance and ecotoxicological studies (e.g. Streibig *et al.* 1993; Cedergreen *et al.* 2005; Knezevic *et al.* 2007; Kursar *et al.* 2009). The effect produced by a drug or treatment typically varies according to the concentration or amount, often up to a point at which further increase provides no additional response. The effective treatment (ET50), therefore, is a specific concentration or exposure that produces a therapeutic response or desired effect. Here we considered the treatment to be the distance or amount of defensible space.

Using the software package DRC in R (Knezevic *et al.* 2007; Ritz and Streibig 2013), we evaluated the treatment–response relationship of defensible space in survival of structures during wildfire. To calculate the effective treatment, we fit a log-logistic model with logistic regression because we had a binary dependent variable (burned or unburned). We specified a 2-parameter model where the lower limit was fixed at 0 and the upper limit was fixed at 1. We again performed separate analyses for data subsets reflecting shallow and steep slope, as well as from measurements of defensible space taken within, or regardless of, property boundaries. We also performed analyses to find the effective treatment of percentage clearance of trees and shrubs within the property.

Multiple regression analysis

To evaluate the role of defensible space relative to other variables, we developed multiple generalised linear regression models (GLMs) (Venables and Ripley 1994). We again had a binary dependent variable (burned versus unburned), so we specified a logit link and binomial response. Although the proportion of 0s and 1s in the response may be important to consider for true prediction (King and Zeng 2001; Syphard *et al.* 2008), our objective here was solely to evaluate variable importance. We developed multiple regression models for all possible combinations of the predictor variables and used the corrected Akaike's Information Criterion (AICc) to rank models and select the best ones for each region using package MuMIn in R (R Development Core Team 2012; Burnham and Anderson 2002). We recorded all top-ranked models that had an AICc value within 2 of that of the model with lowest AICc to identify all models with empirical support. To assess variable importance, we calculated the sum of Akaike weights for all models that contained each variable. On a scale of 0–1, this metric represents the weight of evidence that models containing the variable in question are the best model (Burnham and Anderson 2002). The distance of defensible space measured within property boundaries was highly correlated with the distance of defensible space measured beyond property boundaries ($r = 0.82$), so we developed two separate analyses – one using variables measured only within the property boundary and the other using variables that accounted for defensible space outside of the property boundary as well as the potential effect of neighbours having uncleared vegetation within 30 m (100 ft) of the structure. A test to avoid multicollinearity showed all other variables within each multiple regression analysis to be uncorrelated ($r < 0.5$).

Surrounding matrix

To assess whether the proportion of destroyed structures varied according to their surrounding matrix, we summarised the most common cover type at the end of defensible space measurements (descriptions in Table 1) for all structures. These summaries

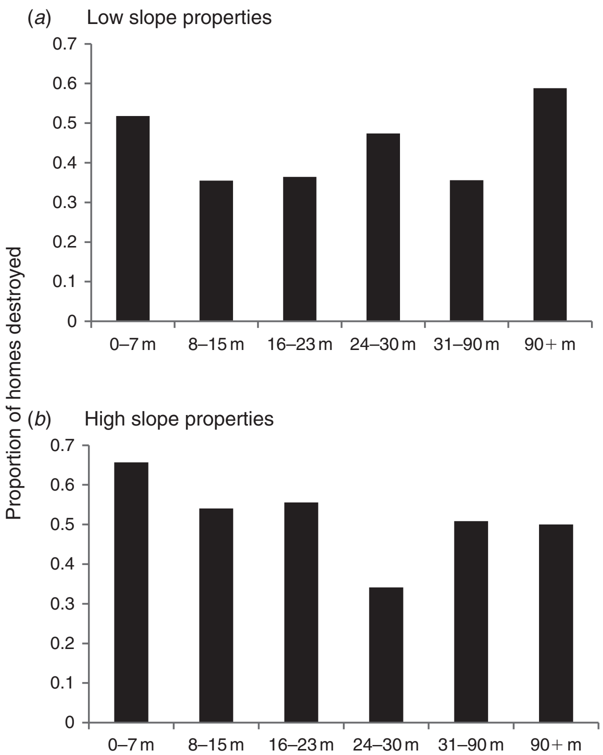

Fig. 3. Proportion of destroyed homes grouped by distances of defensible space based upon total distance of clearance within property boundary, for structures on (*a*) shallow slopes (mean 8%) and (*b*) steep slopes (mean 27%).

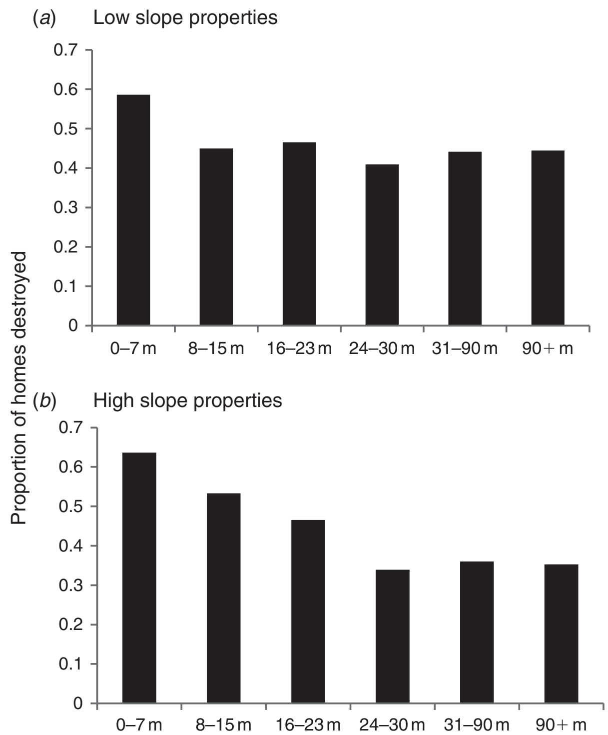

Fig. 4. Proportion of destroyed homes grouped by distances of defensible space based upon total distance of clearance regardless of property boundary, for structures on (*a*) shallow slopes (mean 8%) and (*b*) steep slopes (mean 27%).

were based on the majority surrounding cover type from the four orthogonal sides of the structure. We also noted cases in which there was a tie (e.g. two sides were urban vegetation and two sides were structures).

Results

Categorical analysis

When the distance of defensible space was measured both 'only within property boundaries' (Fig. 3) and 'regardless of property boundaries' (Fig. 4), the Chi-square test showed a significant difference ($P < 0.001$) in the proportion of destroyed structures among the four equal-interval groups of distance ranging from 0 to 30 m (0–100 ft). This relationship was consistent on both shallow-slope and steep-slope properties, although the relative risk analysis showed considerable variation among classes (Table 2) There was a steadily decreasing proportion of destroyed structures at greater distances of defensible space up to 30 m (100 ft) on the steep-slope structures with defensible space measured regardless of property boundaries (Fig. 4*b*). Otherwise, the biggest difference in proportion of destroyed structures occurred between 0 and 7 m (0–25 ft) and 8–15 m (26–50 ft) (Figs 3*a–b*, 4*a*).

When the distance of defensible space was measured in intervals from 24 m (75 ft) and beyond, the Chi-square test showed no significant difference among groups ($P = 0.96$ for shallow-slope properties and $P = 0.74$ for steep-slope properties) (Figs 3, 4), although again, the relative risk analysis showed considerable variation (Table 2).There was a slight increase in the proportion of homes destroyed at longer distance intervals when the defensible space was measured only to the property boundaries (Fig. 3*a–b*). This slight increase is less apparent when distances were measured regardless of boundaries (Fig. 4*a–b*).

The relative risk calculations showed that the ratio of proportions was generally more variable among successive pairs when the distances were measured within property boundaries (Table 2). For these calculations, the risk of a structure being destroyed was significantly lower when the defensible space distance was 8–15 m (25–50 ft) compared to 0–7 m (0–25 ft) on both shallow- and steep-slope properties. On the steep-slope properties, there was an additional reduction of risk when comparing 24–30 m (75–100 ft) to 16–23 m (50–75 ft). However, the risk of a home being destroyed was slightly significantly higher when there was 31–90 m (101–225 ft) compared to 16–23 m (50–75 ft). For distances that were measured regardless of property boundary (total clearance), the only significant differences in risk of burning were a reduction in risk for 8–15 m (25–50 ft) compared to 0–7 m (0–25 ft).

Table 2. Number of burned and unburned structures within defensible space distance categories (m), their relative risk and significance
A relative risk of 1 indicates no difference; <1 means the chance of a structure burning is less than the other group; >1 means the chance is higher than the other group. The relative risk is calculated for pairs that include the existing row and the row above. Confidence intervals are in parentheses

	Distance within property				Total distance			
	Burned	Unburned	Relative risk	*P*	Burned	Unburned	Relative risk	*P*
Shallow slope								
0–7	200	186			162	114		
8–15	109	198	0.69 (0.12)	<0.001	108	132	0.77	0.002

Table 3. Effective treatment results reflecting the distance (in metres, with feet in parentheses) and percentage clearance within properties that provided significant improvement in structure survival during wildfires
The property mean is the average distance of defensible space or percentage clearance that was calculated on the properties before the wildfires and provides a means to compare the effective treatment result to the actual amount on the properties

	All parcels effective treatment ($n = 2000$)	Parcel mean	Shallow slope (mean 8%) effective treatment ($n = 1000$)	Parcel mean	Steep slope (mean 27%) effective treatment ($n = 1000$)	Parcel mean
Defensible space within parcel	10 (33)	13 (44)	4 (13)	14 (45)	25 (82)	11 (35)
Total distance defensible space	10 (32)	19 (63)	5 (16)	20 (67)	20 (65)	18 (58)
Mean percentage clearance on property	36	48	31	51	37	35

Effective treatment analysis

Analysis of the treatment–response relationships among defensible space and structures that survived wildfire showed that, when all structures are considered together, the mean actual defensible space that existed around structures before the fires was longer than the calculated effective treatment (Table 3). Regardless of whether the defensible space was measured within or beyond property boundaries, the estimated effective treatment of defensible space was nearly the same at 10 m (32–33 ft).

The effective treatment distance was much shorter for structures on shallow slopes (4–5 m (13–16 ft)) than for structures on steep slopes (20–25 m (65–82 ft)), but in all cases was <30 m (<100 ft). Although longer distances of defensible space were calculated as effective on steeper slopes, these structures actually had shorter mean distances of defensible space around their properties than structures on low slopes (Table 3).

The calculated effective treatment of the mean percentage clearance on properties was 36% for all properties, 31% for structures on shallow slopes and 37% for structures on steep slopes (Table 3). In total, the properties all had higher actual percentage clearance on their property than was calculated to be effective. However, this mainly reflects the shallow-slope properties, as those structures on steep slopes had less clearance than the effective treatment.

Multiple regression analysis

When defensible space was measured only to the property boundaries, it was not included in the best model, according to the all-subsets multiple regression analysis (Table 4). However, it was included in the best model when factoring in the distance of defensible space measured beyond property boundaries (Table 5). In both multiple regression analyses, low housing density and shorter distances to major roads were ranked as the most important variables according to their Akaike weights. Slope and surrounding fuel type were also in both of the best models as well as other measures of defensible space, including the percentage clearance on property and whether vegetation was overhanging the structure's roof. The number of sides in which vegetation was touching the structure was included in the best model when defensible space was only measured to the property boundary. The total explained deviance for the multiple regression models was low (12–13%) for both analyses.

Table 4. Results of multiple regression models of destroyed homes using all possible variable combinations and corrected Akaike's Information Criterion (AICc)

Includes variables measured within property boundary only. Top-ranked models include all those ($n = 12$) with AICc within 2 of the model with the lowest AICc. Relative variable importance is the sum of 'Akaike weights' over all models including the explanatory variable

Variable in order of importance	Relative variable importance	Model-averaged coefficient	Number inclusions in top-ranked models
Housing density	1	−0.003	12
Distance to major road	1	−0.0005	12
Percentage clearance	1	−0.02	12
Slope	1	0.03	12
Vegetation overhang roof	1	0.5	12
Fuel type	0.67	Factor	9
Vegetation touch structure	0.49	0.07	6
Distance defensible space within property	0.45	−0.0002	5
South-westness	0.36	−0.0007	3
Distance to minor road	0.28	−0.0002	1
D^2 of top-ranked model			0.123

Table 5. Results of multiple regression models of destroyed homes using all possible variable combinations and corrected Akaike's Information Criterion (AICc)

Includes variables measured beyond property boundary. Top-ranked models include all those ($n = 6$) with AICc within 2 of the model with the lowest AICc. Relative variable importance is the sum of 'Akaike weights' over all models including the explanatory variable

Variable in order of importance	Relative variable importance	Model-averaged coefficient	Number inclusions in top-ranked models
Housing density	1	−0.003	6
Distance to major road	1	−0.0005	6
Total distance defensible space	1	−0.004	6
Percentage clearance	1	−0.01	6
Vegetation overhang roof	0.99	0.4	6
Slope	0.99	0.03	6
Fuel type	0.86	Factor	4
South-westness	0.42	−0.0009	2
Distance to minor road	0.36	−0.0009	2
Neighbours' vegetation	0.27	0.08	1
Vegetation touch structure	0.27	0.18	1
D^2 of top-ranked model			0.125

Surrounding matrix

The cover type that most frequently surrounded the structures at the end of the defensible space measurements was urban vegetation, followed by urban vegetation leading into wildland vegetation, and wildland vegetation (Fig. 5). Many structures were equally surrounded by different cover types. There were no significant differences in the proportion of structures destroyed depending on the surrounding cover type. However, a disproportionately large proportion of structures burned (28 *v.* 9% unburned) when they were surrounded by urban vegetation that extended straight into wildland vegetation.

Discussion

For homes that burned in southern Californian urban areas adjacent to non-forested ecosystems, most burned in high-intensity Santa Ana wind-driven wildfires and defensible space increased the likelihood of structure survival during wildfire. The most effective treatment distance varied between 5 and 20 m (16–58 ft), depending on slope and how the defensible space was measured, but distances longer than 30 m (100 ft) provided no significant additional benefit. Structures on steeper slopes benefited from more defensible space than structures on shallow slopes, but the effective treatment was still less than 30 m (100 ft). The steepest overall decline in destroyed structures occurred when mean defensible space increased from 0–7 m (0–25 ft) to 8–15 m (26–50 ft). That, along with the multiple regression results showing the significance of vegetation touching or overhanging the structure, suggests it is most critical to modify vegetation immediately adjacent to the house, and to move outward from there. Similarly, vegetation overhanging the structure was also strongly correlated with structure loss in Australia (Leonard *et al.* 2009).

In terms of fuel modification, the multiple regression models also showed that the percentage of clearance was just as, or more important than, the linear distance of defensible space.

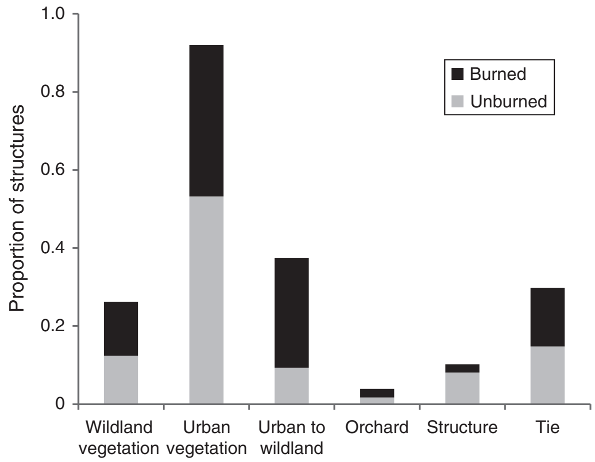

Fig. 5. Proportion of destroyed and unburned structures based on the primary surrounding cover type at the end of defensible space measurements. There were no significant differences in the proportion of burned and unburned structures within cover types ($P = 0.14$). Cover types are defined in Table 1.

However, as with defensible space, percentage clearance did not need to be draconian to be effective. Even on steep slopes, the effective percentage clearance needed on the property was <40%, with no significant advantage beyond that. Although these steep-slope structures benefited more from clearance, they tended to have less clearance than the effective amount, which may be why slope was such an important variable in the multiple regression models. Shallow-slope structures, in contrast, had more clearance on average than was calculated to be effective, suggesting these property owners do not need to modify their behaviours as much relative to people living on steep slopes.

Although the term 'clearance' is often used interchangeably with defensible space, this term is incorrect when misinterpreted to mean clearing all vegetation, and our results underline this difference. The idea behind defensible space is to reduce the continuity of fuels through maintenance of certain distances among trees and shrubs. Although we could not identify the vertical profile of fuels through Google Earth imagery, the fact that at least 60% of the horizontal woody vegetative cover can remain on the property with significant protective effects demonstrates the importance of distinguishing defensible space from complete vegetation removal. Thus, we suggest the term 'clearance' be replaced with 'fuel treatment' as a better way of communicating fire hazard reduction needs to home owners.

The percentage cover of woody shrubs and trees was not evenly distributed across properties, and we did not collect data describing how the cover was distributed. Considering the importance of defensible space and vegetation modification immediately adjacent to the structure, it should follow that actions to reduce cover should also be focussed in close proximity to the structure. The hazard of vegetation near the structure has apparently been recognised for some time (Foote *et al.* 1991; Ramsey and McArthur 1994), but it is not stressed enough, and rarely falls within the scope of defensible space guidelines or ordinances.

In addition to the importance of vegetation overhanging or touching the structure, it is important to understand that ornamental vegetation may be just as, if not more, dangerous than native vegetation in southern California. Although the results showed no significant differences in the cover types in the surrounding matrix, there was a disproportionately large number of structures destroyed (28% burned *v.* 9% unburned) when ornamental vegetation on the property led directly into the wildland. Ornamental vegetation may produce highly flammable litter (Ganteaume *et al.* 2013) or may be particularly dangerous after a drought when it is dry, or has not been maintained, and species of conifer, juniper, cypress, eucalypt, *Acacia* and palm have been present in the properties of many structures that have been destroyed (Franklin 1996). Nevertheless, ornamental vegetation is allowed to be included as defensible space in many codes and ordinances (Haines *et al.* 2008).

One reason that longer defensible space distances did not significantly increase structure protection may be that most homes are not destroyed by the direct ignition of the fire front but rather due to ember-ignited spot fires, sometimes from fire brands carried as far as several km away. Although embers decay with distance, the difference between 30 and 90 m (100 and 300 ft) may be small relative to the distance embers travel under the severe wind conditions that were present at the time of the fires. The ignitability of whatever the embers land on, particularly adjacent to the house, is therefore most critical for propagating the fire within the property or igniting the home (Cohen 1999; Maranghides and Mell 2009).

Aside from roofing or home construction materials and vegetation immediately adjacent to structures (Quarles *et al.* 2010; Keeley *et al.* 2013), the flammability of the vegetation in the property may also play a role. Large, cleared swaths of land are likely occupied at least in part by exotic annual grasses that are highly ignitable for much of the year. Conversion of woody shrubs with higher moisture content into low-fuel-volume grasslands could potentially increase fire risk in some situations by increasing the ignitability of the fuel; and if the vegetation between a structure and a fire is not readily combustible, it could protect the structure by absorbing heat flux and filtering fire brands (Wilson and Ferguson 1986).

The slight increase in proportion of structures destroyed with longer distances of defensible space within parcel boundaries was surprising. However, that increase was not significant in the Chi-square analysis, although there were some significant differences in the pairwise relative risk analysis. Nevertheless, the largest significant effect of defensible space was between the categories of 0–7 m (0–25 ft) to 8–15 m (26–50 ft), and it may be that differences in categories beyond these distances are not highly meaningful or reflect an artefact of the definition of distance categories. These relationships at longer distances are likely also weak compared to the effect of other variables operating at a landscape scale. Although the categorical analysis allowed us to answer questions relative to legal requirements and specific distances, the effective treatment analysis was important for identifying thresholds in the continuous variable.

The multiple regression models showed that landscape factors such as low housing density and longer distances to major roads were more important than distance of defensible space for explaining structure destruction, and the importance of

these variables is consistent with previous studies (Syphard *et al.* 2012, 2013), despite the smaller spatial extent studied here. Whereas this study used an unburned control group exposed to the same fires as the destroyed structures, previous studies accounted for structures across entire landscapes. The likelihood of a fire destroying a home is actually a result of two major components: the first is the likelihood that there will be a fire, and the second is the likelihood that a structure will burn in that fire. In this study, we only focussed on structure loss given the presence of a fire, and the total explained variation for the multiple regression models was quite low at ~12%. However, when the entire landscape was accounted for in the total likelihood of structure destruction, the explained variation of housing density alone was >30% (Syphard *et al.* 2012). One reason for the relationship between low housing density and structure destruction is that structures are embedded within a matrix of wildland fuel that leads to greater overall exposure, which is consistent with Australian research that showed a linear decrease of structure loss with increased distance to forest (Chen and McAneney 2004). That research, however, only focussed on distance to wildland boundaries and did not quantify variability in defensible space or ornamental vegetation immediately surrounding structures. Thus, fire safety is important to consider at multiple scales and for multiple variables, which will ultimately require the cooperation of multiple stakeholders.

Conclusions

Structure loss to wildfire is clearly a complicated function of many biophysical, human and spatial factors (Keeley *et al.* 2009; Syphard *et al.* 2012). For such a large sample size, we were unable to account for home construction materials, but this is also well understood to be a major factor, with older homes and wooden roofs being most vulnerable (Franklin 1996; Cohen 1999, 2000). In terms of actionable measures to reduce fire risk, this study shows a clear role for defensible space up to 30 m (100 ft). Although the effective distances were on average much shorter than 30 m (100 ft), we recognise that additional distance may be necessary to provide sufficient protection to firefighters, which we did not address in this study (Cheney *et al.* 2001). In contrast, the data in this study do not support defensible space beyond 30 m (100 ft), even for structures on steep slopes. In addition to the fact that longer distances did not contribute significant additional benefit, excessive vegetation clearance presents a clear detriment to natural habitat and ecological resources. Results here suggest the best actions a homeowner can take are to reduce percentage cover up to 40% immediately adjacent to the structure and to ensure that vegetation does not overhang or touch the structure.

In addition to defensible space, this study also underlines the potential importance of land use planning to develop communities that are fire safe in the long term, in particular through their reduction to exposure to wildfire in the first place. Localised subdivision decisions emphasising infill-type development patterns may significantly reduce fire risk in the future, in addition to minimising habitat loss and fragmentation (Syphard *et al.* 2013). This study was conducted in southern California, which has some of the worst fire weather in the world and many properties surrounded by large, flammable exotic trees. Therefore, recommendations here should apply to other non-forested ecosystems as well as many forested regions.

Abstract: *Although many roadless areas on federal lands have been mapped in the United States since the 1970s, there has been little specific research on how and to what degree roadless areas contribute to biodiversity conservation. We examined the ecological attributes of mapped roadless areas for the Klamath-Siskiyou ecoregion of northwestern California and southwestern Oregon (U.S.A.). Attributes examined include special elements (such as natural heritage, serpentine geology, late-seral forests, Port Orford cedar* [Chamaecyparis lawsoniana]*), and key watersheds; elevation and habitat representation; and overall landscape connectivity. We compared designated wilderness to roadless areas, giving special attention to the relative importance of small roadless areas (405–2024 ha). We mapped nearly 500 roadless areas of ≥405 ha. Roadless areas occupied more than twice the land area of wilderness (approximately 27% of the entire ecoregion) and contained approximately 36% of the known occurrences of heritage elements, 37% of the mapped serpentine habitats, 36% of the remaining late-seral forests, 60% of Port Orford cedar strongholds, and 42% of key watersheds for aquatic biodiversity. In addition, roadless areas were composed of significant amounts of low- and mid-elevation sites and a substantial number of the 214 mapped physical-biological habitat types with strong complementarity with designated wilderness. Fragmentation analyses showed that roadless areas contributed to regional connectivity in important ways. Also, small roadless areas were an important component of the roadless-areas conservation assessment. For the Klamath-Siskiyou ecoregion, roadless areas and designated wilderness provide an important foundation upon which to develop a comprehensive regional conservation strategy.*

Importancia de Áreas sin Caminos para la Conservación de la Biodiversidad en Ecosistemas Forestales: Estudio de Caso de la Ecoregión Klamath-Siskiyou, E.U.A.

Resumen: *Aunque se ha mapeado una gran cantidad de superficie sin caminos en tierras federales de los E.U.A. desde la década de 1970, se ha investigado poco sobre como y hasta qué grado las áreas sin caminos contribuyen a la conservación de la biodiversidad. Examinamos los atributos ecológicos de áreas sin caminos en la ecoregión de Klamath-Siskiyou en el noroeste de California y suroeste de Oregon (E.U.A.). Los atributos examinados incluyeron elementos especiales (patrimonio natural, geología de serpentina, bosques serales recientes, cedro [*Chamaecyparis lawsoniana*] y cuencas clave), elevación y representación de hábitat y la conectividad general del paisaje. Comparamos áreas designadas para vida silvestre con áreas sin caminos, poniendo especial atención a la importancia relativa de áreas pequeñas sin caminos (405-2024 ha). Hicimos mapas de cerca de 500 áreas sin caminos ≥ (405 ha). Las áreas sin caminos ocuparon más del doble de la superficie de las áreas de vida silvestre (aproximadamente el 27% de toda la ecoregión). Las áreas sin caminos y contenían aproximadamente el 36% de elementos ancestrales conocidos, el 37% de los habitats serpentinos mapeados, el 36% de los bosques serales recientes, 60% de la población de cedro y 42% de las cuencas*

Paper submitted December 28, 1999; revised manuscript accepted February 28, 2001.

clave para la biodiversidad acuática. Adicionalmente, las áreas sin caminos estaban compuestas de cantidades significativas de sitios bajos y de elevación media y cantidades sustanciales de 214 tipos de hábitats fisicobiológicos con una fuerte complementariedad con áreas designadas para vida silvestre. Los análisis de fragmentación mostraron que las áreas sin caminos contribuyeron a la conectividad regional de manera importante. También, las áreas sin caminos pequeñas fueron un componente importante de la evaluación de conservación de las áreas sin caminos. Para la ecoregión Klamath-Siskiyou, las áreas sin caminos y las designadas para vida silvestre son un fundamento importante sobre el que se puede desarrollar una estrategia integral de conservación regional.

Introduction

Natural habitat destruction and fragmentation are the leading causes of the decline and loss of species worldwide and have been a topic of considerable research and review (Harris 1984; Wilcove et al. 1986; Usher 1987; Saunders et al. 1991; Wilson 1992). Fragmentation of forested landscapes has been under particular scrutiny and has been shown to contribute to population declines in many species (Matthiae & Stearns 1981; Harris 1984). The process of deforestation and fragmentation can be complex, having both spatial and temporal components (Zipperer 1993). Roads allow access to pristine areas and fragment native ecosystems into smaller and smaller patches of various sizes and shapes (Dickman 1987; Atkinson & Cairns 1992). Nearly all native ecosystems are destined to resemble ever smaller and more isolated habitat islands as humans continue to encroach on remaining natural habitats (Wilcox 1980).

According to the National Research Council (1997), there are approximately 4 million miles of roadway in the United States. That covers about 1% of the conterminous United States, but the negative ecological effects of the "road-effect zone" are often much greater—18–22% (Forman 2000). Roads constructed to gain access to resources on public lands have been substantial, and in some cases extremely heavy, over the last 50 years. It is difficult to determine the number of all roads currently on public lands, but agency estimates exist. The U.S. Forest Service (USFS) maintains approximately 440,000 miles of roads, nearly 10 times the total length of the interstate highway system.

Roads and the maintenance of roads affect natural terrestrial and aquatic environments in many ways. Increased erosion, air, and water pollution, spread of invasive exotics, road mortality and avoidance, and habitat fragmentation all accompany roads (reviewed by Andrews 1990; Spellerberg 1998; Jones et al. 2000; Trombulak & Frissell 2000). Roads directly fragment natural ecosystems (Reed et al. 1996), but—more importantly—they also provide access to areas, which leads to subsequent human disturbances from activities such as logging, mining, grazing, agriculture, and urban development. These disturbances result in substantial declines in native species and an overall degradation of ecosystem integrity. Roads, deforestation, and fragmentation are intimately related.

On USFS land, two lengthy roadless-area reviews and evaluations (RARE I and RARE II) were performed in the 1970s. The objective of the reviews was to inventory the roadless areas of the national forest system to determine which ones should be considered for wilderness designation as a result of the Wilderness Act of 1964 (Crowell & Cutler 1983). This substantial mapping activity set a minimum size of 2024 ha for designation as "wilderness;" smaller areas would be ineligible for such designation. During the 96th Congress, over half of the 6 million ha of roadless areas recommended by RARE II were declared wilderness. In the early 1980s, with the Reagan administration and new leadership in the 97th Congress, all actions on roadless areas were suspended (Crowell & Cutler 1983). Since that time, roadless areas have been mapped by a wide range of conservationists using a variety of techniques. As large unroaded lands disappear, a minimum size of 405 ha is now being examined for wilderness designation. Geographic information systems (GIS) have been employed extensively in recent years to address this issue. The nongovernmental conservation community has widely promoted roadless areas as important conservation lands (Foreman & Wolke 1992; Noss & Cooperrider 1994), but few studies have evaluated their actual ecological benefits.

On 13 October 1999, President Clinton directed the USFS to provide strong and lasting protection for roadless areas in the national forest system. The President's directive initiated a rule-making process on roadless areas by the USFS that lead to over 517,000 comments from the public (USFS 2000). On 10 May 2000, the USFS released a proposed rule and draft environmental impact statement for which the public provided over 1.1 million additional responses (USFS 2000). The rule-making process for roadless areas marked the biggest public commenting process ever undertaken by the USFS. Given the significance of the impending roadless-area policy, we sought to evaluate the ecological attributes of existing roadless areas in a forest ecoregion, the Klamath-Siskiyou. The ecological attributes we examined included five special elements of conservation concern, two representation evaluations, and regional landscape connectivity.

Methods

Study Area

The Klamath-Siskiyou ecoregion of northwestern California and southwestern Oregon has long been recognized for its outstanding biodiversity (Whittaker 1960; Kruckeberg 1984; DellaSala et al. 1999). The World Conservation Union (IUCN) considers the Klamath-Siskiyou an area of global botanical significance (Wagner 1997), and the World Wildlife Fund chose it as a global 200 ecoregion, meaning that it is of high biodiversity value and under considerable threat (Ricketts et al. 1999). The ecoregion, as we define it, covers over 43,000 km^2, of which approximately 63% is in public ownership (83% of this by the USFS). Nearly 13% of the ecoregion is considered strictly protected, primarily through a number of relatively large, scattered wilderness areas (Fig. 1).

Roadless Area Mapping and Evaluation

As part of a regional conservation assessment (Strittholt et al. 1999), we assembled road data and mapped roadless areas (≥405 ha). We used 1:100,000 road data for the entire ecoregion and 1:24,000 for the public-lands portion. Using the 1:100,000 scaled data, we calculated road density with a 5 × 5 km moving-window operation on density results from a 1 × 1 km fixed grid, which provided a context for the subsequent mapping and evaluation of roadless areas. We mapped roadless areas on existing public lands using a newly developed technique that combines raster and vector GIS operations on 1:24,000–scaled roads data (Strittholt et al. 1999). We included all public lands in mapping and assessing ecological values regardless of agency jurisdiction. In both road density and roadless-area mapping, we excluded trails from the analysis. We used Arc/Info GIS to conduct the computer-mapping analyses.

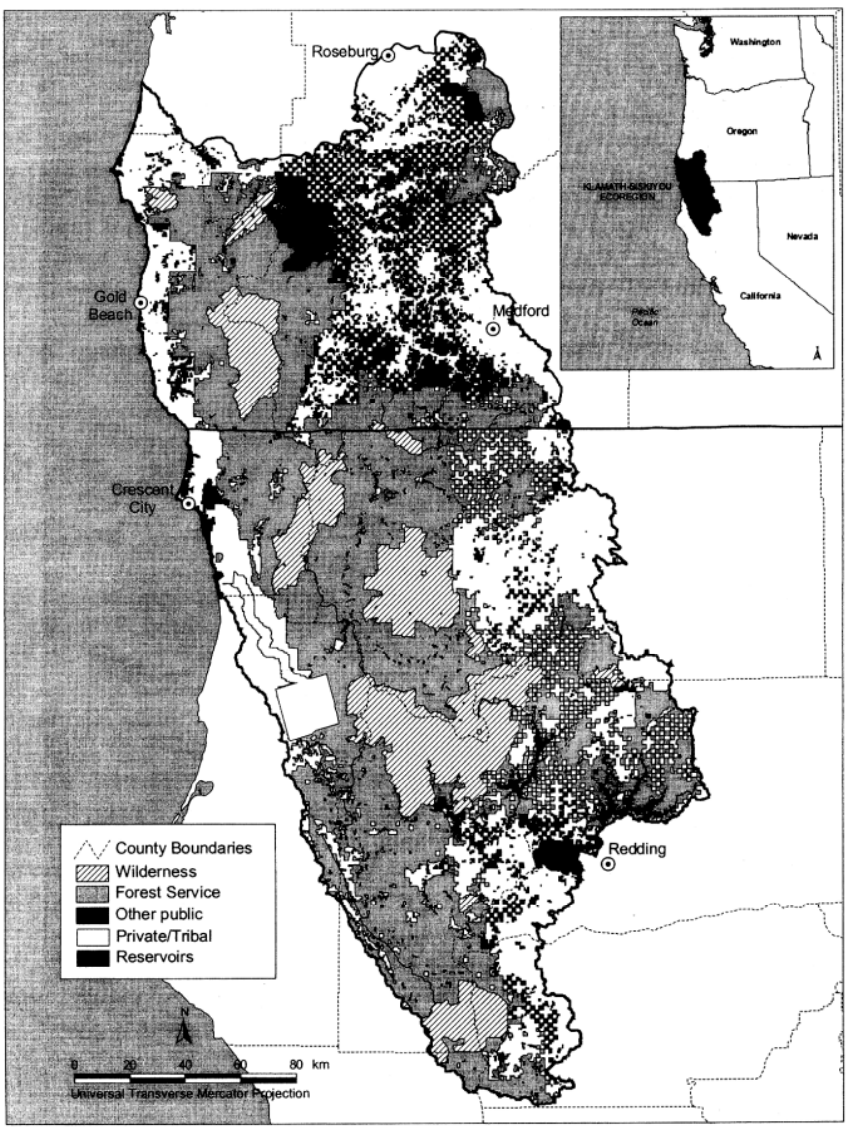

Figure 1. Klamath-Siskiyou primary ownership and existing wilderness areas.

Using all available GIS data layers, we focused on evaluating the ecological or conservation attributes of the remaining roadless areas in the Klamath-Siskiyou ecoregion, and examined large (>2024 ha) and small (405–2024 ha) roadless areas separately. We also subjected the designated wilderness areas to the same data queries and summarized the conservation benefits of adding the roadless areas to the current wilderness system for the ecoregion.

Special Elements

We evaluated the mapped roadless areas in terms of five special-element criteria in the region, including the presence or absence of natural-heritage elements, serpentine geology (of special importance to this region), late-seral forest, high abundances of Port Orford cedar (*Chamaecyparis lawsoniana*) with few or no signs of infestation by a lethal root-rot fungus, and watersheds of aquatic biodiversity importance (or key watersheds) as identified by Forest Ecosystem Management Assessment Team (1993).

Occurrences of natural-heritage elements are known point locations for plant and animal species of special conservation interest, including rare and endangered species. Computer databases are collected and maintained on these species by natural-heritage programs organized by individual U.S. states. For this study, heritage data were obtained from the Oregon Natural Heritage Program and California Natural Diversity Database, and all records since 1970 were included in the analysis. We examined 8793 heritage-element occurrence records, which fell within the Klamath-Siskiyou ecoregion boundary. We treated each record (or point location) equally; rarer species were not weighted. We subdivided all point locations into six categories, primarily by taxonomic group, and overlaid them against data layers for mapped roadless areas and designated wilderness areas.

The Klamath-Siskiyou ecoregion is noted for its abundance of serpentine bedrock geology (13%, or 575,550 ha of the ecoregion). Serpentine is a metamorphic rock upon which ultramafic soils are built. Ultramafic soils are unique in many of their physical and chemical properties: they are low in exchangeable calcium and high in magnesium, and they tend to be deficient in many soil nutrients. Many of these soils contain high levels of heavy metals, such as nickel, chromium, and cobalt, that impede normal plant growth and development (Coleman & Kruckeberg 1999). For these reasons, serpentine geology is one of several known factors that have contributed to species endemism in the Klamath-Siskiyou (DellaSala et al. 1999; Strittholt et al. 1999). Protection of areas of serpentine geology therefore becomes an important regional conservation objective. From existing U.S. Geological Survey state geology maps (1:500,000 map scale) for Oregon and California, we digitized serpentine geology. Using overlay operations, we then calculated the area of serpentine geology in designated wilderness and mapped roadless areas.

Based on interpretation of mid-1990s satellite images, approximately 22% of the Klamath-Siskiyou ecoregion contained late-seral forest (928,356 ha), and 80% of it was on public land (Strittholt et al. 1999). Late-seral forest, which once dominated much of the Pacific Northwest, has been in significant decline since the end of World War II. Many species and natural processes depend upon older forests, and they are of special conservation concern in the Klamath-Siskiyou. We calculated the area of late-seral forest in designated wilderness and mapped roadless areas. Spatial resolution of the forest data was 30 × 30 m and based on two different datasets, one for the Oregon portion of the ecoregion (Cohen et al. 1995) and the other for the California portion (Legacy, unpublished data). Late seral was defined as any forest type more than 100 years of age. Late-seral condition is not equally important among the various forest types found in the Klamath-Siskiyou. For example, some globally imperiled forest types are found in the ecoregion, including white fir (*Abies concolor*), Port Orford cedar, Brewer spruce (*Picea breweriana*), and huckleberry oak (*Quercus vaccinifolia*), and these are of particular concern (DellaSala et al. 1999), but we did not have the data necessary to evaluate this criterion in greater depth. In addition, only a subset of this area could be regarded as old-growth forest, but, again, such detailed information on forest age was not available for the ecoregion.

Port Orford cedar is an important southwestern Oregon–northwest California endemic tree species (Lang 1999) that grows primarily in riparian areas, where it provides channel stabilization, shade for waterways, and microhabitat for numerous aquatic species (Jimerson & Creasy 1997). In an area where migratory species—most notably salmon—make up the bulk of the region's fish fauna, streamside integrity is of paramount importance, and Port Orford cedar is one of the dominant riparian tree species throughout the western sections of the Klamath-Siskiyou ecoregion. These cedars are at risk because of their value in Asian markets (there is no major domestic market for Port Orford cedar) and, more important, from an imported root-rot fungus (*Phytophthora lateralis*) (Lang 1999). This fungus is water-borne and is usually associated with the building and use of roads for logging, mining, and recreation (Jimerson & Creasy 1997). Spores are easily picked up from infected sites and transported to uninfected ones on the tires of vehicles. Infestation usually results in mortality (Zobel et al. 1985). Because of their limited distribution and current threats from management and the exotic root-rot fungus, Port Orford cedar plant communities were classified as G2 (or globally imperiled) by The Nature Conservancy (Grossman et al. 1994).

We mapped Port Orford cedar distribution and root-rot fungus infestation by sixth-field subwatershed, and we evaluated both cedar density and infestation rate against designated wilderness and mapped roadless areas. Watersheds (or catchments) include all lands enclosed by a continuous hydrologic surface-drainage divide and lying upslope from a specified point on a stream (Maxwell et al. 1995). Watersheds are hierarchical and can be modeled from digital elevation models (Maidment & Djokic 2000) or delineated from hydrology and contour maps. The U.S. Geological Survey developed its own hierarchical watershed-delineation system based on a hydrologic unit code-naming convention. In this system, every two digits of a hydrologic unit code correspond to each level in the hydrologic unit system: A 12-digit code identifies six nested subwatersheds, the sixth pair of digits representing the finest subwatershed.

Of the 1135 sixth-field subwatersheds mapped for the Klamath-Sisikyou ecoregion, 215 contained cedar data, all on USFS public lands. We assigned ordinal scores (1–5, with 5 representing the highest cedar density and lowest level of infestation) to cedar density and degree of infestation separately, added them together to obtain a composite score, and assigned the score to each subwatershed (Strittholt et al. 1999). Of the 903,559 ha (n = 215 subwatersheds) containing cedar and infestation data, 19% (179,430 ha, n = 40 subwatersheds) scored low, meaning they had a combination of low cedar density and high infestation. Approximately 22% of the subwatersheds (199,389 ha, n = 48) scored high (i.e., high cedar density and low infestation). We classified the remaining subwatersheds (58% or 524,740 ha, n = 127) as medium (i.e., moderate cedar density and moderate infestation). We then overlaid the designated wilderness and mapped roadless areas on these composite-score categories and summarized the results.

Of the 1135 sixth-field subwatershed basins mapped for the Klamath-Siskiyou ecoregion (Strittholt et al. 1999), 333 were previously identified as key watersheds by fisheries biologists of the Forest Ecosystem Management Assessment Team (1993). Key watersheds are those believed to be of special importance for aquatic biodiversity, with particular emphasis on the salmonid species and stocks at risk throughout the Pacific Northwest. We determined the number and area of key watersheds in designated wilderness and mapped roadless areas.

Representation

We measured elevation bands and natural habitat types to evaluate the contribution roadless areas make to ecosystem representation. Elevations in the Klamath-Siskiyou ecoregion range from sea level to 2700 m. To simplify the assessment, we pooled the elevation values from the U.S. Geological Survey digital elevation models (DEMs) into 305-m intervals, which resulted in nine elevation bands (or classes). We then calculated the area of each elevation class occupied by designated wilderness and roadless areas. We further simplified the results into classes of low (sea level–915 m), medium (915–1525 m), and high (>1525 m) elevation.

We also examined representation by merging physical and biological habitat types. We combined 19 physical habitat types (Vance-Borland 1999) with 26 natural vegetation types, resulting in 214 distinct natural habitat classes (Strittholt et al. 1999). We calculated degree of representation for each of the 214 natural habitat types according to designated wilderness and mapped roadless areas, and we assigned each to one of four possible representation categories: (1) >50% represented, (2) 25–50% represented, (3) <25% represented, and (4) none represented.

Regional Landscape Connectivity

We examined landscape connectivity of the ecoregion with Arc/Info and FRAGSTATS, a versatile fragmentation software. As with the other analyses, we considered the designated wilderness, and mapped large and small roadless areas separately. FRAGSTATS calculates a large number of fragmentation metrics (or indices) on three distinct levels, patch, class, and landscape (McGarigal & Marks 1995). We focused the assessment on six class-level metrics, including (1) class area, (2) core percent of landscape, (3) mean core area, (4) total core area index, (5) mean nearest-neighbor distance, and (6) edge density (see Appendix for definitions).

We applied the fragmentation metrics in two ways. First, we ran FRAGSTATS on a merged raster file containing designated wilderness and the two roadless-area size categories, treating each as a distinct landscape class. Second, we ran FRAGSTATS on a series of map layers to ascertain the level of connectivity each provided. One map contained only designated wilderness, a second contained designated wilderness and large roadless areas (>2024 ha), and a third contained designated wilderness and all roadless areas (≥405 ha). In each case, we assigned all areas of interest as the same class. By analyzing these three cases, we tested the level of landscape connectivity for the current condition (existing protected areas only), a landscape with the existing protected areas plus all large roadless areas, and existing protected areas plus all large and small roadless areas. We put the edge buffer distance at 90 m for all trials, based on the mean edge-effect distance determined for changes in the physical environment at the edges of Pacific Northwest forests (Chen et al. 1992).

Results

Roads and Roadless Areas

The total road length of all surface types for the Klamath-Siskiyou mapped at 1:100,000 scale was 44,522 km. The road data available at 1:24,000 scale (approximately 75% of the ecoregion), added 42% more road length than the data for coarser roads over the same area. Road-density results calculated from the coarser dataset showed sizeable, somewhat isolated regions of low road density. Designated wilderness was at the center of these larger areas.

Designated wilderness in the ecoregion covered 533,700 ha in several large, scattered patches. We mapped nearly 500 roadless areas of ≥405 ha on public lands of the Klamath-Siskiyou ecoregion area, which totaled 1,186,422 ha, approximately 27% of the ecoregion and more than twice the area of designated wilderness (Fig. 2). We mapped 131 large roadless areas covering 871,815 ha and 367 smaller roadless areas covering 314,607 ha, or 26% of the total roadless area. The USFS lands accounted for most (92%) of the roadless area mapped, followed by Bureau of Land Management (7.6%) and other public lands (e.g., National Park Service, 0.4%).

Special Elements

Roadless areas contained nearly four times more heritage elements than designated wilderness areas; the largest gains occurred in the plant and vertebrate categories (Table 1). In general, roadless areas captured approximately 36% of all known heritage elements. When added to those within designated wilderness, the total number increased to 3816 records, or 43% of all known records (Table 1). Small roadless areas accounted for 931 element records, or 29% of the total roadless-area records, adding substantially more plant, vertebrate, and invertebrate occurrences.

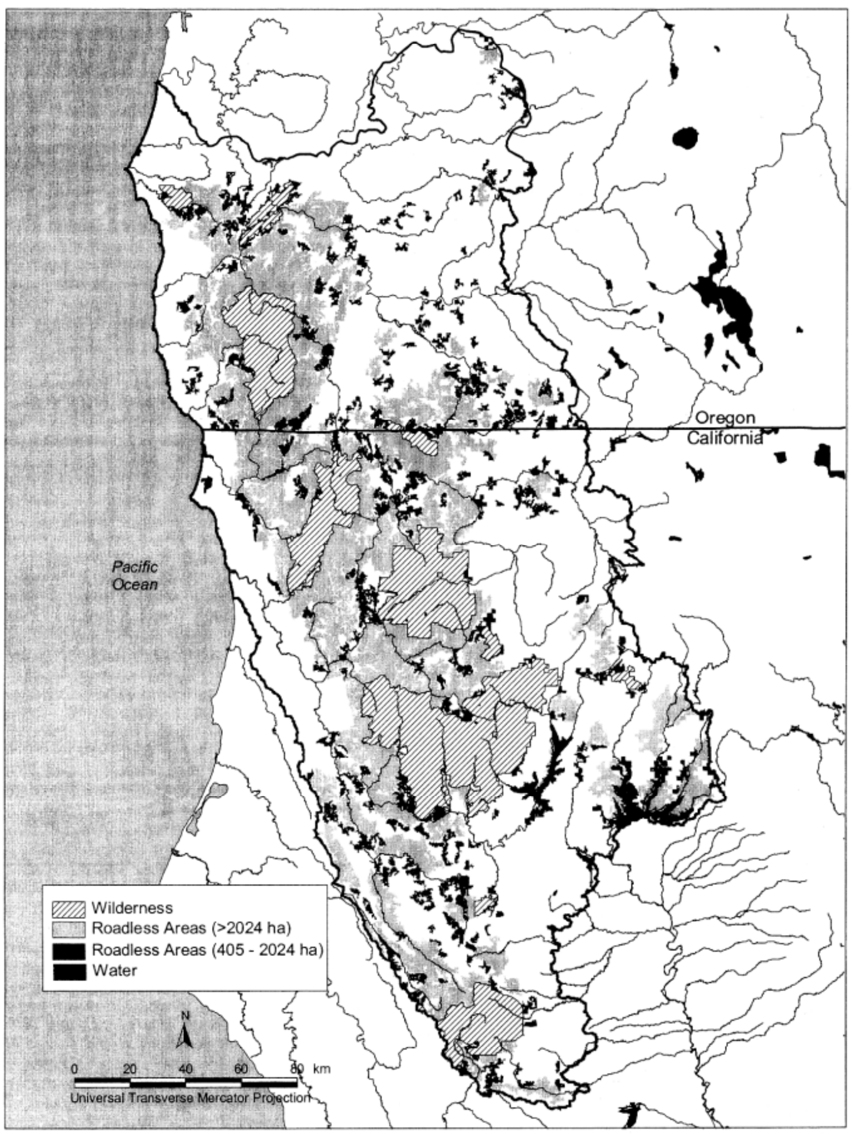

Figure 2. Large (>2024 ha) and small (405–2024 ha) roadless areas within the Klamath-Siskiyou ecoregion.

Table 1. Frequency of heritage-element occurrence records for existing wilderness and mapped roadless areas within the Klamath-Siskiyou ecoregion.

Element category	*No. of records*	*No. in wilderness*	*No. in roadless areas (≥405 ha)*	*No. in roadless areas (405–2,024 ha)*	*Wilderness (%)*	*Roadless areas (%)*	*Combined (%)*
Plants	3837	389	1306	341	10.1	34.0	44.1
Vertebrates	4652	212	1749	562	4.6	37.6	41.2
Invertebrates	132	2	80	26	1.5	60.6	62.1
Community	8	0	6	2	0.0	75.0	75.0
Aquatic	6	0	0	0	0.0	0.0	0.0
Special feature	158	36	36	0	22.8	22.8	45.6
Total	8793	639	3177	931	7.3	36.1	43.4

We found 209,051 ha (36%) of the existing serpentine geology in the Klamath-Siskiyou ecoregion in roadless areas. The contribution from the smaller roadless-area class was 47,090 ha, 22% of the roadless-area total. Designated wilderness areas captured 100,170 ha (17%) of serpentine geology in the ecoregion. Adding all remaining roadless areas to designated wilderness would more than triple the area of serpentine currently protected, bringing the ecoregion protection total to approximately 54%.

Of the 928,356 ha of late-seral forest mapped for the Klamath-Siskiyou, 337,180 ha (36%) were in roadless areas. Small roadless areas accounted for 93,508 ha, or 28% of the roadless-area total. In comparison, designated wilderness areas contained only 16% (149,386 ha) of the remaining late-seral forest. We found no difference in the average density of late-seral forest between wilderness and roadless areas: both contained approximately 28% late-seral forest. The smaller roadless-area class showed a slightly higher percentage of late-seral cover as a group (30%). Of course, individual wilderness areas and roadless areas showed higher and lower percentages of late-seral forest cover. Adding roadless areas into protection brought the total area of late-seral forest protected in the ecoregion to 52% (486,566 ha).

In the Port Orford cedar assessment, roadless areas contained far more subwatershed areas classified as having either low or medium cedar composite scores than did designated wilderness areas (Table 2). These areas require special management, such as road closure and removal, to stop the spread of the root-rot fungus. The area identified as having a high cedar composite score—high cedar density and low fungus infestation—was included largely in designated wilderness or roadless areas and is the remaining stronghold on the public-land portion of the region for protecting cedar and the many ecosystem services this species provides.

Key watersheds covered 1,157,812 ha, or 26% of the Klamath-Siskiyou ecoregion. Over 42% of the key watershed area (491,954 ha) was also roadless. The contribution from smaller roadless areas was 89,506 ha, or 18% of the roadless area total. Of the 333 key watersheds, 190 (57%) were 80% contained (54 were completely contained) within wilderness and roadless areas. Only 13 (4%) contained no roadless area. Key watershed in designated wilderness covered 303,054 ha (26%). The combined key watershed total for both wilderness and roadless areas was 795,008 ha, 68% of all key watershed area.

Representation

Wilderness and roadless areas showed a marked difference in elevation representation (Fig. 3). When compared to wilderness, roadless areas captured much more

Table 2. Scored results of Port Orford cedar density and infestation by root-rot fungus, organized by subwatershed (n = 215) compared with wilderness and roadless areas within the Klamath-Siskiyou ecoregion.

*Cedar composite score categories**	*Total area (ha)*	*Wilderness (ha)*	*Roadless (ha)*	*Wilderness (%)*	*Roadless (%)*	*Combined (%)*
Low (n = 40)	179,430	8,948	79,948	5.0	44.5	49.5
Medium (n = 127)	524,740	88,166	228,352	16.8	43.5	60.3
High (n = 48)	199,389	60,927	113,933	30.5	57.1	87.6
Total (n = 215)	903,559	158,041	422,233	17.5	46.7	64.2

**For details on cedar composite scoring method resulting in categories of low (low cedar density and high infestaion), medium, and high (high cedar density and low infestation), see Strittholt et al. (1999).*

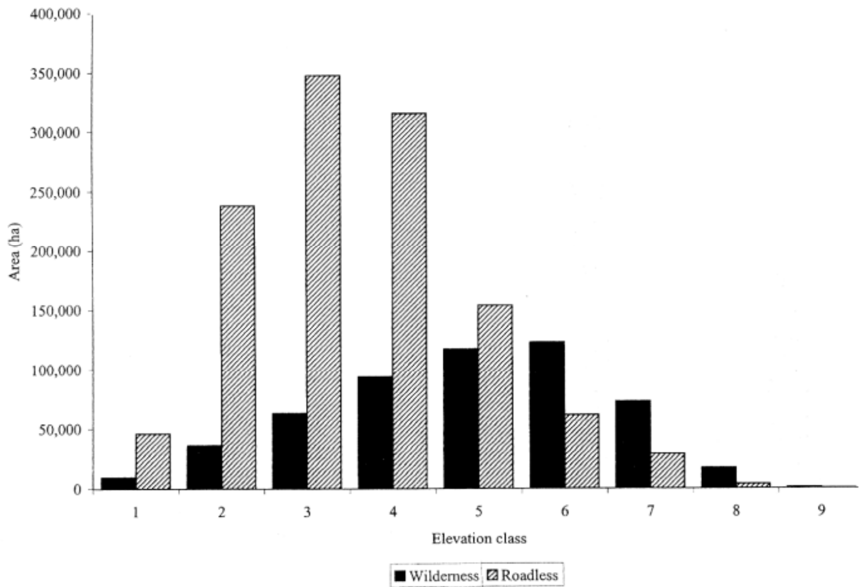

Figure 3. Representation of elevation classes by wilderness and mapped roadless areas for the Klamath-Siskiyou ecoregion. Elevation classes are reported in approximately 305-m intervals from mean sea level to 305 m (elevation class 1).

of the low- and medium-elevation classes (<1525 m) (Table 3). The small roadless areas made up about the same proportion (approximately 26%) of each elevation class, providing additional representation of low and medium elevations. Roadless areas did proportionally better than designated wilderness at representing low and medium elevations. Most of the existing high-elevation sites in the Klamath-Siskiyou were in designated wilderness.

Of the 214 combined physical-biological habitat types described and mapped for the Klamath-Siskiyou, roadless areas contained a wider array of habitat types than designated wilderness. Roadless areas also contained many different habitat types than designated wilderness, with 96 new types (45%) represented at the ≥25% level (Fig. 4). When combined, designated wilderness and roadless areas complimented each other well, with 64% (138/214) of the classes represented at the ≥25% representation level. Although not visible in Fig. 4, smaller roadless areas made important contributions to 148 different habitat types, including 24 not found in any designated wilderness or large roadless areas. In addition, 54 habitat types were highly concentrated in smaller road-

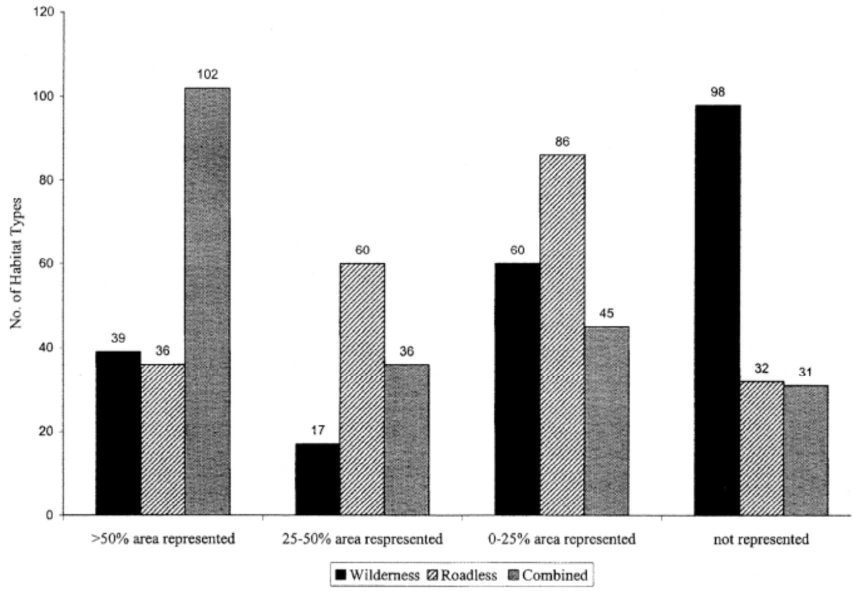

Figure 4. Physical-biological habitat representation (n = 214) for wilderness and mapped roadless areas for the Klamath-Siskiyou ecoregion.

less areas. More than 50% of the total area of these habitat types was located in this roadless-area size class alone.

Regional Landscape Connectivity

Treating each component of a single landscape—wilderness, larger roadless areas, and smaller roadless areas—as a separate class produces a number of interesting but not unexpected results (Table 4). Designated wilderness areas in the Klamath-Siskiyou are large and scattered, centering on the major high-elevation portions of the region. Based on this description, the wilderness areas showed some expected fragmentation results: large values for total core area, mean core area, and mean nearest-neighbor distance. Edge density was also predictably low. Compared to wilderness areas, the larger roadless areas showed a substantial decrease in the mean core-area measurement (26,736 ha) and in the mean nearest-neighbor distance (5356 m). Core percent of landscape and edge density were higher in larger roadless areas than in any other class. The higher edge density signifies that many of the patches, while large, are relatively convoluted. Total core area index was lower than for wilderness, but still high.

Mean core area for the smaller roadless areas was predictably low, but this group still showed a relatively high total core-area index value. Based on a lower edge-density value, smaller roadless areas were less convoluted in shape than the larger size class. This class accounted for nearly 15% of all core area among the three classes examined.

The fragmentation results for each of the three landscape scenarios—wilderness only, wilderness plus large roadless areas, and wilderness plus all roadless areas of ≥405 ha—showed predictable increases in class area and edge density as more land parcels were given theoretical protection status (Table 5). Because only one class type was used for each landscape scenario, the values for core percentage of landscape and total core-area index were identical. Going from the least-protected to the most-protected scenarios, declines were observed for core percentage of landscape; total core-area index, mean core area, and mean nearest neighbor, and increases were observed in class area and edge density. The substantial declines in mean nearest-neighbor values

Table 4. Fragmentation results for the Klamath-Siskiyou ecoregion calculated for a single landscape containing wilderness, small roadless areas (405–2024 ha), and large roadless areas (>2024 ha) treated as separate classes.

Fragmentation index	*Wilderness*	*Roadless areas (>2024 ha)*	*Roadless areas (405-2024 ha)*
Class area (ha)	529,619	872,013	315,297
Core percentage of landscape	30	45	15
Total core area index (%)	97	88	80
Mean core area (ha)	32,178	5,442	665
Mean nearest-neighbor distance (m)	6,459	1,103	864
Edge density (m/ha)	3.88	9.13	5.42

Table 5. Fragmentation results for the Klamath-Siskiyou ecoregion, calculated for three separate landscapes: wilderness only, wilderness + large roadless areas, and wilderness + all roadless areas.

Fragmentation index	*Wilderness only*	*Wilderness + roadless areas (>2024 ha)*	*Widlerness + roadless areas (≥405 ha)*
Class area (ha)	529,619	1,401,632	1,716,929
Core percentage of landscape	97	92	90
Total core area index (%)	97	92	90
Mean core area (ha)	32,178	12,087	3,554
Mean nearest-neighbor distance (m)	6,459	1,370	225
Edge density (m/ha)	3.88	11.50	14.46

provide the best evidence out of these indices that adding roadless areas to the current distribution of protected areas would provide improved regional landscape connectivity. Including the smaller roadless areas added significantly to regional landscape connectivity.

Discussion

The extensive literature on the importance of intact natural habitats makes a compelling case for the potential role of roadless areas as refugia for native biodiversity and as areas crucial to forest integrity and function. Equally impressive is the mounting body of evidence showing the ecological costs of roads. Although some species may benefit from the physical changes and fragmentation caused by roads, their overall and cumulative effect in natural forest landscapes is negative, often seriously so. The suggestion that research on the effects of roads on natural ecosystems is inconclusive (e.g., Heinz Center 1999) is largely unsupported by the literature. Thus, the exclusion of roads from fragmentation assessments presents an incomplete picture of the effects of one of the most predominate anthropogenically induced changes to forested ecosystems in North America. For a variety of reasons, some of which are ecological, roadless areas are once again on the political agenda.

On numerous scientific grounds, our analyses strongly support protecting roadless areas in the Klamath-Siskiyou ecoregion. Roadless areas contained many known locations of species of concern, including rare and endangered species, many more than could be explained by additional land area alone, and the contribution by small roadless areas was noteworthy. That is not to say that roadless areas contained the majority of the known locations of rare species or even all of the known biological hotspots in the ecoregion. For example, there are a few well-known biological hotspots largely within the roaded public and private lands of the Klamath-Siskiyou (Noss et al. 1999; Strittholt et al. 1999). If one conservation goal is to protect most or all of the known rare species, roadless areas contribute only partially to this objective. Additional conservation measures and approaches are needed to achieve this goal in the Klamath-Siskiyou. In addition, our assumption is that rare species located in designated wilderness and roadless areas would be better protected than if they existed under other management practices. This assumption would not always be substantiated by the natural history of a particular species and the individual site conditions under which it lives; a species-specific needs assessment is required to make an accurate determination. We also suspect that many more rare species are present in roadless areas than are presently known because of the remoteness of roadless areas, a lack of organized biological surveys, and a current sampling bias toward areas with road access. The actual importance of roadless areas with regard to this criterion may actually be higher than the current data analysis indicates.

The amount of late-seral forest in roadless areas is considerable, but the percentage is about that found in wilderness areas (both are around 28% late seral). What is important is that these forests are part of relatively large, intact blocks of habitat representing important ecological values. Larger patches of forest that can support a wider range of species, including those requiring large home ranges, are more secure from human-induced effects and are large enough to allow natural processes such as fire to operate without human interference. As with heritage elements, although roadless areas offer some protection to late-seral forests, not all important late-seral stands are included in roadless areas; This includes particular stands of late-seral forest within the Klamath-Siskiyou.

The contribution roadless areas made to Port Orford cedar conservation was particularly significant. The roadless area and designated wilderness components of the best-condition category were high; when combined, they accounted for nearly 88% of the best remaining areas of uninfected cedar. Because root-rot fungus is easily spread by the tires of vehicles moving on roads from infected watersheds to uninfected ones, maintaining large roadless areas is one important strategy for stopping the spread of the disease and therefore protecting this important tree species. At this level of analysis, smaller roadless areas do not seem to be as important for cedar as larger ones; but as in the case of key watersheds, the position of these roadless areas may be as important as the total area they protect.

Our representation analyses suggest that an important role of roadless areas is adding low and medium elevations and many combined physical-biological habitat classes to the reserve network. Other researchers have shown that many of the existing protected areas (especially wilderness areas) are concentrated on higher elevations (Harris 1984; Scott et al. 1993; Strittholt & Frost 1997), and the assumption could be made that most of the remaining roadless areas are much the same. Based on our assessment, this was not the case in the Klamath-Siskiyou. Roadless areas contributed significantly to low and medium elevations. Lower elevations contained most of the region's biological richness (DellaSala et al. 1999), and roadless areas were well represented at these elevations. If full representation of existing habitat types is a regional conservation goal, roadless areas contribute significantly to this objective, but conservation actions on roaded public and private lands need to be taken as well (Strittholt et al. 1999).

The way wilderness and roadless areas complimented one another in representing the various physical-biological classes defined for the Klamath-Siskiyou ecoregion is an important finding for regional conservation. As one would expect from the elevation results, wilderness areas contained large portions of the physical-biological habitat types found at the higher elevations. Wilderness areas are concentrated on most of the forested and non-forested ecosystems at high elevations, including most of the red fir (*Abies magnifica*) and white fir (*A. concolor*) forests and much of the higher Jeffrey pine (*Pinus jeffreyi*), ponderosa pine (*P. ponderosa*), montane-hardwood conifer, and Klamath mixed-conifer forest types. Roadless areas added additional area to some of these habitat types, and—more important—picked up different physical zones for the same plant community types as well as totally new habitat types, including forests of Douglas-fir, montane hardwood, and Sierra mixed conifers growing under various physical zones defined and mapped for the region (Strittholt et al. 1999; Vance-Borland 1999). Smaller roadless areas were particularly important in contributing to 54 different habitat types and were exclusively responsible for capturing 24 habitat types not encountered at all in wilderness or the larger roadless areas.

Our fragmentation results demonstrated the importance of roadless areas to regional connectivity. The larger roadless areas contributed the most, but protecting the smaller roadless areas would contribute to the protection of the overall landscape connectivity in this ecoregion, and it would do so while maintaining a high level of core interior habitat. In the Klamath-Siskiyou, wilderness and roadless-area patches are positioned in such a way that, when they are protected, once-isolated habitat islands become linked throughout the heart of the ecoregion. In the future, the issue of inter-regional linkage will have to be addressed, and roadless areas could provide the nuclei around which future corridors targeting individual species or ecosystem processes could be designed.

Small roadless areas in the Klamath-Siskiyou did not equally address all conservation issues examined, but they address many of them significantly, especially heritage elements, late-seral forests, elevation representation, habitat-type representation, and overall landscape connectivity. Based on the results, small roadless areas warrant inclusion in future assessment and planning of roadless areas. If small roadless areas are important in the Klamath-Siskiyou, where a high proportion of larger roadless areas exist, then they are likely to be even more important in regions where the majority of roadless areas are small, such as the southern Appalachians.

We considered the importance of roadless areas as a whole to the conservation of regional biodiversity. The next logical step in the roadless-areas assessment for the Klamath-Siskiyou and elsewhere will be to evaluate each roadless area individually to measure its relative ecological attributes. To some extent, this has already been done for the Klamath-Siskiyou (Strittholt et al. 1999), and an expansion of this assessment is currently underway that will include the national forests of western Washington, Oregon, and northern California. The better the ecological attributes of each roadless area are quantified, the better regional conservation can be planned. That is not to say that the ecological criteria we examined (or ecological criteria in general) are the only values roadless areas possess, and ecological reasons are not the only criteria for evaluation. Other values humans place on wild places, such as recreational, aesthetic, educational, economic, and scientific values, are all important reasons for establishing greater environmental protection of roadless areas.

The opportunity to protect some of the largest remaining forest habitat in the United States may be a fleeting one. Time is of the essence. Based on agency inventories in 1979, the USFS had about 32 million ha (42%) of roadless areas. Since the 1979 RARE II process, the estimated rate of loss of roadless areas has been about 400,000 ha each year nationally (Foreman & Wolke 1992). Under the new roadless-area rule making (USFS 2000), an average of 95 km of new roads each year are planned for roadless country through 2004.

Providing protection of large natural areas is an indispensable component of an overall conservation strategy (Noss & Cooperrider 1994), but a protected-area network cannot be compoed primarily of poor-quality conservation lands (Hall 1988). Protected-area networks must be carefully designed to maintain regional biodiversity, ecosystem processes, and overall ecosystem integrity. The existing roadless areas on federal lands in the United States are the remaining pieces of the natural landscape that once covered the nation. Most biologically productive lands are already developed, and opportunities are limited to design effective protected-area networks without the necessity for substantial restoration. Roadless areas provide the remaining building blocks toward this end, so it is important to understand the contribution these areas make to an overall conservation strategy. Without this information, there is little hope for effective conservation or informed land-use planning.

The roadless areas in the Klamath-Siskiyou, if protected, would provide a wide range of ecological attributes important in this ecoregion, which is why roadless areas became the cornerstone of a recent reserve design for the ecoregion (Noss et al. 1999; Strittholt et al. 1999). Our results underscore the significance of roadless areas for regional conservation, but roadless areas alone cannot provide all the ecological elements needed to maintain regional biodiversity. Thus, it will be important to manage roadless areas responsibly and restore them where necessary (DellaSala et al. 1999; Strittholt et al. 1999). We do not know if roadless areas in other regions will yield similar results, particularly since, according to the USFS (2000), 60% of roadless areas on national forests are at elevations above 1524 m. But we believe that our methodologies may be applied elsewhere, particularly as the inventory of small roadless areas takes on greater significance in federal-lands policy.

Acknowledgments

We thank all of those who supplied valuable datasets, which made this study possible, including J. Thomson of The Wilderness Society, W. Cohen of the Pacific Northwest Research Station, C. Jacoby of Legacy, T. O'Neil of the Northwest Habitat Institute, J. Kagan of the Oregon Natural Heritage Program, the Remote Sensing Lab in Sacramento, California, and U.S. Forest Service geographic information system labs from the Siskiyou, Klamath, Six Rivers, Shasta-Trinity, Rogue, and Umpqua National Forests. We also thank the anonymous reviewers whose comments improved this manuscript substantially. Finally, we are grateful to Environmental Systems Research Institute, Inc. (ESRI), and ERDAS, Inc., for their continuing and generous software support and the David and Lucille Packard Foundation, Moriah Fund, Park Foundation, and the Laird Norton Foundation for financial support.

Appendix

Descriptions of the six fragmentation metrics used in the Klamath-Siskiyou landscape connectivity analysis.*

Metric	*Description*
Class area (ha)	sum of the areas of all patches of the corresponding patch type (range: ≥0, without limit)
Core percentage of landscape	sum of the core areas of each patch of the corresponding patch type, divided by total landscape area (range: ≥0, ≤ 100)
Mean core area (ha)	sum of the core areas of each patch of the corresponding patch type, divided by the number of patches of the same type (range: ≥0, without limit)
Total core-area index (%)	sum of the core areas of each patch of the corresponding patch type, divided by the sum of the areas of each patch of the same type, multiplied by 100 (range: ≥ 0, ≤ 100)
Mean nearest-neighbor distance (m)	sum of the distance to the nearest neighboring type of the same type, based on nearest edge-to-edge distance for each patch of the corresponding patch type, divided by the number of patches of the same type (range: ≥0, without limit)
Edge density (m/ha)	sum of the lengths of all edge segments involving the corresponding patch type, divided by the total landscape area (range: ≥0, without limit)

The forgotten stage of forest succession: early-successional ecosystems on forest sites

Mark E Swanson[1*], Jerry F Franklin[2], Robert L Beschta[3], Charles M Crisafulli[4], Dominick A DellaSala[5], Richard L Hutto[6], David B Lindenmayer[7], and Frederick J Swanson[8]

Early-successional forest ecosystems that develop after stand-replacing or partial disturbances are diverse in species, processes, and structure. Post-disturbance ecosystems are also often rich in biological legacies, including surviving organisms and organically derived structures, such as woody debris. These legacies and post-disturbance plant communities provide resources that attract and sustain high species diversity, including numerous early-successional obligates, such as certain woodpeckers and arthropods. Early succession is the only period when tree canopies do not dominate the forest site, and so this stage can be characterized by high productivity of plant species (including herbs and shrubs), complex food webs, large nutrient fluxes, and high structural and spatial complexity. Different disturbances contrast markedly in terms of biological legacies, and this will influence the resultant physical and biological conditions, thus affecting successional pathways. Management activities, such as post-disturbance logging and dense tree planting, can reduce the richness within and the duration of early-successional ecosystems. Where maintenance of biodiversity is an objective, the importance and value of these natural early-successional ecosystems are underappreciated.

Front Ecol Environ 2010; doi:10.1890/090157

Severe natural disturbances – such as wildfires, windstorms, and insect epidemics – are characteristic of many forest ecosystems and can produce a "stand-replacement" event, by killing all or most of the dominant trees therein (Figure 1). Typically, limited biomass is actually consumed or removed in such events, but many trees and other organisms experience mortality, leaving behind important biological legacies (structures inherited from the pre-disturbance ecosystem; Franklin *et al*. 2000), including standing dead trees and downed boles (tree trunks; Franklin *et al*. 2000). Such legacies provide diverse physical/biological properties and suitable microclimatic conditions for many species. Thereafter, species-diverse plant communities develop because substantial amounts of previously limited resources (light, moisture, and nutrients) become available. These emerging plant communities create additional habitat complexity and provide various energetic resources for terrestrial and aquatic organisms.

In a nutshell:

- Naturally occurring, early-successional ecosystems on forest sites have distinctive characteristics, including high species diversity, as well as complex food webs and ecosystem processes
- This high species diversity is made up of survivors, opportunists, and habitat specialists that require the distinctive conditions present there
- Organic structures, such as live and dead trees, create habitat for surviving and colonizing organisms on many types of recently disturbed sites
- Traditional forestry activities (eg clearcutting or post-disturbance logging) reduce the species richness and key ecological processes associated with early-successional ecosystems; other activities, such as tree planting, can limit the duration (eg by plantation establishment) of this important successional stage

The ecological importance of early-successional forest ecosystems (ESFEs) has received little attention, except as a transitional phase, before resumption of tree dominance. In forestry, this period is often called the "cohort re-establishment" or "stand initiation" stage, with attention obviously focused on tree regeneration and the re-establishment of closed forest canopies (Franklin *et al*. 2002). Ecological studies have focused primarily on plant-community development and the needs of selected animal (mostly game) species, and not on the diverse ecological roles of ESFEs.

Here, we highlight important features of ESFEs, including their role in sustaining ecosystem processes and biodiversity, so that they may be appropriately considered by resource managers and scientists, and included within management/research programs dedicated to maintaining these functions, particularly at larger spatio-temporal scales. Most published examples focus on sites in western North America, but ESFEs are important elsewhere (Angelstam 1998; DeGraaf *et al*. 2003). We also discuss how traditional forestry practices, such as clearcutting, tree planting, and post-disturbance logging, can affect early-successional communities.

Figure 1. *Stand-replacement disturbance events in forests create large areas free of tree dominance and rich in physical and biological resources, including legacies of the pre-disturbance ecosystem.*

(Franklin *et al.* 2002). Consequently, the duration of ESFEs varies inversely with rapidity of tree regeneration and growth, which, in turn, depend on such variables as tree propagule availability, conditions affecting seedling or sprout establishment, and site productivity. ESFE longevity after natural disturbances is therefore highly variable.

Development of a closed forest canopy may require a century or more in areas with limited seed sources, harsh environmental conditions, severe shrub competition (in some instances), or combinations thereof (Hemstrom and Franklin 1982). For example, tree canopy closure after wildfire in the Douglas fir region of western North America often requires several decades (Poage *et al.* 2009), but can occur much more rapidly when canopy seedbanks are abundant (eg Larson and Franklin 2005). Closed forest canopies may develop quickly in forests dominated by trees with strong sprouting ability (eg many angiosperms) or when windstorms "release" understories of shade-tolerant tree seedling banks by removing all or most of the overstory (Foster *et al.* 1997).

■ Early-successional ecosystems on forest sites

Initial conditions after stand-replacing forest disturbances vary generically, depending on the type of disturbance; this includes the types of physical and biological legacies available. For example, aboveground vegetation may be limited immediately after the disturbance, as in the case of severe wildfires or volcanic eruptions. Conversely, intact understory communities may persist where forests have been blown down by severe windstorms. Spatial heterogeneity in conditions is characteristic, given that disturbances vary greatly in the amount of damage they cause (Turner *et al.* 1998). For instance, severe wildfires frequently include substantial areas of unburned as well as low to medium levels of mortality, creating variability in shade, litterfall, soil moisture, seed distribution, and other factors.

We define ESFEs as those ecosystems that occupy potentially forested sites in time and space between a stand-replacement disturbance and re-establishment of a closed forest canopy. These ecosystems undergo compositional and structural changes (succession) during their occupancy of a site. Changes begin immediately post-disturbance, as a result of the activities of surviving organisms (eg plants, animals, and fungi), including plant growth and seed production. Developmental processes are enriched by colonization of flora and fauna from outside the disturbed area. Successional change is often characterized by progressive dominance of annual and perennial herbs, shrubs, and trees, although all of these species are typically represented throughout the entire sequence of forest stand development (or sere; Halpern 1988).

The ESFE developmental stage ends with re-establishment of tree cover that is sufficiently dense to suppress and often eliminate many smaller shade-intolerant plants

■ Attributes of early-successional ecosystems

After severe disturbances, forest sites are characterized by open, non-tree-dominated environments, but have high levels of structural complexity and spatial heterogeneity and retain legacy materials.

Environmental conditions

Removal of the overstory forest canopy during disturbances dramatically alters the site's microclimate, including light regimes. These changes lead to increased exposure to sunlight, more extreme temperatures (ground and air), higher wind velocities, and lower levels of relative humidity and moisture in litter and surface soil. Shifts in these environmental metrics favor some species, while creating suboptimal or intolerable conditions for others. For example, post-disturbance plant community composition, cover, and physiognomy are altered as shade-tolerant understory herbs are largely displaced by shade-intolerant and drought-tolerant species. New substrates deposited by floods or volcanic eruptions may lack nutrients, provide additional water-holding capacity, or have high albedo, all of which favor shifts in plant communities.

Survivors

Organisms (in a variety of forms) that survive severe disturbances are extremely important for repopulating and

restoring ecosystem functions in the post-disturbance landscape. Even in severely disturbed areas, organisms may survive as individuals (mature or immature) or as reproductive structures (eg spores, seeds, rootstocks, and eggs), which become in situ propagule sources. For example, after the 1980 volcanic eruption of Mount St Helens (Washington State), most pre-eruption flora and many fauna (especially aquatic and burrowing terrestrial species) survived within the blast zone through several different mechanisms (Dale *et al*. 2005).

Surviving organisms are also often vital for the prompt re-establishment of important ecosystem functions, such as conservation of nutrients and stabilization of substrates. For instance, the important role of resprouting vegetation in curbing massive losses of nitrogen was demonstrated by experimentally clearcutting and applying herbicides in a watershed at Hubbard Brook Experimental Forest (Bormann and Likens 1979).

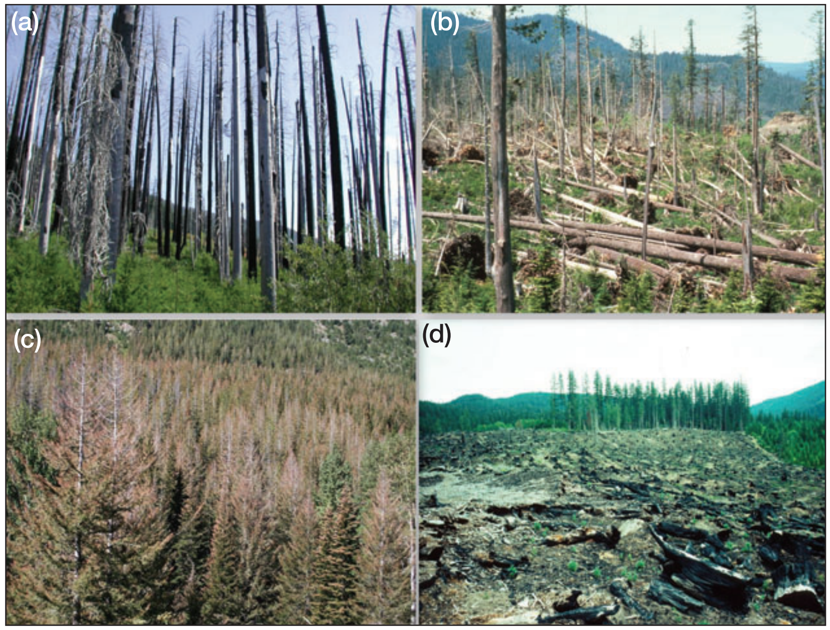

Figure 2. *Different types of disturbances produce different types of biological legacies, including living organisms and structures: (a) standing dead trees (snags) are dominant structural legacies after severe wildfires; (b) downed tree trunks and nearly intact understory communities are characteristic legacies after major windstorms; (c) standing dead trees are also dominant structural legacies after heavy insect infestations; and (d) clearcuts typically eliminate most aboveground structural legacies. Values for each metric are shown in Table 1 and are described in detail in the text.*

Structural complexity

The structural complexity of ESFEs depends initially on legacies, the general nature of which varies with the type of disturbance (Table 1; Figure 2); for example, snags and shrubs originating from belowground perennating (ie resprouting) parts or seeds are dominant legacies after wildfires, whereas downed boles and largely intact understories are typical post-disturbance characteristics of windstorms.

Woody legacies, such as snags and downed boles, play numerous roles in structuring and facilitating the development of the recovering ecosystem – providing habitat for survivors and colonists, moderating the physical environment, enriching aquatic systems in the disturbed area (Jones and Daniels 2008), and providing long-term sources of energy and nutrients (Harmon *et al*. 1986). Although subject to decomposition, these legacies can persist for many decades and sometimes even centuries.

Table 1. Different types of intense disturbances generate different types of biological legacies

	Disturbance				
Biological legacies	*Wildfire*	*Wind*	*Insect*	*Volcano*	*Clearcut*
Live trees	Infrequent	Variable	Variable (depends on stand composition)	Infrequent – confined to margins	Infrequent or absent
Snags	Abundant	Variable	Abundant	Abundant (spatially variable)	Infrequent or absent
Downed woody debris	Variable, but typically abundant	Abundant	Variable, but eventually abundant	Abundant (spatially variable)	Infrequent
Undisturbed understory	Infrequent	Abundant	Abundant	Infrequent – confined to disturbance margins	Infrequent
Spatial heterogeneity of recovery	High	Variable	High	High	Variable – usually low
Time in early-successional condition	Variable	Variable	Long	Variable – usually long	Variable – usually short

Figure 3. *Plant communities with well-developed shrub and perennial herb species are characteristic of early-successional communities on forest sites and provide diverse food resources. Twenty-five years after the Mount St Helens eruption in 1980, this community, which was within the blast zone, includes well-developed shrubs (eg* Sorbus *and* Vaccinium *spp), trees, and perennial herbs (eg* Epilobium angustifolium*).*

Structural complexity is further enhanced by the establishment and development of a variety of plant species, which often include perennial herbs and shrubs characteristic of open environments, as well as individual trees (Figure 3). The diversity of plant morphologies (maximum height, crown width, etc) increases structural richness, so that this associated flora contributes to both horizontal and vertical heterogeneity.

Spatial heterogeneity

Spatial heterogeneity is evident in early-successional ecosystems and has multiple causes: (1) natural variability in the geophysical template (topography and lithology) of the affected landscape; (2) variability in conditions in the pre-disturbance forest ecosystem; (3) variability in the intensity of the disturbance event; and (4) variability in rates and patterns of subsequent developmental processes in the ESFE. The first two sources relate to existing geophysical and biological patterns within the disturbed area. Land formations and patterns of geomorphic processes are certainly key geophysical elements (Swanson *et al.* 1988). The presence of surface water, such as streams and ponds, can be particularly influential in facilitating survival and re-establishment of biota.

Natural disturbances create heterogeneous environments at multiple spatial scales (Heinselmann 1973), because disturbances do not cause damage uniformly. Disturbances such as wildfires and windstorms are variable in intensity (eg "spotting", or initiation of new flame fronts by wind-thrown firebrands, during fire events). Alternatively, geographic variation in environmental conditions and topography (Swanson *et al.* 1988) influences the intensity of the disturbance and results in heterogeneity at multiple scales. Variability in the structure and composition of the pre-disturbance forest also creates spatial and temporal variability (Wardell-Johnson and Horowitz 1996). Some of these patterns may be transient, such as residual snowbanks protecting tree regeneration after the aforementioned Mount St Helens eruption (Dale *et al.* 2005).

Post-disturbance developmental processes also lead to spatial heterogeneity. For example, varying distances to sources of tree seed result in different rates and densities of tree re-establishment (Turner *et al.* 1998). Structural legacies can greatly influence the rates at which wind- or waterborne organic (including propagules) and inorganic materials are deposited. Finally, animal activity can strongly influence patterns of revegetation, as illustrated by the multiple effects that gophers (*Thomomys* spp) can have on post-disturbance landscapes (Crisafulli *et al.* 2005b) or the way ungulate browsing may impede tree regeneration (Hessl and Graumlich 2002).

Biological diversity

ESFEs in temperate forest seres show great diversity in the abundance of plant and animal species (Fontaine *et al.* 2009). Species composition may consist of a mix of forest survivors, opportunists, or ruderals (plants that grow on disturbed or poor-quality lands), and habitat specialists that co-exist in the resource-rich ESFE environment (Figure 3). Most forest understory flora can survive disturbances as established plants, perennating rootstocks, or seeds. In one study, in western North America, over 95% of understory species survived the combined disturbance of logging and burning of an old-growth Douglas-fir–western hemlock stand (Halpern 1988). Some important early-successional species (eg *Rubus* spp [blackberry; raspberry], *Ribes* spp [gooseberry], and *Ceanothus* spp [buckbrush]) may persist as long-lived seedbanks.

Opportunistic herbaceous species are often conspicuous dominants early in the development of ESFEs (Figure 4). Many of these weedy species (particularly annuals) decline quickly, although other opportunists will persist as part of the plant community until overtopped by slower growing shrubs or trees. Consequently, diverse plant communities of herbs, shrubs, and young trees emerge in ESFEs; this, combined with the structural legacies from the pre-disturbance ecosystem, often results in high levels of structural richness (Figure 3).

Many animals, including habitat specialists and species typically absent from the eventual tree-dominated com-

munities, thrive under the conditions found in ESFEs. For some species, this is the only successional stage that can provide suitable foraging or nesting habitat. As an example, many butterflies and moths (Lepidoptera) found in forested regions depend on the high diversity and quality of plant forage in ESFEs (eg Miller and Hammond 2007), whereas jewel beetles (Coleoptera: Buprestideae) depend on abundant coarse woody debris. Also, a number of ground-dwelling beetle species occur as habitat specialists in early-successional communities (Heyborne *et al.* 2003).

Figure 4. *Early-successional communities are often dominated by annual herbaceous species for the first few years after disturbance; these are quickly displaced by perennial herbaceous species and shrubs.*

Many vertebrates also respond positively to ESFEs, which may provide the only suitable habitat at a regional scale for some species. Ectothermic animals, such as reptiles (eg Rittenhouse *et al.* 2007), generally respond favorably to sunnier and drier conditions, colonizing early-successional habitat or increasing in abundance if present as survivors. Many amphibians also thrive in ESFEs, provided resources such as water bodies and key structures (eg logs) are available. The diversity and abundance of amphibians in the area affected by the 1980 Mount St Helens eruption is illustrative (Crisafulli *et al.* 2005a); eleven of 15 amphibian species survived the event, and some (eg western toad, *Bufo boreas*) have since had exceptional breeding success.

The broad array of birds using the abundant and varied food sources (eg fruits, nectar, herbivorous insects) and nesting habitat in ESFEs includes many raptors and neotropical migrants, often making bird diversity highest during the ESFE stage of succession (Klaus *et al.* in press). Some species are habitat specialists that directly utilize the legacy of recently killed trees; for instance, black-backed woodpeckers (*Picoides arcticus*) are almost completely restricted to early post-fire conditions (Hutto 2008). Mountain bluebirds (*Sialia currucoides*) and several other woodpecker species also favor structurally rich, early-successional habitats (Figure 5). Observed population declines of many avian species in eastern North America – which, in some cases, have proceeded to a point of conservation concern – are linked to conversion of early-successional habitat to closed forest (Litvaitis 1993).

Small mammal communities in ESFEs typically show high levels of diversity as well, including some obvious habitat specialists. The eastern chestnut mouse (*Pseudomys gracilicaudatus*), for example, inhabits early-successional environments in coastal eastern Australia for 2–5 years after a wildfire, and then declines dramatically until these environments are burned again (Fox 1990). Populations of mesopredators (medium-sized predators, such as raccoons [*Procyon lotor*] and fox species) benefit from the abundance of small vertebrate prey items characteristic of ESFEs. Likewise, some species of large mammals are well known to favor ESFEs (Nyberg and Janz 1990). Utilizing the diverse and luxuriant forage characteristically present in these ecosystems, ungulates, such as members of the Cervidae, in turn serve to benefit large predators (eg wolves [*Canis lupus*]) as well as scavengers, making ESFEs important elements within those species' typically extensive home ranges. Omnivores, such as bears (*Ursus* spp), also rely on the diversity of food sources often present in ESFEs.

■ Food web diversity

ESFEs are exceptional in the diversity and complexity of food webs they support. Simply stated, a diverse plant community produces many food sources. Food resources for herbivores (grasses, shrubs, forbs) – as well as nectar, seeds, and shrub-borne fruit (eg produced by *Rubus* and *Vaccinium* spp [huckleberry]) – can reach high levels before site dominance by trees. In the temperate Northern Hemisphere, biologically important berry production is maximized in slowly reforesting ESFEs. Resource production in early-successional patches may even augment the richness of adjacent undisturbed forests, as in the case of fluxes of key prey species (Sakai and Noon 1997).

Aquatic biologists have, perhaps, best appreciated the greater complexity of food chains in early-successional versus closed forest environments (Bisson *et al.* 2003). In established forest stands, trees strongly dominate the physical and biological conditions in nearby small streams by controlling light and temperature, stabilizing channels, providing woody debris, and, importantly, offering allochthonous inputs (organic matter originating outside the aquatic ecosystem) – the primary energy and nutrient source for such ecosystems (Vannote *et al.* 1980).

Stand-replacement disturbances remove forest constraints on conditions and processes, and shift streams to an early-

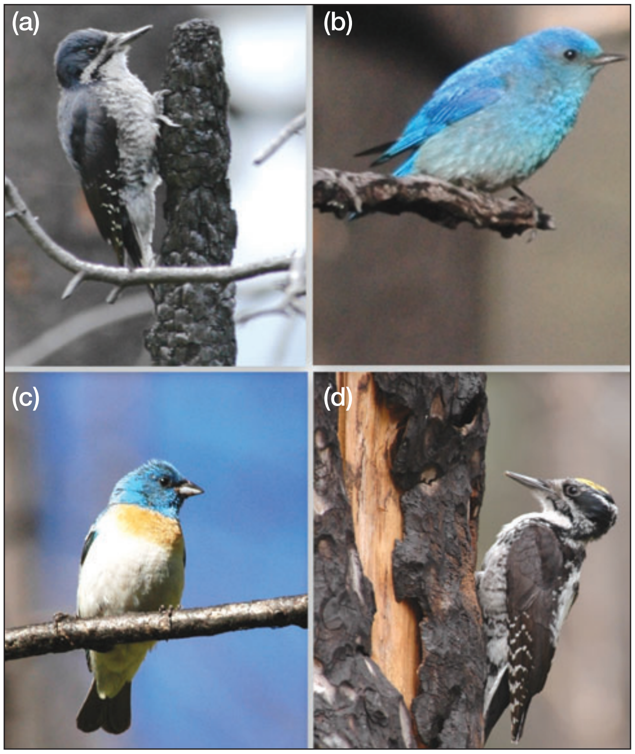

Figure 5. *Bird diversity is typically high in early-successional communities on forest sites and includes many habitat specialists: (a) black-backed woodpeckers (*Picoides arcticus*) are almost entirely restricted to early post-fire habitat; (b) mountain bluebirds (*Sialia currucoides*) favor early-successional ecosystems; (c) lazuli buntings (*Passerina amoena*) and (d) three-toed woodpeckers (*Picoides tridactylus*) have similar requirements.*

successional context (Minshall 2003; Figure 6). This greatly diversifies the types and timing of allochthonous inputs, as well as increases primary productivity. Allochthonous inputs are shifted from primarily tree-derived litter (coniferous-based in many systems) to material from a range of flowering herbs, shrubs, and trees, as well as from conifers. Consequently, litter inputs are highly variable in quality (eg decomposability) and delivery time, as compared with litterfall contributed primarily by evergreen conifer species. Also, inputs to post-disturbance streams often include material with a high nitrogen content, such as litter from the early-successional genera *Alnus* and *Ceanothus* (Hibbs *et al.* 1994).

Greater algal production may increase the diversity and abundance of aquatic invertebrate populations, which, in turn, become prey for fish and other organisms. However, increases in sediment production associated with disturbances can negate some benefits to aquatic processes and organisms (Gregory *et al.* 1987).

■ Processes in ESFEs

Ecosystem processes in ESFEs can be more diverse than those in closed forest systems, where the primary productivity of trees is dominant and organic matter is processed primarily through detrital food webs. Development of more diverse, and perhaps more "balanced", trophic pathways is possible when a disturbance opens a previously closed forest canopy. The contrast is probably greatest in forests dominated by a single tree type, such as evergreen conifers, as opposed to more diverse forests, such as mixed evergreen associations.

Recharging nutrient pools

ESFEs provide major opportunities for recharge of nutrient pools, such as additions to the nitrogen pool by leguminous (eg *Lupinus*) and some non-leguminous early-successional (eg *Alnus* and *Ceanothus*) plant species. These genera are commonly absent from late-successional forests, but are well represented in ESFEs. Nitrogenous additions from these sources are particularly important where the disturbance – eg a wildfire – has volatilized a substantial amount of the existing nitrogen pool.

Mineralization rates of organic material are typically accelerated (sometimes profoundly) after disturbances, as a result of warmer growing season temperatures. Diversified litter inputs in ESFEs, including a greater proportion of easily decomposed litter from herbs and deciduous shrubs, also result in more rapid mineralization. Finally, successional changes in the fungal and microbial communities can also hasten decomposition processes. As noted, these changes will be most profound in forest ecosystems dominated by a single species, including evergreen conifers or hard-leaved, evergreen hardwoods (such as the ash-type eucalypt forests of southeastern Australia).

In aquatic ecosystems that experience fire in adjacent forests, greater post-disturbance light and nutrient availability enhance primary productivity within the water body, causing shifts in food webs from the level of primary producers up through high-level consumers, such as fish (Spencer *et al.* 2003).

Modifying hydrologic and geomorphic regimes

Hydrologic regimes associated with ESFEs contrast greatly with those characterizing closed forest cover. For example, transpiration and interception are dramatically reduced and recover only gradually as forest canopies redevelop. Increases in normally low summer flows and annual water yields may occur immediately after a disturbance, as compared with levels in the dense young forests that may subsequently develop (Jones and Post 2004). The opposite may be true in systems where condensation of cloud or fog on tree crowns is an important component of the hydrologic cycle. ESFEs may also contribute to increased discharge peak runoff flows in hydrologic events of smaller magnitude (Harr 1986), but appear to have little effect on the magnitude of peak flows during large runoff events (Grant *et al.* 2008). From an ecological perspective, this may have a positive outcome, however, because floods restructure and rejuvenate many riparian communities (Gregory *et al.* 1991).

Rates and patterns of geomorphic processes, such as erosion and nutrient leaching losses, are also different between ESFEs and later successional stages. Tree death results in a loss of root strength that is critical for stabilizing soils and deeper rock layers on mountain slopes (Perry *et al.* 2008). Erosion and landslides may occur at higher rates in ESFEs, contributing to the variability of sediment budgets in watersheds (Reeves *et al.* 1995) and creating long-lasting substrates for ruderals. While enhancing erosion processes, ESFEs also provide materials and processes that counteract this effect, such as woody debris, which retain sediments and organic materials, and surviving vegetation, which stabilizes slopes and nutrient stores (eg Bormann and Likens 1979).

J Halofsky

Figure 6. *Streams within early-successional forest ecosystems contrast with forest-dominated reaches in many ecosystem attributes, including physical parameters (temperature and insolation), structure, plant and animal composition, and ecosystem processes, such as primary productivity.*

Land management implications

Incorporating ESFE attributes into forest policy and management is highly desirable, given the numerous advantages provided by these ecosystems. Many species and ecological processes are strongly favored by conditions that develop after stand-replacement disturbances. Rapid, artificially accelerated "recovery" of disturbed forest areas (eg via dense planting) to closed forest conditions has serious implications for many species. Clearly the term "recovery" has a different meaning for such early-successional specialists or obligates.

To fulfill their full ecological potential, ESFEs require their full complement of biological legacies (eg dead trees and logs) and sufficient time for early-successional vegetation to mature. Where land managers are interested in conservation of the biota and maintenance of ecological processes associated with such communities, forest policy and practices need to support the maintenance of structurally rich ESFEs in managed landscapes. Natural disturbance events will provide major opportunities for these ecosystems, and managers can build on those opportunities by avoiding actions that (1) eliminate biological legacies, (2) shorten the duration of the ESFEs, and (3) interfere with stand-development processes. Such activities include intensive post-disturbance logging, aggressive reforestation, and elimination of native plants with herbicides.

In particular, post-disturbance logging removes key structural legacies, and damages recolonizing vegetation, soils, and aquatic elements of disturbed areas (Foster and Orwig 2006; Lindenmayer *et al.* 2008). Where socioeconomic considerations necessitate post-disturbance logging, variable retention harvesting (retention of snags, logs, live trees, and other structures through harvest) can maintain structural complexity in logged areas (Eklund *et al.* 2009).

Prompt, dense reforestation can have negative consequences for biodiversity and processes associated with ESFEs, by dramatically shortening their duration. Such efforts reduce spatial and compositional variability characteristic of natural tree-regeneration processes, promote structural uniformity, and initiate intense competitive processes that eliminate elements of biodiversity that might otherwise persist. Artificial reforestation can also reduce genetic diversity by favoring dominance by fewer tree species/genotypes, and may make the system more prone to subsequent, high-severity disturbances (Thompson *et al.* 2007). The elimination of shrubs and broad-leaved trees through herbicide application can alter synergistic relationships, such as the belowground mycorrhizal processes provided by certain shrub species (eg *Arctostaphylos* spp).

Naturally regenerated ESFEs are likely to be better adapted to the present-day climate and may be more adaptable to future climate change. The diverse genotypes in naturally regenerated ESFEs are likely to provide greater resilience to environmental stresses than nursery-grown, planted trees of the same species. Given that climate change is also resulting in altered behavior of pests and pathogens (Dale *et al.* 2001), encouraging greater tree species diversity may also increase ecosystem resilience.

Clearcutting has been proposed as a technique to create ESFEs, but this can provide only highly abridged and simplified ESFE conditions. First, traditional clearcuts leave few biological legacies (eg Lindenmayer and McCarthy 2002), limiting habitat and biodiversity potential. Second, clearcuts are often quickly and densely reforested, and often involve the use of herbicides to limit competition with desired tree species. Clearcuts can provide some early-successional functionality (eg serving as nurseries or post-breeding habitat for many bird species in the southern US; Faaborg 2002), but this service is often truncated by prompt reforestation.

Management plans should provide for the maintenance of areas of naturally developing ESFEs as part of a diverse landscape. This should be in reasonable proportion to *historical* occurrences of different successional stages, as based on region-specific historical ecology. Major disturbance events provide managers with opportunities to incorporate a greater diversity of species and processes in forest landscapes and to enhance landscape heterogeneity. Some aspects of ESFEs can be incorporated into areas managed for production forestry as well, such as through variable retention harvest methods, the incorporation of natural tree regeneration, and extending the duration of herb/shrub communities in some portions of a stand by deliberately maintaining low tree stocking levels.

Finally, we suggest that adjustments in language are needed. Ecologists and managers often refer to "recovery" when discussing post-disturbance ecosystems, inferring that early seral conditions are undesirable and need to be restored to closed canopy conditions as quickly as possible. Emphasizing recovery as the management goal fails to acknowledge the essential ecological roles played by early-successional ecosystems on forest sites. It should also be considered that climate change and other factors may not permit "recovery" to pre-disturbance conditions.

Conclusions

Twentieth-century forest management objectives were centered on wood production and, later, on conservation and development of late-successional forests. Rapid regeneration of dense timber stands was frequently seen as a way to address both of these divergent objectives. Recognizing the ecological value of early-successional ecosystems on forest sites extends the ecological concerns associated with old growth to another "rich" period in a forest sere. This represents an important development in the evolution of holistic management of forest ecosystems, whereby large landscapes are managed for diverse seral stages.

ESFEs provide a distinctive mix of physical, chemical, and biological conditions, are diverse in species and processes, and are poorly represented and undervalued in traditional forest management. Forest policy and practice must give serious attention to sustaining substantial areas of ESFEs and their biological legacies. Similarly, scientists need to initiate research on the structure, composition, and function of ESFEs in different regions and under different disturbance regimes, as well as on the historical extent of these systems, to serve as a reference for conservation planning.

Acknowledgements

We are grateful to KN Johnson for insightful comments. Abstract. Fire Regime Condition Class (FRCC) has been developed as a nationally consistent interagency method in the US to assess degree of departure between historical and current fire regimes and vegetation structural conditions across differing vegetation types. Historical and existing vegetation map data also are being developed for the nationwide LANDFIRE project to aid in FRCC assessments. Here, we compare selected FRCC and LANDFIRE vegetation characteristics derived from simulation modeling with similar characteristics reconstructed from tree-ring data collected from 11 forested sites in Utah. Reconstructed reference conditions based on trees present in 1880 compared with reference conditions modeled by the Vegetation Dynamics Development Tool for individual Biophysical Settings (BpS) used in FRCC and LANDFIRE assessments showed significance relationships for ponderosa pine, aspen, and mixed-conifer BpS but not for spruce–fir, piñon–juniper, or lodgepole pine BpS. LANDFIRE map data were found to be ~58% accurate for BpS and ~60% accurate for existing vegetation types. Results suggest that limited sampling of age-to-size relationships by different species may be needed to help refine reference condition definitions used in FRCC assessments, and that more empirical data are needed to better parameterize FRCC vegetation models in especially low-frequency fire types.

Additional keywords: reference conditions, successional classes, Vegetation Dynamics Development Tool (VDDT).

Introduction

Altered fire regimes and associated changes in vegetation structure, composition, and fuels pose risks to biodiversity, sustainable ecosystems, and economic and community interests across the United States (USDA/USDI 2000). However, the magnitude of these risks varies between ecosystems as a result of differences in their fire and vegetation histories, successional, compositional, and structural dynamics, and the influence of invasive species (Morgan *et al*. 2001; Schoennagel *et al*. 2004). Fire exclusion over the 20th century has not affected all ecosystems uniformly, and accurate characterization of historical fire regimes and recent vegetation changes is critical to inform management decisions about the need for fuel treatments or ecological restoration across differing plant communities.

Use of historical fire regimes and vegetation conditions to inform fire and fuel management decisions in the US has been refined into the Fire Regime Condition Class (FRCC) concept (Hann and Bunnell 2001; Schmidt *et al*. 2002; Hann and Strohm 2003; Hann *et al*. 2003; Shlisky and Hann 2003). FRCC is an index that compares current with historical fire regimes and vegetation composition and structure to assess degree of departure on a scale from one (least departed) to three (most departed). FRCC is based on an assumption that historical processes and patterns (those present before widespread Euro-American settlement in the mid- to late-1800s) represent longer-term sustainable ecosystem conditions, and that greater departure in current conditions represents a greater risk for uncharacteristic fire behavior and associated ecosystem impacts. Initial coarse-level (1-km^2 resolution) FRCC maps described the degree of departure at a national scale (Schmidt *et al*. 2002). After this initial effort, a set of standard guidebook methods was developed to assess FRCC at landscape to stand scales for local management and planning needs (at time of writing, FRCC Guidebook v1.3; Hann *et al*. 2004). FRCC maps of 30-m^2 resolution are also being developed as part the LANDFIRE project, an effort to provide consistent vegetation, fuels, and fire regime data for the entire US (Rollins and Frame 2006; www.landfire.gov, accessed 19 October 2007). FRCC is now a key variable for defining wildfire risk to ecosystems as a result of its explicit incorporation into the Healthy Forests Restoration Act of 2003 (HFRA 2003). FRCC represents a significant advance in the integration of fire and forest histories and landscape and vegetation ecology to provide an ecologically based method for setting fire-management priorities and objectives across the US (Shlisky and Hann 2003).

Definition of departure indices in FRCC assessments begins with simulation modeling of historical vegetation composition and structure using the Vegetation Dynamics Development Tool (VDDT; Beukema and Kurz 2003). VDDT is used to develop non-spatially defined reference conditions within Biophysical Settings (BpS; formerly referred to as Potential Natural Vegetation Groups (PNVG); Küchler 1964; NRCS 2003). For LANDFIRE, BpS are derived from Nature Serve's ecological

 10.1071/WF08001 1049-8001/10/010001

classification system (Comers *et al*. 2003) and are not directly comparable with those used in FRCC assessments. However, both systems use BpS in a similar manner to represent the vegetation communities that would likely exist under given environmental conditions (climate, soils, and landscape physiography) and historical disturbance regimes. BpS in LANDFIRE are assigned to specific locations in their nationwide mapping efforts, whereas BpS in FRCC assessments are non-spatial and assigned based on individual user needs for specific projects or management requirements. Reference conditions are the proportions of vegetation successional stages (community structure and composition) as affected by varying fire frequencies, severities, and successional pathways within each BpS (Hann *et al*. 2004).

FRCC and LANDFIRE vegetation models (also known as Vegetation Dynamics Models) were defined during regional professional workshops conducted between 2002 and 2009 (2005–09 for LANDFIRE). VDDT model inputs for individual BpS are based on historical fire regime characteristics (frequency and severity) and vegetation data derived from published and unpublished studies and expert opinion developed both at the regional workshops and through subsequent peer reviews (Hann *et al*. 2004). The amount and quality of available historical data for each BpS vary, which can affect the quality and accuracy of the resulting modeled reference conditions. In an FRCC assessment, a field evaluation is conducted of existing vegetation structure, which, in forests, is based on cover type, density of tree stands, tree size, and current successional status. Successional status is determined by visually estimating stand composition, tree density, and average tree age, the latter of which is based on tree diameters. Proportions of current successional classes in a project or management area are estimated during the field assessment and then compared with the proportions of reference conditions derived from VDDT model output. The FRCC departure index (1 to 3) is assigned based at least partially on differences in proportions of successional classes present in the current forest relative to modeled reference conditions in the historical forest.

There is a need to test the process of development of reference conditions by comparing VDDT model output with known fire and vegetation histories. This comparison is critical for assessing consistency and accuracy in the modeling process. Here, we compare VDDT-modeled reference conditions with tree-ring-based reconstructions of reference conditions from 11 forested sites in Utah and eastern Nevada (tree-ring data reported in Heyerdahl *et al*. 2005, and Brown *et al*. 2008*a*). The tree-ring reconstructions span transects aligned along elevation gradients that include multiple forest types. We ask the following questions with this comparison: (1) do FRCC methods of evaluating stand structure based on diameter estimates accurately represent ages of forest vegetation and is there variation based on species and site? (2) Do FRCC and LANDFIRE BpS models adequately capture the range of variation in proportions of reference conditions reconstructed by the tree-ring data? (3) Do LANDFIRE mapped data layers for BpS and Existing Vegetation Types (EVT) match the tree-ring plot data? (4) Can further empirical fire history and tree recruitment data be used to strengthen FRCC evaluation and reference condition modeling outputs? We consider this study to be only an initial test of FRCC and LANDFIRE vegetation modeling methods, but one that may provide an example for future testing needs.

Methods

Study area

Tree-ring sites used for this study extend from the Colorado Plateau of southern Utah, west to the Wah Wah Mountains in the eastern Great Basin of western Utah, and north to the Uinta and Bear River Mountains in northern Utah (Fig. 1, Table 1; Heyerdahl *et al*. 2005; Brown *et al*. 2008*a*). The region is a complex of valleys, mesas, canyons, plateaus, and mountains that range in elevation from ~900 to >3600 m. Forest types vary generally across elevation gradients. Piñon (*Pinus edulis* (PIED; four-letter codes are used in tables) and *P. monophylla* (PIMO)) and juniper (*Juniperus scopulorum* (JUSC) and *J. osteosperma* (JUOS)) savannas and woodlands occur at the lowest forest margins above desert shrublands or grasslands. Ponderosa pine (*Pinus ponderosa* (PIPO)) forests occur in montane zones in pure and mixed stands. Douglas-fir (*Pseudotsuga menziesii* (PSME)) often occurs in association with ponderosa pine on north-facing aspects and in relatively mesic sites. Mixed-conifer forests occur at intermediate elevations and include combinations of ponderosa pine, Douglas-fir, piñons, junipers, and firs (*Abies lasiocarpa* (ABLA) or *A. concolor* (ABCO)). Mixed-conifer forests also often occur in association with aspen (*Populus tremuloides* (POTR)). Aspen forms large (>100 ha) pure stands throughout the upper montane and lower subalpine zones across the study area except in the Great Basin. Lodgepole pine (*Pinus contorta* (PICO)) often forms pure stands at mid-elevations (1900 to 2800 m) or occurs in the mixed-conifer zone in northern Utah. Subalpine forests dominated by Engelmann spruce (*Picea engelmannii* (PIEN)) and firs occur at upper elevations (2350 to 3500 m). At the highest forested elevations (generally above 3000 m), pure Engelmann spruce forests occur in mesic sites whereas bristlecone pine (*Pinus longaeva* (PILO)) or limber pine (*P. flexilis* (PIFL)) are typically found in dry or rocky sites.

There was, in general, a gradient in fire frequency across the elevational gradient before fire exclusion that began at all sites in the late 1800s (Heyerdahl *et al*. 2005; Brown *et al*. 2008*a*). Fire occurrence was highest in the middle of the elevation range in ponderosa pine and drier mixed-conifer sites. Fire frequency progressively declined both above and below this middle-elevation zone. At upper elevations, generally moist conditions led to high fuel biomass, both living and dead, in many stands, but fewer years in which fuels were dry enough to ignite and spread. At lower elevations in the piñon–juniper woodlands, fuels were often dry enough to burn because of hotter and dryer fire seasons, but because of lower productivity, there were in general less continuous both aerial and surface fuels and fires were not able to spread. In the middle zone, both fuel amounts and moistures were just right (what has come to informally be called the 'Goldilocks effect'), and able to burn often in wide-spreading fires.

Utah forests underwent a period of intensive grazing and land use beginning in the 1850s as a result of Euro-American settlement. Intensive grazing removed understorey species and began alteration of longer-term historical forest dynamics. Logging also affected forest structure in many areas. The tree-ring study found that cessation of historical patterns of fires began in

the 1860s to 1890s depending on location (Brown *et al*. 2008*a*), similar to patterns seen in forests throughout the western US. Initial reduction in fire frequency was likely the result of grazing that removed grass and herbaceous fuels, followed later by direct fire suppression in the 20th to 21st centuries.

Tree-ring data

The tree-ring study used a systematic sampling design to characterize stand and age structure and fire regimes across forest gradients in each site (Table 1; Heyerdahl *et al*. 2005; Brown *et al*. 2008*a*). Similar methods have been used in multiple studies

around the western US and are described in more detail in Heyerdahl *et al*. (2005, 2006), Brown and Wu (2005), Brown (2006), Brown *et al*. (2008*a*, 2008*b*), and Brown and Schoettle (2008). A 500-m grid was established at each site and plots sampled at grid points. Plot centers were located in the field using hand-held global positioning system (GPS) units. An *n*-tree density-adapted sampling method (Jonsson *et al*. 1992) was used to collect data from the nearest ~30 remnant (logs, snags, or stumps) or living trees >20 cm diameter at breast height (DBH) to each plot center. Maximum plot radius was set at 40 m (~0.5 ha) and most plots were ~<0.2 ha in size. For each plot tree, species was recorded and an increment core (on living trees) or cross-section (from logs, snags, and stumps) was collected from ~10 cm height above ground. Sampled cores had to be no more than a field-estimated 10 years from pith to minimize pith offset when assessing pith date. Diameter at sample height (DSH) and DBH were measured on living trees, and DSH was measured or estimated for remnant trees missing bark, sapwood, or heartwood. Distance from plot center and azimuth were measured on all trees for reconstruction of tree basal areas, density, and spatial patterning. To reconstruct surface fire history, cross-sections were cut from any fire-scarred trees found within plots. Additional fire-scarred trees also were sampled within ~80 m of each grid point and between grid points when discovered. GPS coordinates and species of fire-scarred trees outside of plots were recorded.

Standard dendrochronological methods were used to crossdate all samples using locally developed master chronologies (Heyerdahl *et al*. 2005). Pith dates were estimated on cores that did not intersect pith based on the curvature of the innermost rings sampled. The tree recruitment date is considered to be the date of tree pith at 10-cm height. No corrections were made for time to grow from germination to 10 cm sample heights because of the widely varying species and environmental conditions at the sites that were collected for the study. Once crossdating of ring series was completed on all samples, dates for any fire scars seen within the ring series were assigned. Any trees that were not able to be dated were not used in subsequent analyses.

FRCC and LANDFIRE vegetation models

VDDT modeling estimates the relative proportions of non-spatially defined reference conditions that would have occurred under a historical fire regime and an equilibrium (current) climate regime within each BpS (Beukema and Kurz 2003). VDDT input includes average fire frequencies, severities, and other disturbances defined as probabilistic events, and vegetation structural stage development pathways, including changes in species composition and density through a successional sequence. VDDT runs are commonly made for 500 years to allow vegetation conditions to equilibrate over time. VDDT output is proportions of vegetation successional classes – the reference conditions – across a non-spatially referenced landscape at the end of the 500-year model run. Reference conditions for most forest types are summarized into five seral stages that approximate overall developmental characteristics of community age and structure: early-replacement, mid-open, mid-closed, late-open, and late-closed. Each developmental stage represents a successional class defined by average tree age, species composition, structural characteristics, and response to disturbances. LANDFIRE and FRCC assessments use VDDT in a similar manner, but in LANDFIRE, reference condition proportions are then coupled with the spatial model LANDSUM (Keane *et al*. 2002) to map resulting vegetation conditions for each BpS across actual landscapes at a 30-m^2 spatial resolution.

FRCC and LANDFIRE developed their own BpS models using two different vegetation classification systems (Küchler 1964 *v.* Comers *et al*. 2003). Both systems attempt to describe the same historical vegetation using VDDT; however, their models use different probabilities for disturbance, and have somewhat different species distributions and geographic extents (often based on expert opinion; see http://frcc.gov, accessed 19 October 2007; www.landfire.gov for details).

Comparing tree-ring with FRCC and LANDFIRE data

We performed three tests to compare the tree-ring data with FRCC and LANDFIRE vegetation models. First, we compiled age and DBH data derived from the tree-ring study to assess whether FRCC methods of visual estimates of tree diameters accurately represent the age of forest vegetation for defining mid- and late-development classes of reference conditions. FRCC guidebook methods define >23 cm DBH as a visual indicator of a mature tree when conducting field assessments. For this analysis, we assumed that plots with trees averaging ≤23 cm DBH would be considered to be in a mid-development reference condition, and >23 cm would be in late-development. We conducted least-squares linear regressions to estimate fitness of tree age to DBH by species and site. As many of the regression models did not meet the statistical requirements of homoscedasticity, normality, and constant variance in model residuals, a logarithmic transformation was applied to the tree ages before regression. Models that had significant P values ($P < 0.05$) were considered to be representative of species growth estimates. We also conducted an analysis of variance (ANOVA) of age and diameter by species and site to both determine the strength of these relationships and how they varied by species and location across the region. All statistical analyses were conducted using the *Statistica* software (StatSoft Inc. 2008). The tree-ring study sampled a total of ~10 000 remnant and living trees; however, we only used data from the living trees for this part of our assessment. Dead trees (stumps, snags, and logs) often were missing bark, sapwood, or portions of the heartwood that reduced confidence in diameter estimates. The DBH-to-age analysis therefore consisted of 5173 living trees from 13 species from the 11 sites.

Our second test was whether VDDT modeled reference conditions captured the range of variation in reference conditions reconstructed by the tree-ring data as of a date of 1880. Dates of initial Euro-American settlement varied across the study area but all sites showed some Euro-American impact by 1880, including cessation of spreading fires in almost all of the sites (Brown *et al*. 2008*a*). As current vegetation may not be representative of past vegetation type, only species present in 1880 and their corresponding ages were used to assign BpS and reference condition to each of a total of 273 plots that were sampled from the 11 sites (Heyerdahl *et al*. 2005; Brown *et al*. 2008*a*). Both living and remnant trees were used to estimate the 1880 plot compositions. FRCC and LANDFIRE use key species to

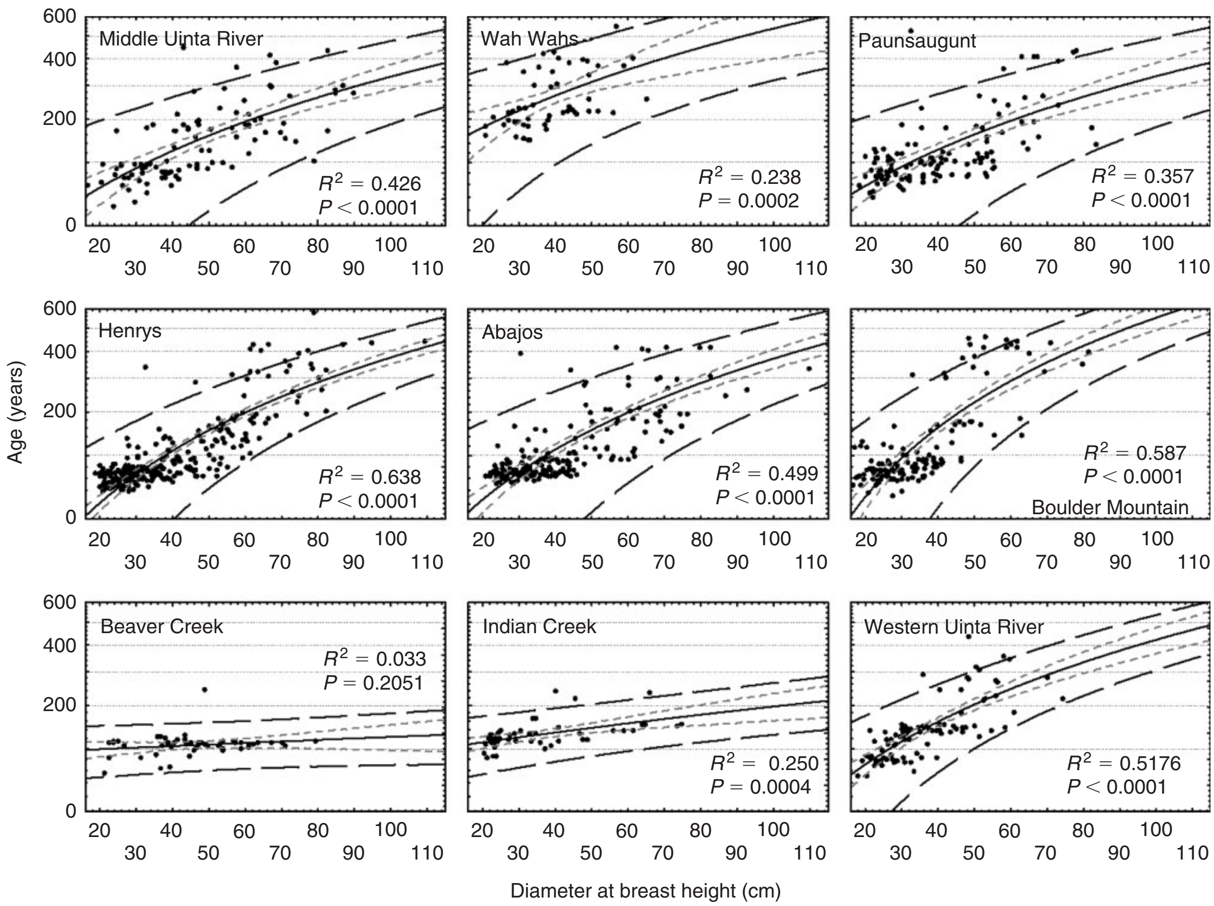

Fig. 2. Diameter at breast height (DBH) and log(age) regressions for ponderosa pine trees by site, with linear fits (solid lines), 95% confidence intervals (gray dashed lines), and 95% prediction intervals (black dashed lines). Overall R^2 for ponderosa pine trees across all sites was 0.44.

define vegetation characteristics when conducting an assessment and we used these species as the basis for assigning BpS and reference condition to each plot.

Historical age class and species composition in 1880 for each plot were compared with FRCC and LANDFIRE reference conditions for selected BpS. FRCC and LANDFIRE BpS descriptions are available on their respective project websites (www.frcc.gov; www.landfire.gov). We did not evaluate the typical five-stage VDDT models because of difficulties in using the tree-ring data to accurately recreate smaller size classes in historical stand densities as a result of probable tree mortality and decay since pre-settlement periods (e.g. Brown and Cook 2006; Brown *et al*. 2008*b*). However, we assume that we are able to define with some confidence mid- and late-development stands based on crossdated ages of trees present in each plot in 1880. The mean age of a 23-cm-DBH live tree varied by species, and we used the tree-ring results to estimate the upper 95% confidence interval for predicted tree size to consider whether a stand was late developmental stage in 1880. We grouped data from open and closed stands together based on age and composition for comparison with succession classes from VDDT output. If any trees in a plot were older than their predicted age-to-size confidence interval, the plot was considered to be in late-development in 1880. If there were no older trees during the historical period, then the plot was considered to have been in mid-development. If there were no trees during the historical period, the plot was considered to have no data and not used in this analysis. Once plots were categorized by BpS and reference condition, they were compared with FRCC and LANDFIRE BpS model proportions of mid- and late-development vegetation based on VDDT output. We used a Chi-square test to determine if the observed tree-ring reference condition proportions were significantly different than the expected based on the VDDT output.

Finally, we compared tree-ring plot data with LANDFIRE BpS and EVT map layers produced by the LANDFIRE project. LANDFIRE data are spatially mapped, which provided a unique opportunity to evaluate vegetation models at a high spatial resolution through comparison with the mapped tree-ring data. Plots were first located through their GPS coordinates relative to LANDFIRE map data. The BpS assignments we made for each plot in 1880 were then compared with LANDFIRE BpS map data. We also compiled the living tree composition in each plot and compared that with the LANDFIRE EVT map data. If key

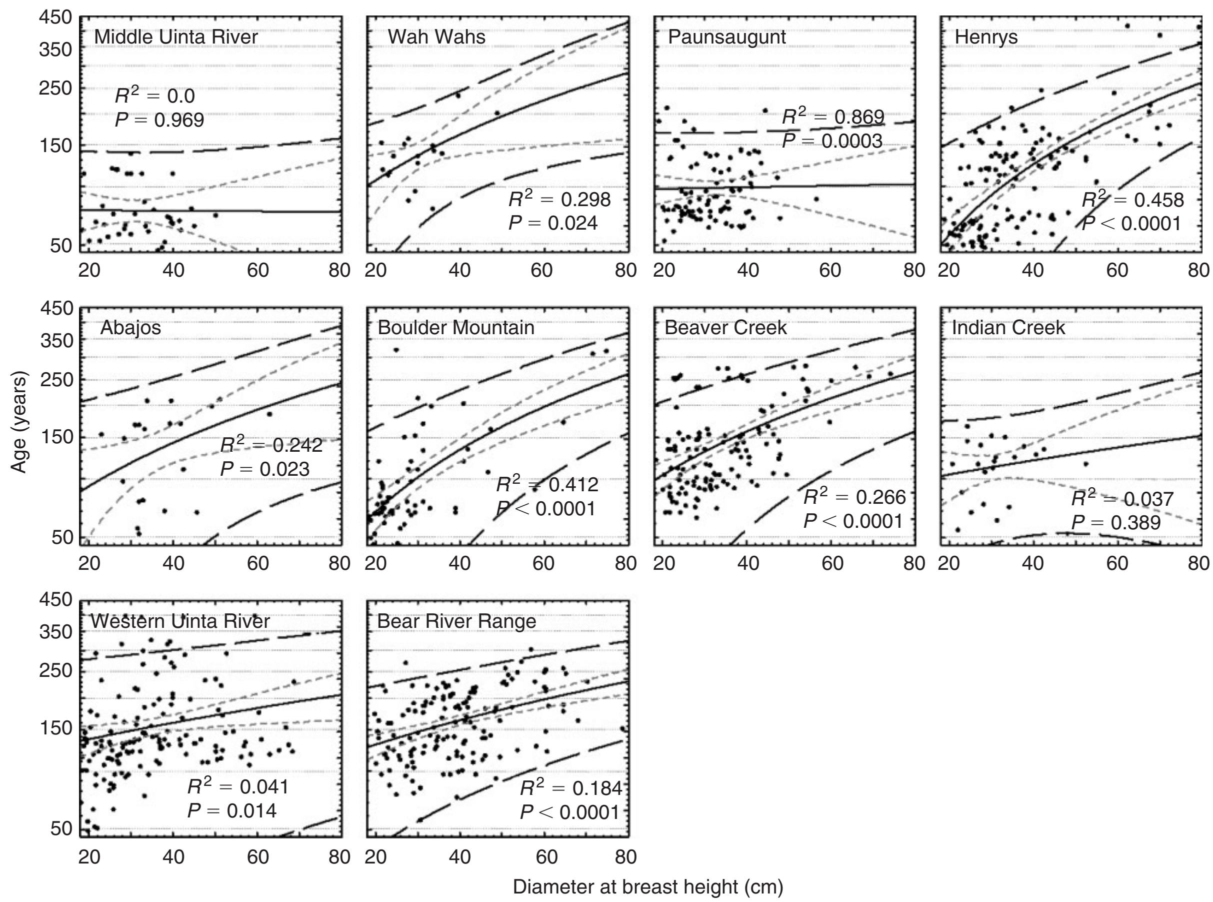

Fig. 3. Diameter at breast height (DBH) and log(age) regressions for Douglas-fir trees by site, with linear fits (solid lines), 95% confidence intervals (gray dashed lines), and 95% prediction intervals (black dashed lines). Overall R^2 for Douglas-fir trees across all sites was 0.21.

species were present in the tree-ring data in comparison with the mapped BpS or EVT, then the grid point was considered to have been accurately mapped in LANDFIRE.

Results

Age–diameter relationships

DBH and tree ages exhibited generally broad relationships, both within species and among sites (Figs 2–4; Tables 2, 3). Ponderosa pine was the only species where age and size were strongly correlated using data from all sites ($R^2 = 0.438$, $P < 0.001$) and were strongly correlated over most of the individual sites (Table 2). There were outliers for most species by DBH and age; however, their deviance did not significantly change the results. Median tree age was predicted for trees at 23 cm using an inverse prediction with 95% confidence interval (Table 3). ANOVA results indicate that species associated with infrequent fire regimes (piñon–juniper, spruce–fir, and bristlecone pine; Heyerdahl *et al.* 2005) were found to have greater average ages than frequent fire species (especially ponderosa pine and Douglas-fir; Fig. 5). Variance of diameters relative to ages for species that contained a large sample *n*, such as Douglas-fir (PSME), ponderosa pine (PIPO), and Engelmann spruce (PIEN) was small. There was greater variance found in species that had fewer sampled trees and plots, such as bristlecone pine (PILO), Rocky Mountain juniper (JUSC), one-seed juniper (JUOS), limber pine (PIFL), and single leaf piñon (PIMO), but this result is likely an artifact of the smaller number of trees used in each regression. ANOVA indicated that DBH and age estimates for all sites were similar with the exception of WAH (Fig. 5). This may be explained by the large presence of fire-infrequent and older species (bristlecone pine, Rocky Mountain juniper, and one-seed juniper) that were sampled in that site.

FRCC and LANDFIRE BpS models

Median ages of trees >23 cm DBH were used to define the proportions of mid- and late-development reference conditions for trees present in plots in 1880 (Table 3). Reference condition proportions reconstructed from the tree-ring data compared favorably with FRCC BpS models for ponderosa pine (PPIN5), mixed-conifer (SPDF), and lodgepole (CHPI) but not for piñon–juniper (JUPI1, JUPI2), south-western mixed-conifer (MCAN) and spruce–fir (SPFI2, SPFI7; Table 4, Fig. 6). Reference condition proportions reconstructed from the tree-ring data

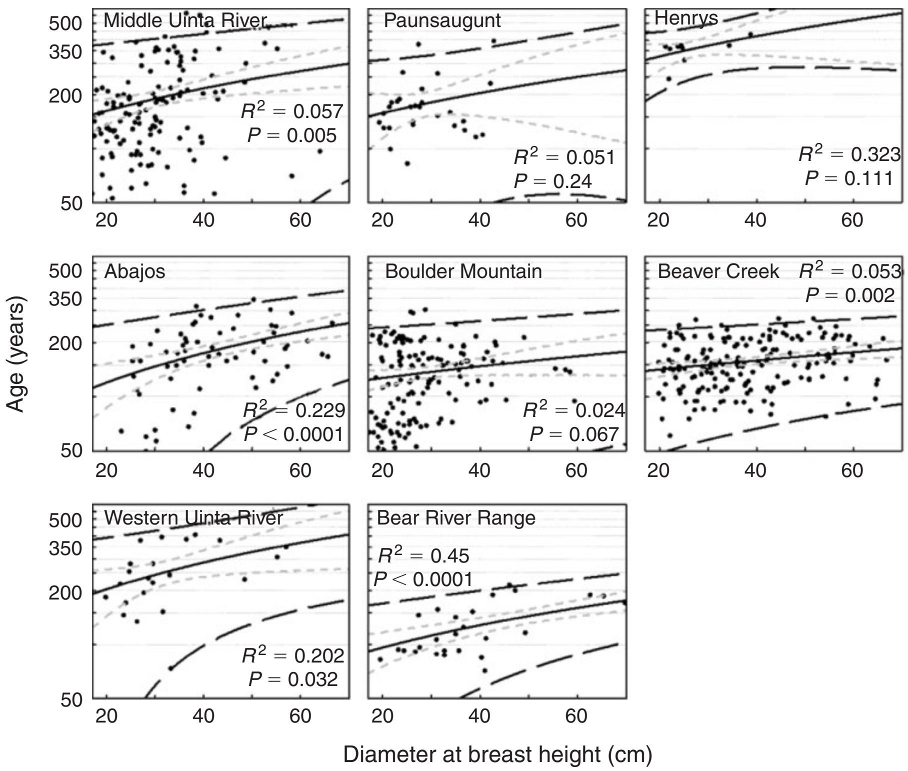

Fig. 4. Diameter at breast height (DBH) and log(age) regressions for Engelmann spruce trees by site, with linear fits (solid lines), 95% confidence intervals (gray dashed lines), and 95% prediction intervals (black dashed lines). Overall R^2 for Engelmann spruce trees across all sites was 0.06.

Table 2. Observed two-sided *P* values for DBH–age regressions for all species at all sites

compared favorably with LANDFIRE BpS models for Rocky Mountain dry–mesic montane mixed-conifer (10510), aspen and aspen–mixed-conifer low- and high-elevation forests (10110, 10611, 10612), but not for piñon–juniper (10160), ponderosa pine (10540), Rocky Mountain mesic montane mixed-conifer (10520), Rocky Mountain subalpine dry–mesic spruce–fir forest and woodland (10550), and Rocky Mountain lodgepole pine (10500; Table 4, Fig. 6). The JUPI1 BpS model (Table 4) was the most different from the tree-ring data, although the JUPI2 model had a similar trend of a larger proportion of late-successional

stands in comparison with the tree-ring data (Fig. 6). Spruce–fir and lodgepole pine data both showed low correspondence with VDDT model results, including opposite trends of more older than younger stands in the tree-ring data in contrast to the VDDT modeled reference conditions (Fig. 6).

LANDFIRE map data

LANDFIRE map layers were found to be overall ~58% accurate for BpS and 60% accurate for EVT when compared with the tree-ring data for each plot (Table 5). LANDFIRE maps were 38% accurate for both BpS and EVT, 28% accurate for at least one type (17% EVT accurate and BpS inaccurate, with 11% BpS accurate and EVT inaccurate), and 34% inaccurate. Mixed-conifer and spruce–fir types had the highest accuracies by BpS for LANDFIRE with accuracies ranging from 64 to 82% for BpS and 67 to 79% for EVT. Piñon–juniper was the least accurately mapped BpS and EVT with 13 and 37% accuracy respectively.

Discussion

FRCC and LANDFIRE BpS models

Current stand conditions are determined through visual estimates of stand structure, including tree diameters, in FRCC assessments (Hann *et al*. 2004). FRCC assessments are designed to be a relatively rapid method of characterizing current vegetation and fire regime departures from historical conditions. The expense of collecting field data, such as canopy closure, canopy base height, tree density, stand age structure, and fire and stand histories, make field sampling impractical for FRCC assessments. However, based on the limited findings of this study, it appears that FRCC methods may result in inaccurate measures of plant community departure based on visually estimated

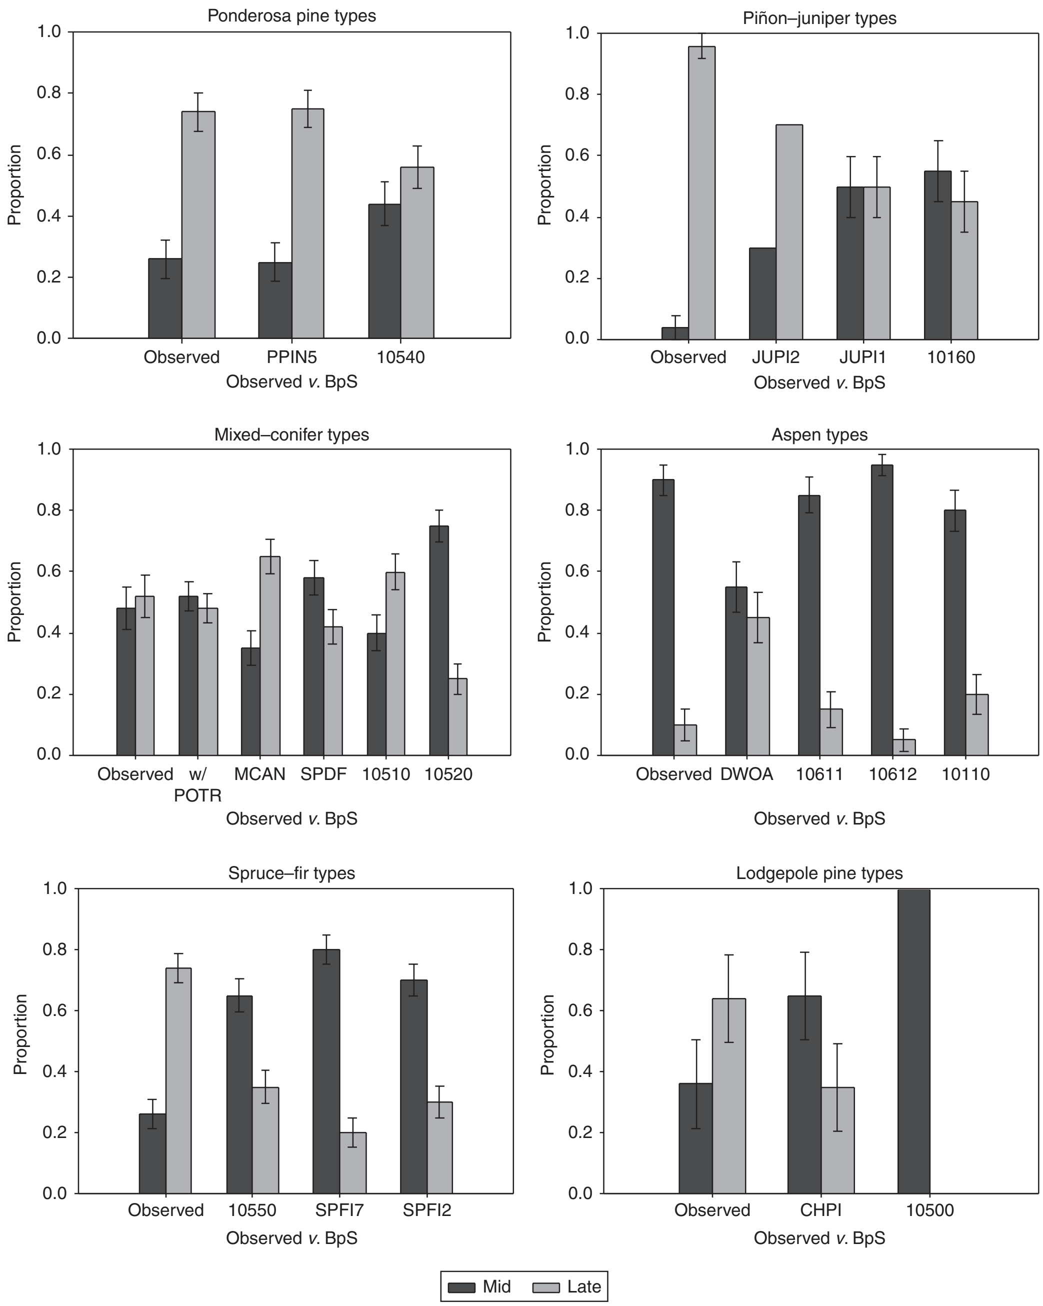

Fig. 6. Proportion of plots observed in the tree-ring data compared to FRCC (Fire Regime Condition Class) and LANDFIRE modeled reference condition proportions. Error bars were generated by calculating the 95% confidence interval from sample variance and standard error of observed points. Tree-ring results are on the left (e.g. observed), FRCC and LANDFIRE models are listed by their four-letter abbreviations on the right (e.g. PPIN5, 10540, etc.).

age–diameter relationships for determining reference condition proportions. Variations in age–size relationships both within species and among sites (Figs 2–5) may limit the ability to accurately gauge departure from estimated historical composition based on VDDT model results. Generally poor relationships between size and age may result in misassignment of current reference condition proportions based only on visual estimates, which may in turn lead to misassignment of the FRCC index.

Better correspondence between the tree-ring data and some BpS models indicates that VDDT models more accurately reflect historical forest structure in frequent-fire forest types such as ponderosa pine, mixed-conifer and aspen, than in

Table 5. LANDFIRE accuracy by BpS (biophysical settings) and EVT (existing vegetation type)

infrequent-fire types such as spruce–fir and piñon–juniper (Fig. 6). BpS reference condition models were determined by managers and scientists familiar with the local ecology of each region during regional workshops. BpS types that are considered to be representative of each region were identified and described based on available historical and ecological data. Some BpS types, such as ponderosa pine and dry mixed-conifer forests, have extensive fire and forest history data with which to parameterize VDDT model runs. Other BpS types are less well studied and their fire and vegetation histories less certain, especially across the range of environmental and community variation within and between regions. The better correspondence between modeled and reconstructed reference conditions in frequent-fire-type models (ponderosa pine and mixed-conifer forest types; Fig. 6) is likely related to the greater amount of fire and forest history research that has been conducted in these forest types. Conversely, fire-infrequent types (spruce, and piñon–juniper woodland types; Fig. 6) have had less fire history research conducted, with the result that their fire regimes and successional patterns are less well documented for input to VDDT modeling. Furthermore, infrequent-fire types generally have fewer observations of historical fires and forest successional changes available for adequate characterization of fire regime parameters for VDDT modeling (e.g. Brown *et al*. 2008*a*).

Another factor that undoubtedly results in varying model and data results is that individual-site fire histories often have experienced contingent historical events that lead to differences from a ‘typical’ or average fire regime of a particular forest type. Stochastic modeling in FRCC and LANDFIRE generalizes vegetation and its fire regimes into generic types and does not take into account site-specific variability or, more importantly, the history of climate variations or other disturbances that may have affected changes in community structure through time. Variations in site histories undoubtedly contribute to variations in ratios of actual from modeled reference conditions. For example, spruce–fir and lodgepole pine FRCC and LANDFIRE BpS models predict more mid- than late-development stands, but the Utah tree-ring data found the opposite (Fig. 6). This may be due to longer fire intervals in this region than in other areas, leading to generally older stands across landscapes. Many spruce trees found in the tree-ring study were >300 years old at the time of sampling and probably resulted from fires that occurred in the late 1600s, most commonly in 1685 (Heyerdahl *et al*. 2005). However, the current presence of older rather than younger stands does not mean that these forests are outside their historical ranges of variability in either their fire regime or forest structure, but rather that they have not had extensive fires in the intervening period that would have resulted in a larger proportion of mid-successional stands as suggested should be present based on VDDT model results. Without taking into account this history of the forest landscapes, the VDDT models suggest that there is current departure in the landscape proportions of reference conditions in Utah spruce–fir and lodgepole pine forests.

Taking into account differences in fire histories, the trend of model results toward older or younger successional classes in each BpS may be more important to consider in FRCC assessments rather than the absolute proportions of stand structures. This may provide a more realistic perspective for assessing whether a particular BpS should be considered as inside or outside of its historical range of variation. For example, the tree-ring fire data for piñon–juniper (P-J) woodlands show the majority of stands are currently in late-development structural stages (Fig. 6). The FRCC BpS model JUPI2 (Table 4) also predicts more late-development trees than younger, but underpredicts what was found in the tree-ring data. The sensitivity of the VDDT model to fire frequency is critical to the setting of reference conditions. The model inaccuracy may be due to the model’s fire

return interval, currently predicted to be ~450 years. If the interval is increased (~1000 years), the model begins to more closely reflect the tree-ring results. A recent assessment of (P-J) ecosystems in the western US concluded that fire was only a minor disturbance in many less productive stands because of lack of both surface and crown fuels with which to carry fire (Romme *et al*. 2009). We believe that many of the Utah stands sampled probably fell into this category of fire regime historically, which means that if the longer intervals had been used in VDDT modeling, the reference conditions would likely be closer to what was found in the tree-ring data. The error may also be due to the definition of a mid-development stand in terms of the age; the mean ages of sampled piñon and juniper were among the highest in the tree-ring study. The mid-definition could be changed for P-J to an older age class by species to define the mid- from late-successional classes in the reference conditions.

Good correspondence between the tree-ring data and models for ponderosa pine (PPIN5), aspen (10110), and mixed-conifer (SPDF, 10510; Fig. 6) suggests that the reference conditions for these BpS were accurately modeled by VDDT parameters, at least in the Utah study sites. However, results of this study suggest that inaccuracy in piñon–juniper and subalpine types makes any decision based on a VDDT output possibly subject to error. For BpS types in which disturbance may not be the major or only factor in tree recruitment, VDDT models may need further evaluation. Additional empirical disturbance and forest history sampling in piñon–juniper, spruce–fir, and lodgepole pine types should increase the available information about these systems to use in VDDT modeling. However, because of generally longer fire intervals in these forests, any departure from historical to present conditions may be less than in frequent-fire BpS such as ponderosa pine and mixed-conifer forests. A possible result of inaccurate estimations of departure and wrong FRCC classification may be the application of incorrect management actions that could lead to even further departure from historical conditions (see also Romme *et al*. 2009).

The only accurate way to establish the age of a stand is to physically sample the trees for ages. We suggest based on the results of our comparison that at least some limited age sampling is needed for FRCC assessments. This sampling probably should include removing cores from the field and crossdating by trained dendrochronologists to most accurately characterize age and successional status of stands. Additional field-sampled fire history and stand establishment data, especially in the less-well-studied ecosystems, should further increase the accuracy of VDDT models through better dynamic estimations of age structures and relationships with fire regimes. However, we also realize that this type of sampling is expensive and – perhaps more critically to the efficient use of FRCC in forest management decisions – more time-consuming than FRCC visual assessment methods as currently practiced. Nevertheless, we suggest that some sort of compromise solution could be found that would provide both the most accurate as well as timely data possible for FRCC assessment needs.

LANDFIRE maps

Zhu *et al*. (2006) used a cross-validation technique to determine that existing vegetation data layer accuracies are between 60 and 89% in LANDFIRE maps. Our study's comparison of LANDFIRE and tree-ring data falls on the lower end of the estimate of Zhu *et al*. (2006) (Table 4). When broken down by BpS and EVT, some types are more accurately represented in LANDFIRE data than others. EVT mapping in LANDFIRE is most accurate for the mixed-conifer and spruce–fir types. These forests generally have the densest and most continuous canopies, and may have been easiest to identify through remote sensing methods because of their continuous canopies and more distinctive NDVI reflectance in Landsat spectral bands (Zhu *et al*. 2006). Conversely, sparser canopy cover may have led to lower accuracy in other types such as piñon–juniper, which is similar to what Zhu *et al*. (2006) found. It should be noted, however, that piñon–juniper plots sampled for the tree-ring study were generally found in ecotonal areas near lower ends of study sites, and may not be wholly representative of piñon–juniper BpS as defined in the LANDFIRE mapping effort.

Conclusion

Historical forest conditions reconstructed from tree-ring data provide opportunities for comparison with FRCC and LANDFIRE modeled vegetation data across multiple forest types. The tree-ring reconstructions we examined suggest that reference conditions are better modeled in frequent-fire forest types but not necessarily in infrequent-fire forest types, at least in Utah forests. Additional studies in fire-infrequent forest types should increase understanding of historical stand compositions, fire histories, and other disturbances with which to better parameterize VDDT reference condition models. The greatest amount of fire history research has been conducted in ponderosa pine and mixed-conifer forests, which likely contributed to the better correspondence between tree-ring data and VDDT model results that we found in this study. We consider this study as only a first step in comparison of empirical vegetation data with vegetation models used in both FRCC assessments and the nationwide LANDFIRE mapping effort. Tree-ring data provide an opportunity to compare site-specific vegetation patterns and fire regime variations that are often not easily accounted for in modeling efforts. Revised methods for assessing FRCC may need to take into greater account both tree ages and stand histories to more accurately compare with model results. We also suggest that ranges of reference conditions be incorporated into the BpS classifications to better take into account fire and forest histories rather than trying to establish average conditions that must be met for a FRCC index to be assigned.

Acknowledgements

We are especially grateful to Emily Heyerdahl, Stan Kitchen, and Marc Weber for sharing data from the tree-ring project in Utah. The Utah project was funded by the Joint Fire Science Program, Fishlake National Forest, Rocky Mountain Research Station, Utah Bureau of Land Management, and Rocky Mountain Tree-Ring Research. We thank Brendan Ward, Kathy Schon, and Jim Menakis with the LANDFIRE project for sharing their expertise and data for this research. Phil Guertin, Steve Yool, Tom Swetnam, Wendel Hann, Steve Barrett, and three anonymous reviewers provided valuable comments on the manuscript. This research was funded by the National Interagency Fuels Technology Transfer Team that is responsible for development and updating of FRCC methods and vegetation models.

Abstract

Increasing numbers of homes are being destroyed by wildfire in the wildland-urban interface. With projections of climate change and housing growth potentially exacerbating the threat of wildfire to homes and property, effective fire-risk reduction alternatives are needed as part of a comprehensive fire management plan. Land use planning represents a shift in traditional thinking from trying to eliminate wildfires, or even increasing resilience to them, toward avoiding exposure to them through the informed placement of new residential structures. For land use planning to be effective, it needs to be based on solid understanding of where and how to locate and arrange new homes. We simulated three scenarios of future residential development and projected landscape-level wildfire risk to residential structures in a rapidly urbanizing, fire-prone region in southern California. We based all future development on an econometric subdivision model, but we varied the emphasis of subdivision decision-making based on three broad and common growth types: infill, expansion, and leapfrog. Simulation results showed that decision-making based on these growth types, when applied locally for subdivision of individual parcels, produced substantial landscape-level differences in pattern, location, and extent of development. These differences in development, in turn, affected the area and proportion of structures at risk from burning in wildfires. Scenarios with lower housing density and larger numbers of small, isolated clusters of development, i.e., resulting from leapfrog development, were generally predicted to have the highest predicted fire risk to the largest proportion of structures in the study area, and infill development was predicted to have the lowest risk. These results suggest that land use planning should be considered an important component to fire risk management and that consistently applied policies based on residential pattern may provide substantial benefits for future risk reduction.

Introduction

The recognition that homes are vulnerable to wildfire in the wildland-urban interface (WUI) has been established for decades [e.g., 1,2]; but with a recent surge in structures burning, this issue is now receiving widespread attention in policy, the media, and the scientific literature. Single fire events, like those in Greece, Australia, southern California, and Colorado have resulted in scores of lost lives, thousands of structures burned, and billions of dollars in expenditures [3–6]. With the potential for increasingly severe fire conditions under climate change [7] and projections of continued housing development [8], it is becoming clear that more effective fire-risk reduction solutions are needed. "Fire risk" here refers to the probability of a structure burning in a wildfire within a given time period.

Traditional fire-risk reduction focuses heavily on fire suppression and manipulation of wildland vegetation to reduce hazardous fuels [9]. Enormous resources are invested in vegetation management [10], but as increasing numbers of homes burn down despite this massive investment, the "business-as-usual" approach to fire management is undergoing reevaluation. One issue is that fuel treatments may not be located in the most strategic positions, i.e., in the wildland-urban interface [11]. Yet, even if treatments surrounded all communities, scattered development patterns are difficult for firefighters to reach [12–14], and fuel treatments do little to protect homes without firefighter access [15–16]. Fuel treatments may also be ineffective against embers or flaming materials that blow ahead of the fire front [17].

One alternative to traditional fire management that is receiving widespread attention is to prepare communities through the use of fire-safe building materials or creating defensible space around structures [17–18]. These actions represent an important shift in emphasis from trying to prevent wildfires in fire-prone areas to better anticipating fires that are ultimately inevitable. Nevertheless, the cost of building and retrofitting homes to be fire-safe can be prohibitive, and these actions do not guarantee immunity from fire [19].

Land use planning is an alternative that represents a further shift in thinking, beyond the preparation of communities to withstand an inevitable fire, to preventing new residential structures from being exposed to fire in the first place. The reason homes are vulnerable to fires at the wildland-urban interface is a function of its very definition: "where homes meet or intermingle with wildland vegetation" [20]. In other words, the location and

pattern of homes influence their fire risk, and past land-use decision-making has allowed homes to be constructed in highly flammable areas [21]. Land use planning for fire safety is beginning to receive some attention in the literature [22–23], and there is growing recognition of the potential benefits of directing development outside of the most hazardous locations [8,19,24].

Despite recent attention in the literature, land use planning for wildfire has yet to gain traction in practice, particularly in the United States. However, fire history has been used to help define land zoning for fire planning in Italy [22], and bushfire hazard maps are integrated into planning policy in Victoria, Australia [25]. Although some inertia inevitably arises from complications with existing policy and plans, a primary impediment to the design and implementation of fire-smart land use planning is lack of guidance about specific locations, patterns of development, or appropriate methodology to direct the placement of new development. Without a solid knowledge base to draw from, planners will be misinformed about which planning decisions may result in the greatest overall reduction of residential landscape risk. Even worse, poor science could result in placement of homes in areas that actually have high fire hazard.

Research on how planning decisions contributed to structures burning in the past provides some guidance about what actions may work in the future. Analysis of hundreds of homes that burned in southern California the last decade showed that housing arrangement and location strongly influence fire risk, particularly through housing density and spacing, location along the perimeter of development, slope, and fire history [26]. Although high-density structure-to-structure loss can occur [27–28], structures in areas with low- to intermediate- housing density were most likely to burn, potentially due to intermingling with wildland vegetation or difficulty of firefighter access. Fire frequency also tends to be highest at low to intermediate housing density, at least in regions where humans are the primary cause of ignitions [29–30].

These results suggest, for example, that placing new residential development within the boundaries of existing high-density developments or in areas of low relief may reduce fire risk. However, it is difficult to know whether broad-scale planning policies would actually result in the intended housing arrangement and pattern at the landscape scale, and whether those patterns would result in lower fire risk. Our objective here was to simulate three scenarios of future residential development, and to project wildfire risk, in a rapidly urbanizing and fire-prone region where we have studied past structure loss [25]. We based all future development on an econometric subdivision model, but we varied the emphasis of subdivision decision-making based on three broad and common growth types.

Although cities vary in extent, fragmentation, and residential density [31–32], urban form typically adheres to a set of common patterns [33–34], and we based our development scenarios on the three primary means by which residential development typically occurs: infill, expansion, or leapfrog [34]. Infill is characterized by development of vacant land surrounded by existing development, typically in built-up areas where public facilities already exist. [35–36], and should result in higher structure density rather than increased urban extent. Expansion growth occurs along the edge of existing development, extends the size of the urban patch to which it is adjacent, and may have variable influence on structure density. Leapfrog growth occurs when development occurs beyond existing urban areas such that the new structure is surrounded by undeveloped land. This type of growth would expand the urban extent and initially result in lower structure density; but these areas may eventually become centers of growth from which infill or expansion can occur. We asked:

1) Do residential development policies reflecting broad growth types affect the resulting pattern and footprint of development across the landscape?
2) Do differences in extent, location, and pattern of residential development translate into differences in wildfire risk, based on the current configuration of structures?
3) Which development process, infill, expansion, or leapfrog, results in the lowest projected fire risk across the landscape?

Methods

Study Area

The study area included all land within the South Coast Ecoregion of San Diego County, California, US, encompassing an area of 8312 km^2. The region is topographically diverse with high levels of biodiversity, and urban development has been the primary cause of natural habitat loss and species extinction [37]. Owing to the Mediterranean climate, with mild, wet winters and long summer droughts, the native shrublands dominating the landscape are extremely fire-prone. San Diego County was the site of major wildfire losses in 2003 and 2007 [38], although large wildfire events have occurred in the county since record-keeping began, and are expected to continue, as fire frequency has steadily increased in recent decades [29,39]. The county is home to more than three million residents, and approximately one million more people are expected by 2030 [40]. Although most residential development has been concentrated along the coast, expansion of housing is expected in the eastern, unincorporated part of the county.

Econometric Subdivision Model

A host of alternative modeling approaches exist to simulate future land use scenarios [41], including a cellular automaton model that we previously applied to the study area [42]. We chose to use an econometric modelling approach for this study because we wanted to capture fine-scale, structure-level patterns and processes that are correlated with housing loss to wildfire [26]; and econometric models may perform better at the scale of individual parcels [43].

Although we based the three development scenarios on generalized planning policies, we also wanted to ensure that the residential projections were realistic and adhered to current planning regulations. The objective of the econometric modeling was to estimate the likelihood that residential parcels will subdivide in the future. Therefore, we used a probit model to estimate the transition probability of each parcel based on a range of potential explanatory variables typically associated with parcel subdivision and housing development [44–45].

To develop the model of subdivision probability, we acquired GIS data of the county's parcel boundaries in years 2005 and 2009 from the San Diego Association of Governments (SANDAG). The dependent variable was equal to 1 if a parcel subdivided between 2005 and 2009, and zero otherwise. Using these data layers we first determined which parcels were legally able to subdivide given current land use regulations. Minimum lot size restrictions are typically considered the most import restriction for determining future land use. We deemed a parcel eligible for subdivision if the current lot size was greater than twice the minimum legal size given the land class. To determine which parcels subdivided between 2005 and 2009, we queried parcel IDs where the total

area was reduced by at least the minimum lot size between the two time periods. Finally, we were able to generate a suite of variables that determine the likelihood of a parcel developing in the future (Table S1).

We overlaid the parcel boundaries over a range of GIS layers representing our explanatory variables. These data are available to download at (http://www.sandag.org/index.asp?subclassid = 100&fuseaction = home.subclasshome). Our explanatory variables included: parcel size, parcel size squared, six dummy variables which capture non-linear effects of parcel size, distance to the coast, distance to the coast squared; distance to city center and its square, current zoning, slope, land use, roads, if the parcel is in a protected area, if the parcel is in a development area, if the parcel is in the redevelopment area (Table 1).

Spatial Model of Future Development under Planning Alternatives

The outcome of the land use change econometric model is the subdivision probability for each parcel for a five-year time step. Based on these probabilities, we developed a GIS spatial simulation model of future land use under three distinct planning scenarios: infill (development in open or low density parcels within already developed areas), expansion (development on the fringe of developed areas), and leapfrog (development in open areas). The model runs in four 5-year time steps from 2010 to 2030, and generates the spatial locations of new housing units in the county.

Although development decisions could feasibly depend on fire risk, we did not model that here. There is no evidence that fire has influenced past regional planning decisions, so it was not used as an explanatory variable in the econometric model. Although we could have evaluated the potential for future development decisions to be based in part on fire risk, this would have required simulation of feedbacks between fires and probability of development. Because our objective in this study was to isolate the effects of the three distinct growth types, we modeled fire risk only as a function of development pattern and not vice versa.

We constructed a complete spatial database of existing residential structures in the study area [26]. These structures and their corresponding parcel boundaries served as the initial conditions for all three scenarios of the spatial simulation model. The current and projected future GIS layers of structures were also subsequently used in the fire risk model (see below). The

dataset of existing housing includes locations of 687,869 structures, of which 4% were located within the perimeter of one of 40 fires that burned since 2001. During these fires, 4315 structures were completely destroyed, and another 935 were damaged.

For future development scenarios, we wanted to allocate an equal number of new structures to the landscape. This was to ensure that any predicted difference in fire risk was a function of the arrangement and location of structures, not the total number of structures. Nevertheless, differences in the total number of structures were simulated with each of the 5-year time steps. We determined the number of housing units to add during the simulations based on projections made by San Diego County [46]. Using factors such as development proposals, general plan densities, and information from jurisdictions, the county estimated that between 331,378 units and 486,336 units could be supported within the developable residential land by 2030. Because the eastern, desert portion of the county was not included in our study area, we used a conservative approach and simulated the addition of 331,378 new dwelling units. We divided this number by four to define the number of new dwelling units to add at each time step, assuming a linear growth rate.

One output of the econometric model was the prediction of the maximum number of new dwelling units that could be added to each parcel. However, dwelling units may consist of apartments as well as single family homes. The mix of single and multifamily units in the region has remained relatively constant over time, and the overall trend has been a mix of roughly 1/3 multifamily and 2/3 single family units. Because the fire risk model is based on points representing structure locations across the landscape, regardless of the number of dwelling units per structure, we needed to generate a conversion factor from dwelling units to structures. We therefore defined a minimum lot size of 0.25 acre on which no more than a single structure could be built, regardless of the number of dwelling units in it (i.e., a single family home or apartment complex). Then, once a parcel was selected for development by the model (see details below), we divided its total area by the maximum number of dwelling units to be added, according to the econometric model. If the result was larger than 0.25, we subdivided parcels according to the result. If not, we quantified how many 0.25 acre parcels fit into the original parcel, and generated the new parcel boundaries accordingly.

Using the initial map of parcels (year 2010), we classified each parcel that was defined as eligible for development (in the previous stage) as suitable for one of the three planning scenarios described above, according to the number of developed parcels in its immediate neighborhood (i.e., those parcels that share a boundary with the focal parcel). We defined 'developed parcels' as ones that had more than one house per 20 acres (8.09 ha). Therefore, according to these density thresholds, we allowed some parcels with nonzero housing density to be considered as 'undeveloped' because these large, rural parcels might contain a single or a handful of houses but they exist within a large open area. In other words, the overall land cover of these parcels was effectively undeveloped, and we therefore assumed that development in adjacent parcels would be akin to development in open areas.

We defined infill parcels as those that were completely surrounded by developed parcels. Expansion parcels had at least one neighboring parcel that was undeveloped; and leapfrog parcels were those with no developed parcels in their immediate surroundings. We reclassified the type of each available parcel in the same manner after each time step, to account for changing dynamics in the development map of the county.

We conducted three simulations, one for each development scenario (infill, expansion, and leapfrog). In each simulation, all parcels were eligible to subdivide, regardless of their class. Therefore, to build a simulation for a specific scenario, we increased the development probability of parcels of the selected scenario by 20%, to favor their development compared to the other types of parcels, without prohibiting development in the other parcel types. This approach was necessary because the projected number of dwelling units was much larger than it would be possible to fit in infill and leapfrog class parcels solely. For example, as the spatial coverage of developed parcel expands, there is less contiguous area that is undevelopable and suitable for leapfrog development. Therefore, the scenarios are not exclusive, but rather a mixture of the three development types. Yet, in each scenario, there is one main type of development, and smaller amounts of development events of the other two types.

Due to the immense computational demand of the simulations, we adopted a deterministic, rather than a stochastic approach to decide on which parcels were subdivided. After enhancing the transition probability according to the corresponding scenario, we ranked and then sorted all parcels according to their probability of subdivision. We then sequentially selected parcels, while simultaneously tallying the number of dwelling units in them, until the development target in that time step (one fourth of the total number of dwelling units to be added: 82,795) was reached. Once the development target was reached, we moved to the next time step. After each time step, the remaining parcels that were still eligible for development were re-classified to development types according to the new spatial configuration of the landscape.

Once a parcel was selected for subdivision, and the number of new parcels to develop in it was calculated (as detailed above), an equal-area spatial splitting model was employed to split the parent parcel to the predefined number of equal-area child parcels. We developed a simple splitting model which is based on iterative splitting of larger parcels into two smaller parcels using a straight line splitting boundary. Once the parcel was fully split into the needed number of sub-parcels, we allocated a new structure inside each new parcel by generating a point at its centroid (center of gravity). The point datasets of all structure locations per time step per scenario were passed over to the fire risk model, which is described below.

Fire Risk Modeling and Analysis

To project the distribution of fire risk under alternative scenarios, we used MaxEnt [47–48], a map-based modeling software used primarily for species distribution modeling [48], but we have used it successfully for ignition modeling [50] and for projecting current fire risk in the study area [26]. For this study, we slightly modified the model from Syphard et al. [26]. The dependent variable was the location of structures destroyed by fire between 2001 and 2010. Although inclusion of damaged structures in the data set does not significantly affect results [26], we only included completely destroyed structures to avoid the introduction of any uncertainty.

The MaxEnt software uses a machine-learning algorithm that iteratively evaluates contrasts among values of predictor values at locations where structures burned versus values distributed across the entire study area. The model assumes that the best approximation of an unknown distribution (i.e., structure destruction) is the one with maximum entropy. The output is an exponential function that assigns a probability to every cell of a map. Thus, the resulting continuous maps of fire risk represented the probability of a structure being destroyed by fire. In these output maps, areas of predicted high fire risk that did not have structures on them represented environmental conditions similar to those in which structures have actually burned.

We based the explanatory variables on those that were significantly related to burned structures in Syphard et al. [26], including maps depicting housing arrangement and pattern, housing location, and biophysical factors. Housing pattern variables reflected individual structure locations as well as the arrangement of structures within housing clusters. We calculated housing clusters, defined as groups of structures located within a maximum of 100 m from each other, by creating 100 m buffers around all structures and dissolving the overlapping boundaries [51].

Because burned structures were significantly related to small housing clusters [26], we calculated the area of every cluster as an attribute, and then created raster grids based on that attribute. Low-to intermediate housing density and distance to the edge of the cluster were also significant explanatory variables relative to housing pattern and location [26], so we also created raster grids for those. GIS buffer measures at 1-km have been found to explain approximately 90% of the variation in rural residential density [52], so we developed density grids using simple density interpolation based on a 1-km search radius, with area determined through square map units. To create grids representing distance to the edge of clusters, we first collapsed the cluster polygons into vector polyline files, and then created grids of interpolated Euclidean Distance to the edge within each cluster.

Because the MaxEnt model randomly selects background samples in the map to compare with locations of destroyed structures, we used a mask to restrict sampling to the developed environment within cluster boundaries; the distance to the edge of the cluster would represent a different relationship inside a cluster boundary versus outside in the wildland. We also modified the grids to ensure that any random sample located within the 100m buffer zone would receive a value of 100m; thus, all points within the buffer were considered "the edge of the development".

After creating the grids representing housing pattern and arrangement of the current configuration of structures, we applied the same algorithms to the maps of simulated future structure locations. We thus generated grids representing future housing pattern and arrangement under alternative development scenarios. The other explanatory variables, including fire history, slope, fuel type, southwest aspect, and distance to coast [26] remained constant through time for current and future scenarios. Although historic fire frequency and fuel type typically change through time, we did not simulate their dynamics here because we wanted to isolate the effect of planning decisions on housing pattern and arrangement while holding everything else constant.

We conditioned the MaxEnt model on present distributions of housing using ten thousand random background points and destroyed structures located no closer than 500-m to minimize any effect of spatial autocorrelation. We used 80% (260 records) of these data for model training, and 20% [66 records) for testing. We repeated the process using cross-validation with five replicates and used the average of these five models for analyses. For smoother functions of the explanatory variables, we used hinge features, linear, and quadratic with an increase in regularization of beta set at 2.5, based on Elith et al. [48]. The smoother response curves minimize over fitting of the model. We conducted jackknife tests of explanatory variable importance.

We first developed the model using mapped explanatory variables derived from the current configuration of structures. To project fire risk under the different time steps of the alternative development scenarios, projected the model conditioned upon current conditions onto maps representing future conditions by substituting the grids representing future housing pattern and arrangement. This is similar to how potential future distributions of species are projected under climate change scenarios [49].

To quantify differences among current and future alternative scenarios, we calculated metrics representing housing density, pattern, and footprint to determine the extent to which the planning policies produced differences in housing pattern and location. We compared the modeled structure fire risk of the scenarios by overlaying all maps of structure locations with their respective mapped output grids from the MaxEnt models and calculating probability of burning for every structure point. We also calculated total area of risk by selecting three threshold criteria [53]. These criteria, at 0.05, 0.25, and 0.5 represented three different degrees of risk, and we calculated the proportion of structures that were located in risk areas for every time step in all scenarios.

Results

The probit econometric model, run on 113 001 observations, showed that larger parcels were most likely to subdivide, although the relationship between parcel size and subdivision probability was non-linear (Table 1). Parcels closer to existing roads, the ocean, those with lower slopes, and those designated as fit for development were all most likely to develop. Parcels designated in redevelopment areas were less likely to develop. Overall, the model had a pseudo r –squared of 0.22.

The land use simulation model, based on a combination of the econometric subdivision model and three different growth policies, resulted in substantial differences in the extent and pattern of housing of the three scenarios. The total area of housing development, or the housing footprint, was largest for simulations where leapfrog growth dominated, followed by expansion-type development, and then infill (Figure 1a). The differences in the housing footprint became larger among the scenarios over time, but the largest difference was between infill and the other two development types. As the housing footprint expanded in the three scenarios, the corresponding housing density declined, so that leapfrog growth resulted in the lowest housing density per 1-km, followed by expansion and then infill (Figure 2b). Despite the near inverse of this relationship, there was generally a larger separation among scenarios with regard to housing density. With larger housing footprints and lower housing density, the number of separate housing clusters increased while their size decreased (Figure 2c).

In the first two time steps of the model (2015 and 2020), the simulated development pattern closely followed the desired pattern in the scenario, although some of the growth in the infill scenario ended up becoming expansion or leapfrog (Table 2). In the last two time steps (2025 and 2030), there were not enough infill parcels left, and thus, the majority of growth in these simulations became expansion, followed by infill, and then leapfrog. In the last time step, there were not enough isolated parcels in the leapfrog scenario and thus, the majority of development became expansion. Thus in general, as more development occurred in the simulations by the year 2030, the majority took the form of expansion.

The area under the curve (AUC) of receiver operating characteristic (ROC) plots, indicating the ability of the MaxEnt model to discriminate between burned and unburned structures, averaged across five cross-validated replicate runs was 0.91. The AUC represents the probability that, for a randomly selected set of observations, the model prediction was higher for a burned structure than for an unburned structure [49].The two most important variables in the model according to the internal jackknife tests in MaxEnt [47] were related to housing pattern:

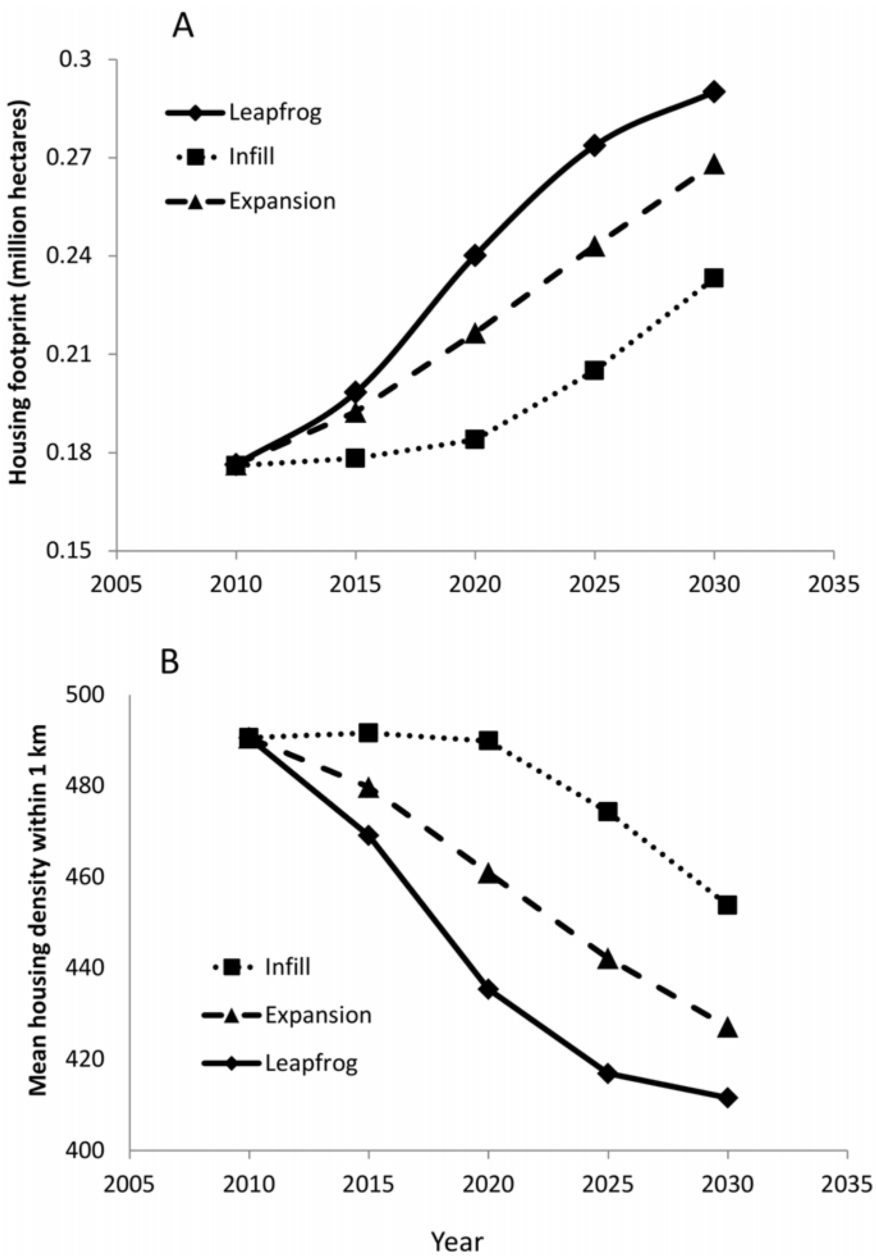

Figure 1. Trends of development extent and pattern for three planning policy simulations from 2010–2030, including A) total housing footprint representing the area of land within all housing clusters, and B) mean housing density averaged across all housing clusters.
doi:10.1371/journal.pone.0071708.g001

low to intermediate housing density and small cluster size and housing density (Figure 3). The distance to the edge of housing cluster was a less important contribution.

Maps showing the probability of a structure being destroyed in a wildfire, displayed as a gradient from low to high risk, show broad agreement relative to the general areas of the landscape that are riskiest, with correlation coefficients ranging from 0.85–0.91 (Figure 4). Nevertheless, subtle differences are apparent in the three development-scenario maps by year 2030, with the highest-risk areas in the expansion scenario located farther east than infill, and the highest-risk areas in leapfrog occupying a wider extent than either of the other two scenarios.

Differences among current housing and the three development scenarios are clearly illustrated through the mean landscape risk, or total probability of all structures burning (Figure 5). All three development scenarios were predicted to experience an increase in mean landscape risk over the duration of the simulations, except for infill at year 2015. The highest landscape risk to structures was predicted for the leapfrog scenario, followed by expansion, and then infill. The increase in risk over time is more gradual for the infill scenario than the other two scenarios.

The ranking of scenarios varied according to the proportion of structures located within different levels of risk defined through binary thresholding (Figure 6). When the continuous risk maps were thresholded at the lowest number of 0.05, a large proportion

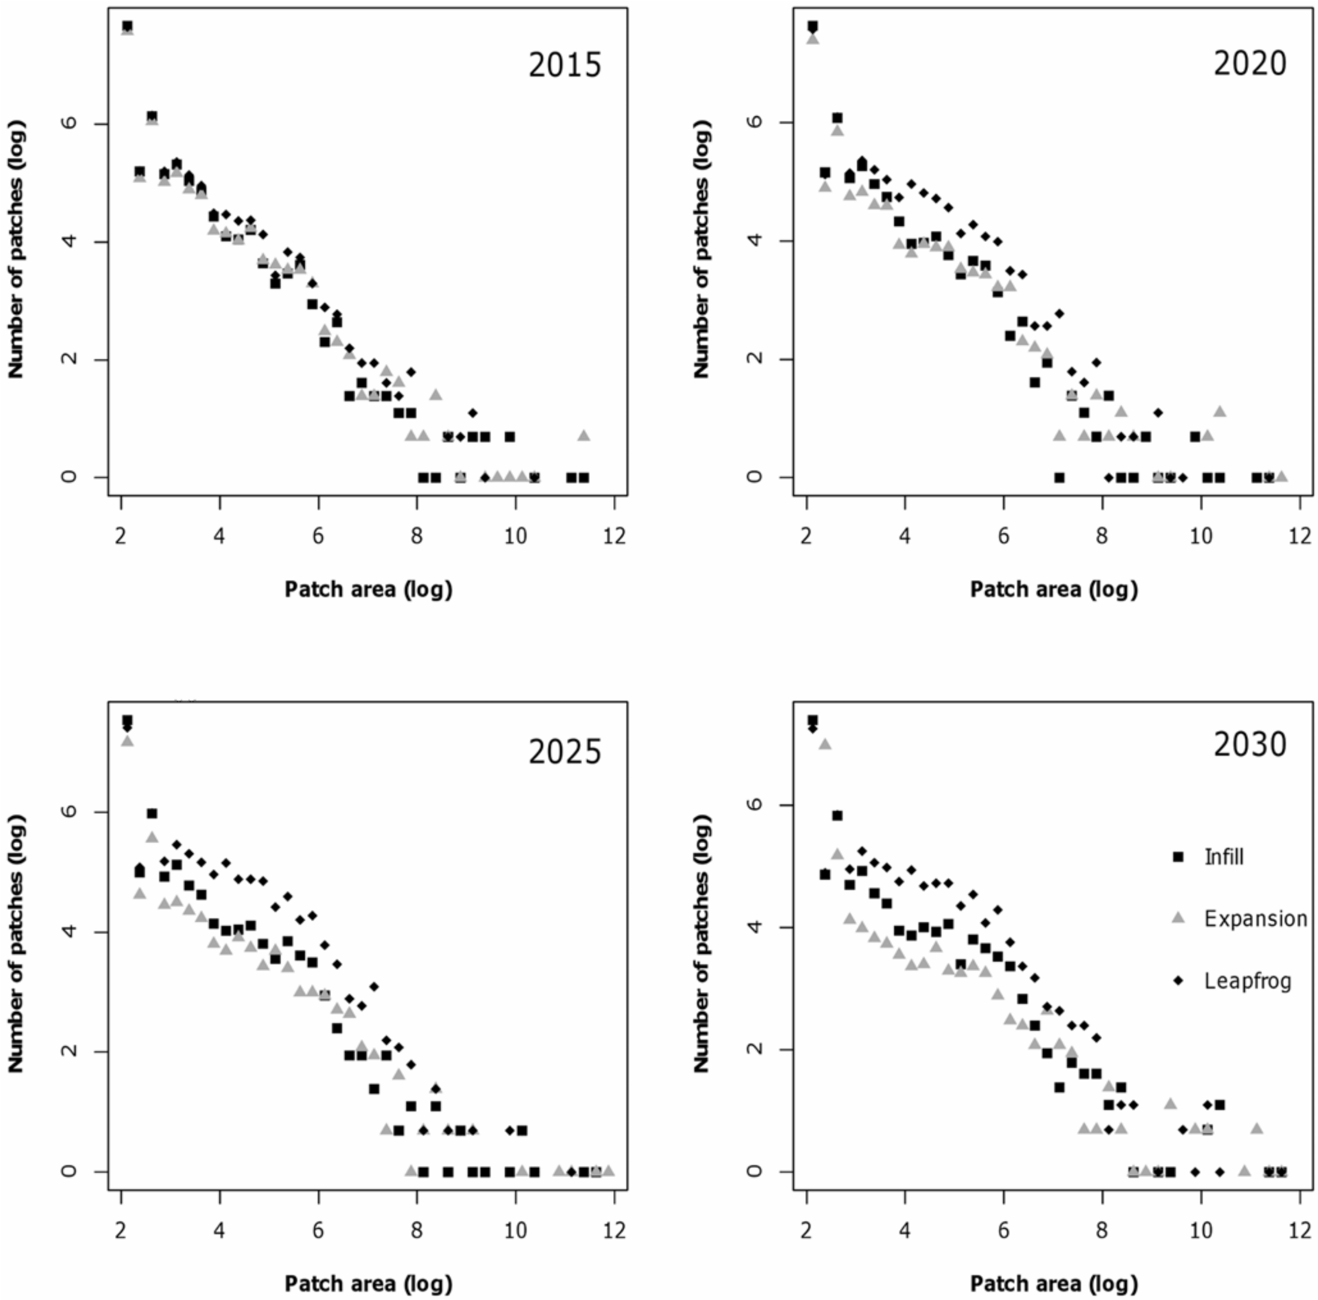

Figure 2. Trends in number of patches and patch area for three planning policy simulations from 2010–2030. Numbers were log-transformed for better visual representation of the scenarios.
doi:10.1371/journal.pone.0071708.g002

of structures in all scenarios fell within areas defined as risky according to this criterion. At this threshold, the proportion of structures in high-risk areas increased linearly for the expansion and leapfrog development scenarios while the proportion of infill homes increased more gradually. When risk was defined more conservatively at 0.25, temporal trends for the leapfrog and infill scenarios were similar to the 0.05 threshold. However, the proportion of structures at risk in the expansion scenario initially increased to 2020, but this proportion leveled off and declined by 2030. When the threshold was highest at 0.50, a very low proportion of structures in any scenario were located in areas at risk. But in these high-risk areas, the expansion scenario switched places with infill to have the lowest proportion of structures at risk in all time steps. Leapfrog had the largest proportion of homes at risk. This proportion of homes located in areas at risk with a threshold at 0.5 declined over time for all three scenarios.

Discussion

Our simulations of residential development showed that planning policies based on different growth types, applied locally for subdivision of individual parcels, will likely produce substantial and cumulative landscape-level differences in pattern, location, and extent of development. These differences in development pattern, in turn, will likely affect the area and proportion of

Table 2. Pattern of simulated development under infill, expansion, and leapfrog growth policies.

		Actual development		
Development scenario	**year**	*Infill*	*Expansion*	*Leapfrog*
Infill	2015	9450	18	6
	2020	11787	153	29
	2025	236	624	144
	2030	325	890	179
Expansion	2015	0	772	0
	2020	0	1243	2
	2025	0	1871	1
	2030	0	2662	0
Leapfrog	2015	0	10	408
	2020	0	5	1132
	2025	1	83	3563
	2030	34	917	0

The numbers in the table denote the numbers of patches of a given development type.

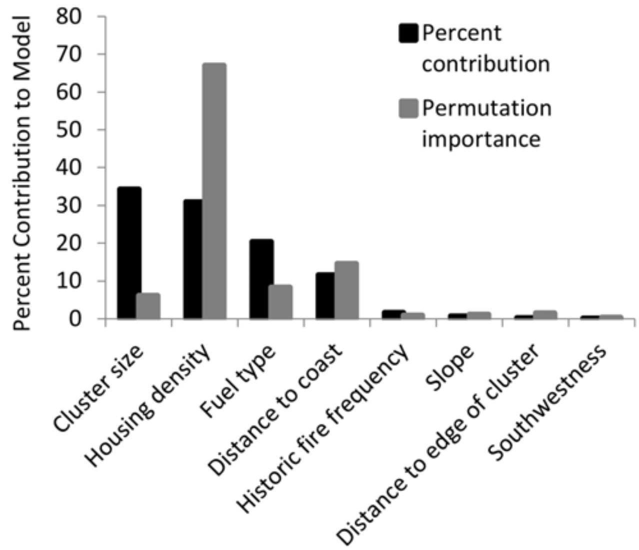

Figure 3. The importance of explanatory variables averaged across five cross-validated replications in the MaxEnt fire risk model. Percent contribution is determined as a function of the information gain from each environmental variable throughout the MaxEnt model iterations. Permutation importance reflects the drop in model accuracy that results from random permutations of each environmental variable, normalized to percentages.
doi:10.1371/journal.pone.0071708.g003

structures at risk from burning in wildfires. In particular, the scenarios with lower housing density and larger numbers of small, isolated clusters of development, i.e., leapfrog followed by expansion and infill, were generally predicted to have the highest predicted fire risk to the largest proportion of structures in the study area. Nevertheless, rankings of scenarios were affected by the definition of risk.

Theoretically, it makes sense that leapfrog development produced fragmented development with larger numbers of small patches, lower housing density, and a larger housing footprint; and that infill resulted in the opposite, with expansion in the middle. By definition, leapfrog development requires open space around all sides of the newly developed parcel, whereas infill requires development on all sides, and expansion requires development on one side and open space on another. Implementing these planning policies on real landscapes, however, can be complex if there are more houses to build than there are parcels that meet the definitions of the three planning rules, and thus not all development conforms strictly to the policy [54]. In our simulations, parcels meeting the definition of each growth type had a higher probability of subdividing; yet, as we were simulating a real landscape, many newly developed parcels did not meet the scenario criteria. That the three scenarios nevertheless produced substantial differences in landscape-level development patterns shows that decision-making at the individual level can lead to meaningful broad-scale effects.

The objective of the econometric model was to provide a baseline probability to predict which parcels were most likely to subdivide; thus, the econometric model itself provides no explanation of how a given policy affects likelihood of subdivision, although it does indicate the correlation between the policy and the outcome. In our setting, which areas are protected, marked for redevelopment, or marked for development may be endogenous to the land owner decision to subdivide. In the case of these variables especially, our results should not be interpreted as causal predictors. Likewise, we use data only from 2005–2009 to predict changes to 2030. If major changes in the land market take place over this time horizon our model will not be able to take this into account.

Although some differences in predicted fire risk among the three scenarios likely stemmed from location of new structures relative to variables such as distance to coast, fuel type, or slope, the most important variables in the fire risk model were housing density and cluster size, with most structure loss historically occurring in areas with low housing density and in small, isolated housing clusters. Thus, leapfrog development was generally the riskiest scenario and infill the least risky. The most surprising result was the variation in predicted risk for the expansion scenario over time and at different thresholds. While leapfrog and infill showed similar trajectories across thresholds, expansion went from being the highest-risk scenario at the low threshold to being the lowest-risk scenario at the highest threshold. Because the threshold is merely a way to group structures into a binary classification, this means that, while the average risk calculated across all homes shows expansion to rank in the middle of infill and leapfrog throughout the simulation (Figure 5), the other two scenarios have a relatively larger proportion of homes that are modeled to be at a very high risk (i.e., 0.25 or 0.5), particularly by the end of the simulations. Because the total number of structures with a risk greater than 0.25 or 0.5 is relatively low in all scenarios, this difference in distribution of homes at the highest risk is not reflected in the mean. Another reason for the shift in rank of expansion over time is that, as more development occupied the landscape, there were fewer parcels remaining to accomplish infill or leapfrog type growth in the other scenarios. Thus, by the end of the simulations in year 2030, the majority of growth in all scenarios was expansion, and there was some convergence between scenarios. Finally, the change in risk of expansion growth over time may reflect that, despite the relatively low importance of distance to edge of cluster as an explanatory variable, expansion growth is characterized as having an initially fragmented landscape pattern that eventually merges into large patches with low edge.

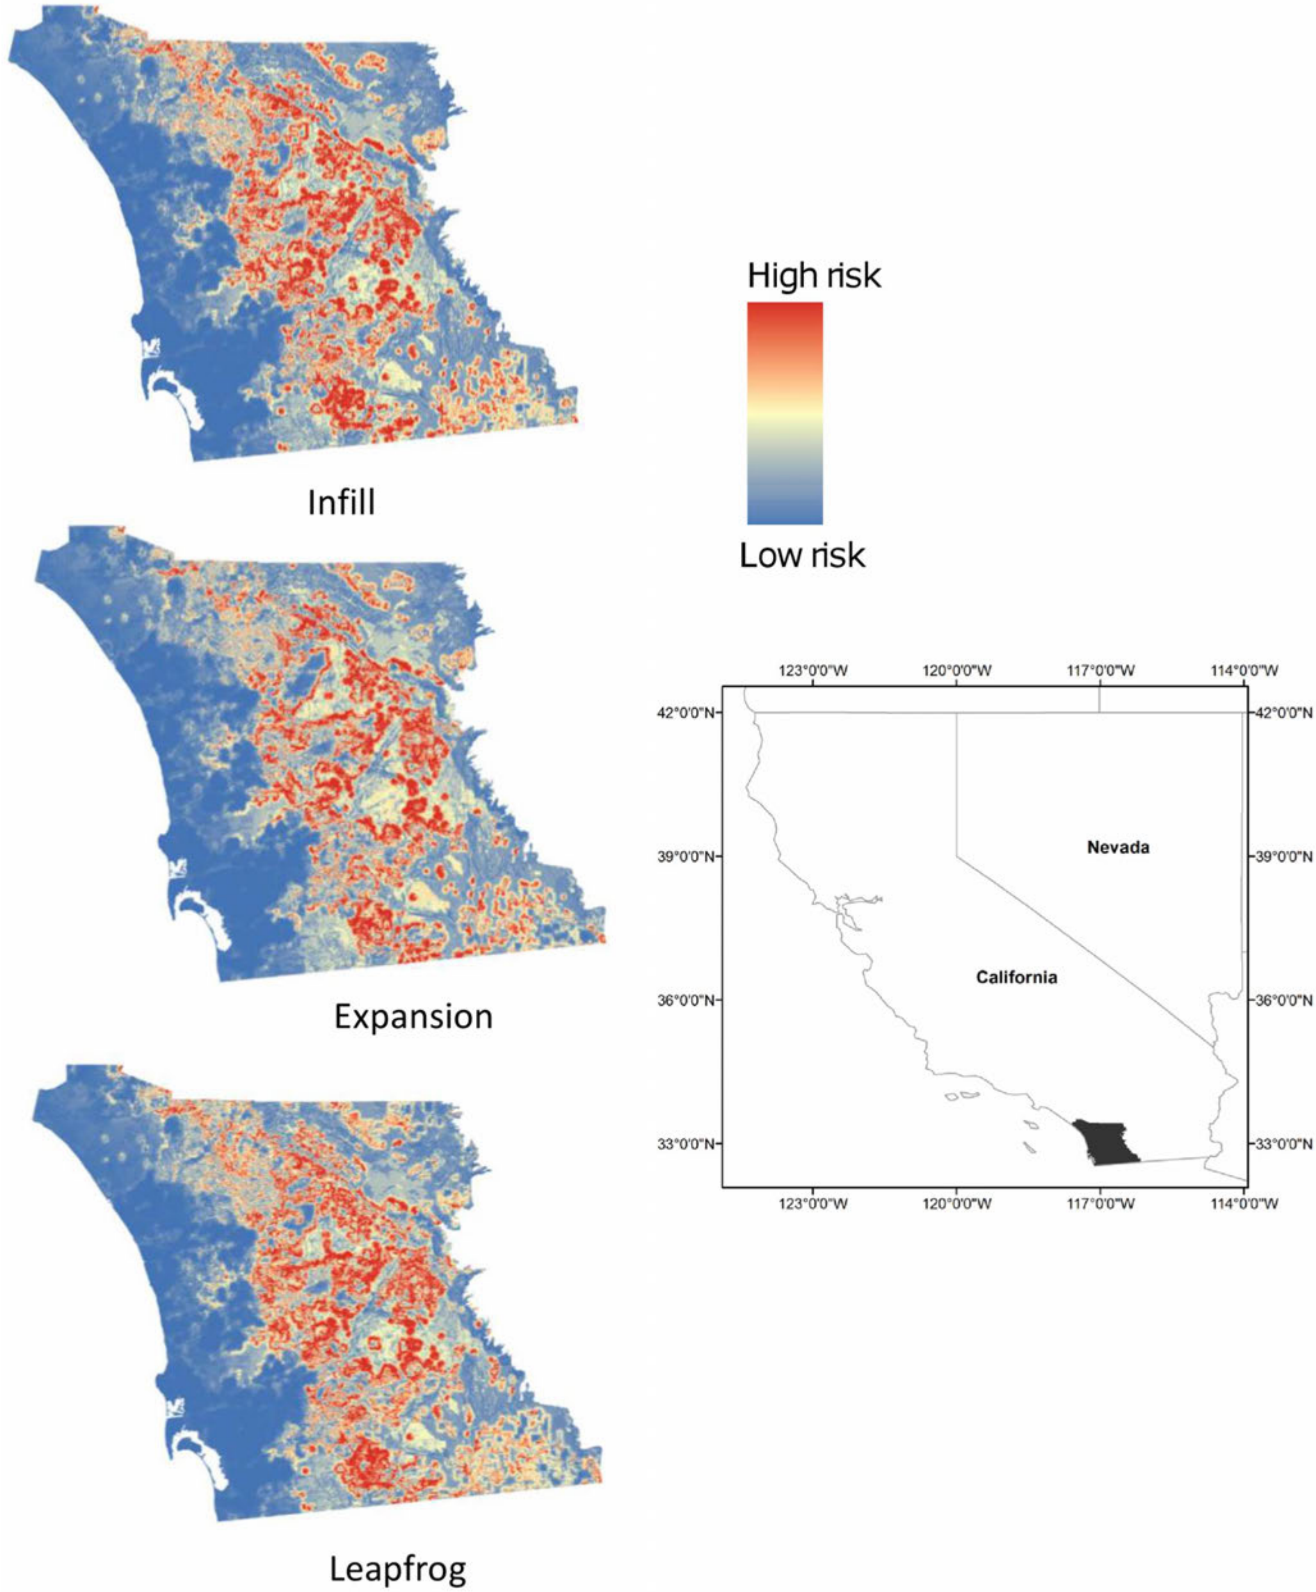

Figure 4. Maps of the study area showing projected wildfire risk at year 2030 for simulations of residential development under policies emphasizing infill, expansion, or leapfrog growth.
doi:10.1371/journal.pone.0071708.g004

Although leapfrog development clearly ranked highest in terms of fire risk, the interpretation of which planning policy is best may depend on fire management objectives and resources, as well as other considerations such as biodiversity or ecological impacts.

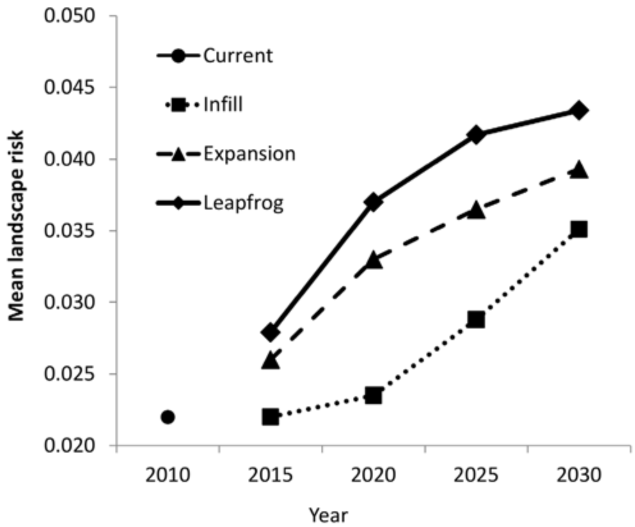

Figure 5. Projected landscape fire risk, reflecting the probability of burning in a wildfire averaged across all residential structures on the current landscape and in three development scenarios of infill, expansion, and leapfrog for year 2030.
doi:10.1371/journal.pone.0071708.g005

The spatial pattern of development affects multiple ecological functions and services [55], with potentially varying conservation implications; both leapfrog and expansion development consumed more land than infill, which would likely lead to more ecological degradation [56]; nevertheless, higher-density clustered development may be dominated by more invasive species [57]. Trade-offs between fire protection and conservation are common, but techniques are available for identifying mutually beneficial solutions [58].

Different perceptions of the fire risk results could also potentially translate into different planning priorities for management. For example, if the priority is to plan for the lowest overall risk to structures, then the mean landscape risk clearly delineates the rankings of options, with infill being the winner. However, if the objective is to reduce the number of structures at the highest risk threshold, i.e., $>=0.5$, then expansion is the best option, at least by 2030. An important consideration for fire management is the total area that needs to be protected, as well as the length of wildland-urban interface [8,13]. Therefore, despite the lower number of structures at the highest risk thresholds, expansion creates more edge than infill and may translate into greater challenges for firefighter protection.

Although we did not create separate scenarios for high or low growth, the results at different time steps can be substituted to envision the potential outcome of developing more or fewer houses. In the short term, the total fire risk is projected to increase proportionately as more land is developed. However, given the inverse relationship between housing density and fire risk, it is possible that this trend could reverse if housing growth eventually resulted in expansive high-density development.

Land use planning is one of a range of options available for reducing fire risk, and the best outcome will likely be achieved through a combination of strategies that include homeowner actions, improvements in fire-safe building codes, and advanced fire suppression tactics. Although we isolated the effect of land use planning policy in the three development scenarios, the fire risk model nevertheless showed that the pattern and location of structures in this study area were the most important out of a suite of factors influencing structure loss. We used a correlative approach that did not incorporate mechanisms or feedbacks, but our models clearly illustrated differences in the cumulative effects of individual planning decisions. The relationship between spatial pattern of development and fire risk is likely related to the intermixing of development and wildland vegetation [29,59]; thus, these results likely apply to a wide range of fire-prone ecosystems with large proportions of human-caused ignitions. Nevertheless, because fire risk is highly variable over space and time, and due to a range of human and biophysical variables [60], we recommend planners develop their own models for the best understanding of where the most fire-prone areas are in their region [19].

With projections of substantial global change in climate and human development, we recommend that land use planning should be considered as an important component to fire risk management, potentially to become as successful as the prevention of building on flood plains [61]. History has shown us that preventing fires is impossible in areas where large wildfires are a natural ecological process [4,9]. As Roger Kennedy put it, "the

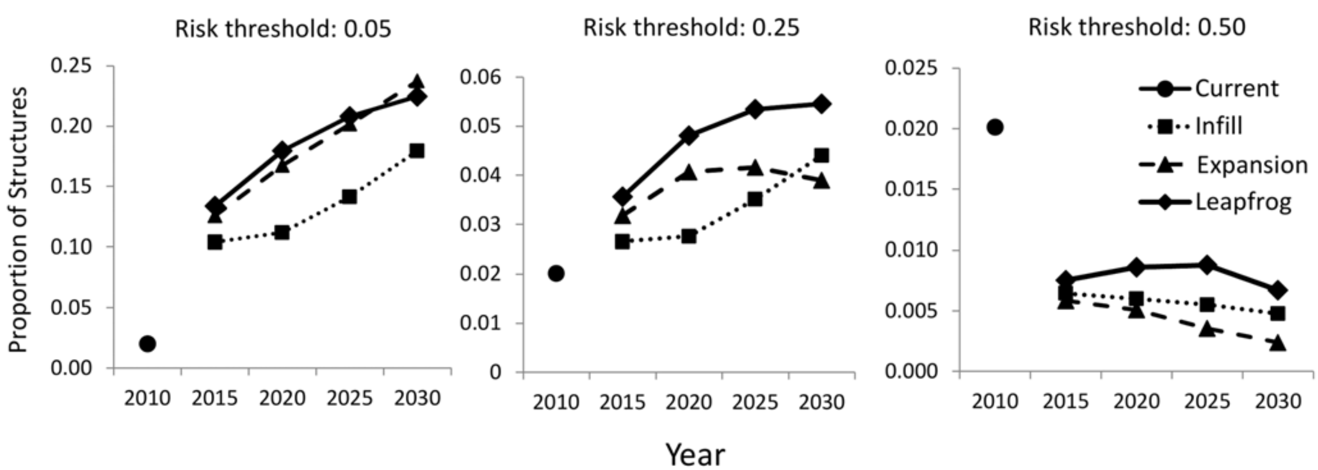

Figure 6. Proportion of residential structures that are located in areas of high fire risk defined using thresholds from the fire risk model of 0.05, 0.25, and 0.5 for current structures and for structures simulated under infill, expansion, and leapfrog growth policies.
doi:10.1371/journal.pone.0071708.g006

problem isn't fires; the problem is people in the wrong places [62]."

Abstract. With the potential for worsening fire conditions, discussion is escalating over how to best reduce effects on urban communities. A widely supported strategy is the creation of defensible space immediately surrounding homes and other structures. Although state and local governments publish specific guidelines and requirements, there is little empirical evidence to suggest how much vegetation modification is needed to provide significant benefits. We analysed the role of defensible space by mapping and measuring a suite of variables on modern pre-fire aerial photography for 1000 destroyed and 1000 surviving structures for all fires where homes burned from 2001 to 2010 in San Diego County, CA, USA. Structures were more likely to survive a fire with defensible space immediately adjacent to them. The most effective treatment distance varied between 5 and 20 m (16–58 ft) from the structure, but distances larger than 30 m (100 ft) did not provide additional protection, even for structures located on steep slopes. The most effective actions were reducing woody cover up to 40% immediately adjacent to structures and ensuring that vegetation does not overhang or touch the structure. Multiple-regression models showed landscape-scale factors, including low housing density and distances to major roads, were more important in explaining structure destruction. The best long-term solution will involve a suite of prevention measures that include defensible space as well as building design approach, community education and proactive land use planning that limits exposure to fire.

Received 16 September 2013, accepted 30 May 2014, published online 14 October 2014

Introduction

Across the globe and over recent decades, homes have been destroyed in wildfires at an unprecedented rate. In the last decade, large wildfires across Australia, southern Europe, Russia, the US and Canada have resulted in tens of thousands of properties destroyed, in addition to lost lives and enormous social, economic and ecological effects (Filmon 2004; Boschetti *et al.* 2008; Keeley *et al.* 2009; Blanchi *et al.* 2010; Vasquez 2011). The potential for climate change to worsen fire conditions (Hessl 2011), and the projection of continued housing growth in fire-prone wildlands (Gude *et al.* 2008) suggest that many more communities will face the threat of catastrophic wildfire in the future.

Concern over increasing fire threat has escalated discussion over how to best prepare for wildfires and reduce their effects. Although ideas such as greater focus on fire hazard in land use planning, using fire-resistant building materials and reducing human-caused ignitions (e.g. Cary *et al.* 2009; Quarles *et al.* 2010; Syphard *et al.* 2012) are gaining traction, the traditional strategy of fuels management continues to receive the most attention. Fuels management in the form of prescribed fires or mechanical treatments has historically occurred in remote, wildland locations (Schoennagel *et al.* 2009), but recent studies suggest that treatments located closer to homes and communities may provide greater protection (Witter and Taylor 2005; Stockmann *et al.* 2010; Gibbons *et al.* 2012). In fact, one of the most commonly recommended strategies in terms of fuels and fire protection is to create defensible space immediately around structures (Cohen 2000; Winter *et al.* 2009). Defensible space is an area around a structure where vegetation has been modified, or 'cleared,' to increase the chance of the structure surviving a wildfire. The idea is to mitigate home loss by minimising direct contact with fire, reducing radiative heating, lowering the probability of ignitions from embers and providing a safer place for fire fighters to defend a structure against fire (Gill and Stephens 2009; Cheney *et al.* 2001). Many jurisdictions provide specific guidelines and practices for creating defensible space, including minimum distances that are required among trees and shrubs as well as minimum total distances from the structure. These distances may be enforced through local ordinances or state-wide laws. In California, for example, a state law in 2005 increased the required total distance from 9 m (30 ft) to 30 m (100 ft).

Despite these specific guidelines on how to create defensible space, there is little scientific evidence to support the amount and location of vegetation modification that is actually effective

at providing significant benefits. Most spacing guidelines and laws are based on 'expert opinion' or recommendations from older publications that lack scientific reference or rationale (e.g. Maire 1979; Smith and Adams 1991; Gilmer 1994). However, one study has provided scientific support for, and forms the basis of, most guidelines, policy and laws requiring a minimum of 30 m (100 ft) of defensible space (Cohen 1999, 2000). The modelling and experimental research in that study showed that flames from forest fires located 10–40 m (33–131 ft) away would not scorch or ignite a wooden home; and case studies showed 90% of homes with non-flammable roofs and vegetation clearance of 10–20 m (33–66 ft) could survive wildfires (Cohen 2000). However, the models and experimental research in that study focussed on crown fires in spruce or jack pine forests, and the primary material of home construction was wood. Therefore, it is unknown how well this guideline applies to regions dominated by other forest types, grasslands, or nonforested woody shrublands and in regions where wooden houses are not the norm.

Some older case studies showed that most homes with non-flammable roofs and 10–18 m (33–ft) of defensible space survived the 1961 Bel Air fire in California (Howard *et al.* 1973); most homes with non-flammable roofs and more than 10 m (33 ft) of defensible space also survived the 1990 Painted Cave fire (Foote and Gilless 1996). Also, several fire-behaviour modelling studies have been conducted in chaparral shrublands. One study showed that reducing vegetative cover to 50% at 9–30 m (30–ft) from structures effectively reduced fireline intensity and flame lengths, and that removal of 80% cover would result in unintended consequences such as exotic grass invasion, loss of habitat and increase in highly flammable flashy fuels (A. Fege and D. Pumphrey, unpubl. data). Another showed that separation distances adequate to protect firefighters varied according to fuel model and that wind speeds greater than 23 km h^{-1} negated the effect of slope, and wind speed above 48 km h^{-1} negated any protective effect of defensible space (F. Bilz, E. McCormick and R. Unkovich, unpubl. data, 2009). Results obtained through modelling equations of thermal radiation also found safety distances to vary as a function of fuel type, type of fire, home construction material and protective garments worn by firefighters (Zárate *et al.* 2008).

Although there is no empirical evidence to support the need for more than 30 m (100 ft) of defensible space, there has been a concerted effort in some areas to increase this distance, particularly on steep slopes. In California, a senate bill was introduced in 2008 (SB 1618) to encourage property owners to clear 91 m (300 ft) through the reduction of environmental regulations and permitting needed at that distance. Although this bill was defeated in committee, many local ordinances do require homeowners to clear 91 m (300 ft) or more, and there are reports that some people are unable to get fire insurance without 91 m (300 ft) of defensible space (F. Sproul, pers. comm.). In contrast, homeowner acceptance of and compliance with defensible space policies can be challenging (Winter *et al.* 2009; Absher and Vaske 2011), and in many cases homeowners do not create any defensible space.

It is critically important to develop empirical research that quantifies the amount, location and distance of defensible space that provides significant fire protection benefits so that guidelines and policies are developed with scientific support. Data that are directly applicable to southern California are especially important, as this region experiences the highest annual rate of wildfire-destroyed homes in the US. Not having sufficient defensible space is obviously undesirable because of the hazard to homeowners. However, there are clear trade-offs involved when vegetation reduction is excessive, as it results in the loss of native habitats, potential for increased erosion and invasive species establishment, and it potentially even increases fire risk because of the high flammability of weedy grasslands (Spittler 1995; Keeley *et al.* 2005; Syphard *et al.* 2006).

It is also important to understand the role of defensible space in residential structure protection relative to other factors that explain why some homes are destroyed in fires and some are not. Recent research shows that landscape-scale factors, such as housing arrangement and location, as well as biophysical variables characterising properties and neighbourhoods such as slope and fuel type, were important in explaining which homes burned in two southern California study areas (Syphard *et al.* 2012; 2013). Understanding the relative importance of different variables at different scales may help to identify which combinations of factors are most critical to consider for fire safety.

Our objective was to provide an empirical analysis of the role of defensible space in protecting structures during wildfires in southern California shrublands. Using recent pre-fire aerial photography, we mapped and measured a suite of variables describing defensible space for burned and unburned structures within the perimeters of major fires from 2001 to 2010 in San Diego County to ask the following questions:

1. How much defensible space is needed to provide significant protection to homes during wildfires, and is it beneficial to have more than the legally required 30 m (100 ft)?
2. Does the amount of defensible space needed for protection depend on slope inclination?
3. What is the role of defensible space relative to other factors that influence structure loss, such as terrain, fuel type and housing density?

Methods

Study area

The properties and structures analysed were located in San Diego County, California, USA (Fig. 1) – a topographically diverse region with a Mediterranean climate characterised by cool, wet winters and long summer droughts. Fire typically is a direct threat to structures adjacent to wildland areas. Native shrublands in southern California are extremely flammable during the late summer and fall (autumn) and when ignited, burn in high-intensity, stand-replacing crown fires. Although 500 homes on average have been lost annually since the mid-1900s (Calfire 2000), that rate has doubled since 2000. Most of these homes have burned during extreme fire weather conditions that accompany the autumn Santa Ana winds. The wildland–urban interface here includes more than 5 million homes, covering more than 28 000 km^2 (Hammer *et al.* 2007).

Property data

The data for properties to analyse came from a complete spatial database of existing residential structures and their

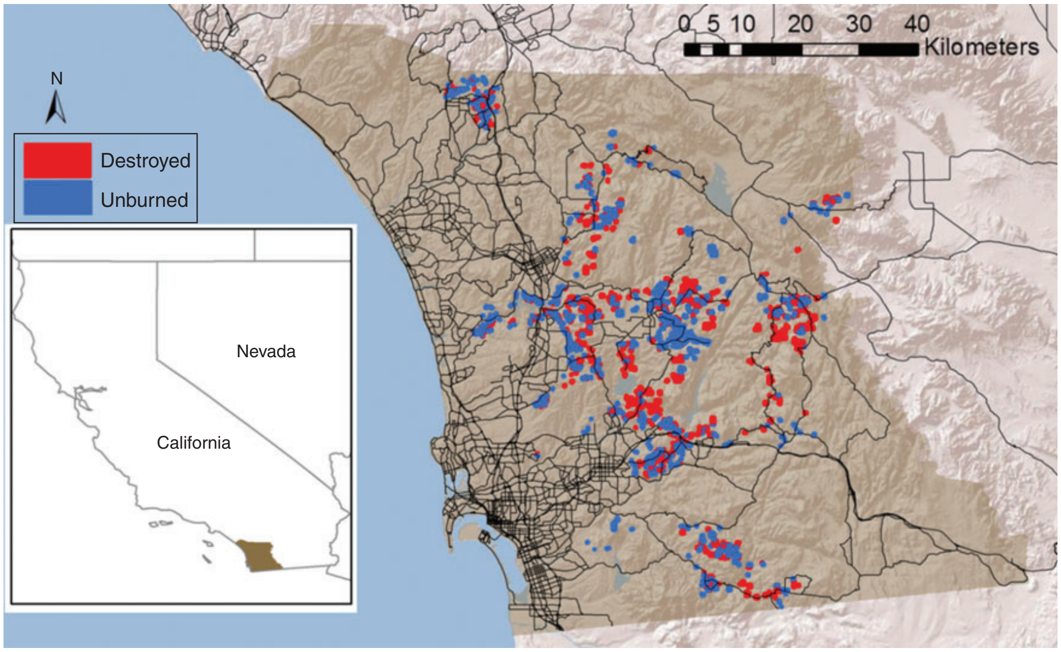

Fig. 1. Location of destroyed and unburned structures within the South Coast ecoregion of San Diego County, California, USA.

corresponding property boundaries developed for San Diego County (Syphard *et al.* 2012). This dataset included 687 869 structures, of which 4315 were completely destroyed by one of 40 major fires that occurred from 2001 to 2010. Our goal was to compare homes that were exposed to wildfire and survived with those that were exposed and destroyed. To determine exposure to fire, we only considered structures located both within a GIS layer of fire perimeters and within areas mapped as having burned at a minimum of low severity through thematic Monitoring Trends in Burn Severity produced by the USA Geological Survey and USDA Forest Service. From these data, we used a random sample algorithm in GIS software to select 1000 destroyed and 1000 unburned homes that were not adjacent to each other, to minimise any potential for spatial autocorrelation. Our final property dataset included structures that burned across eight different fires. More than 97% of these structures burned in Santa Ana wind-driven fire events (Fig. 1).

Calculating defensible space and additional explanatory variables

To estimate defensible space, we developed and explored a suite of variables relative to the distance and amount of defensible space surrounding structures, as well as the proximity of woody vegetation to the structure (Table 1). We measured these variables based on interpretation of Google Earth aerial imagery. We based our measurements on the most recent imagery before the date of the fire. In almost all cases, imagery was available for less than 1 year before the fire.

Our definition of defensible space followed the guidelines published by the California Department of Forestry and Fire Protection (Calfire 2006). 'Clearance' included all areas that were not covered by woody vegetation, including paved areas or grass. Although Google Earth prevents the identification of understorey vegetation, woody trees and shrubs were easily distinguished from grass, and our objective was to measure horizontal distances as required by Calfire rather than assess the relative flammability of different vegetation types. Trees or shrubs were allowed to be within the defensible space zone as long as they were separated by the minimum horizontal required distance, which was 3 m (10 ft) from the edge of one tree canopy to the edge of the next (Fig. 2). Although greater distances between trees or shrubs are recommended on steeper slopes, we followed the same guidelines for all properties. For all structures, we started the distance measurements by drawing lines from the centre of the four orthogonal sides of the structure that ended when they intersected anything that no longer met the requirements in the guidelines. A fair number of structures are not four sided; thus, the start of the centre point was placed at a location that approximated the farthest extent of the structure along each of four orthogonal sides.

We developed two sets of measurements of the distance of defensible space based on what is feasible for homeowners within their properties *v.* the total effective distance of defensible space. We made these two measurements because homeowners are only required to create defensible space within their own property, and this would reflect the effect of individual homeowner compliance. Therefore, even if cleared vegetation extended beyond the property line, the first set of distance measurements ended at the property boundary. The second set of measurements ignored the property boundaries and accounted for the total potential effect of treatment. For all measurements, we recorded the cover types (e.g. structure >3 m (10 ft) long, property boundary, or vegetation type) at which the distance measurements stopped (Table 1). Because property

Table 1. Defensible space variables measured for every structure

Urban veg, landscaping vegetation that was not in compliance with regulations within urban matrix; wildland veg, wildland vegetation that was not in compliance with regulations; orchard, shrub to tree-sized vegetation in rows; urban to wildland, landscaping vegetation that leads into wildland vegetation; structure, any building longer than 3 m (10 ft)

Variable	Definition
Distance defensible space within property	Measure of clearance from side of structure to property boundary calculated for four orthogonal directions from structure and averaged
Total distance defensible space	Measure of clearance from side of structure to end of clearance calculated for four orthogonal directions from structure and averaged
Cover type at end of defensible space	Type of cover encountered at end of measurement (urban veg, wildland veg, orchard, urban to wildland, structure)
Percentage clearance	Percentage of clearance calculated across the entire property
Neighbours' vegetation	Binary indicator of whether neighbours' uncleared vegetation was located within 30 m (100 ft) of the main structure
Vegetation touching structure	Number of sides on which woody vegetation touches main structure (1–4) Structure with more than 4 sides were viewed as a box and given a number between 1 and 4
Vegetation overhanging roof	Was vegetation overhanging the roof? (yes or no)

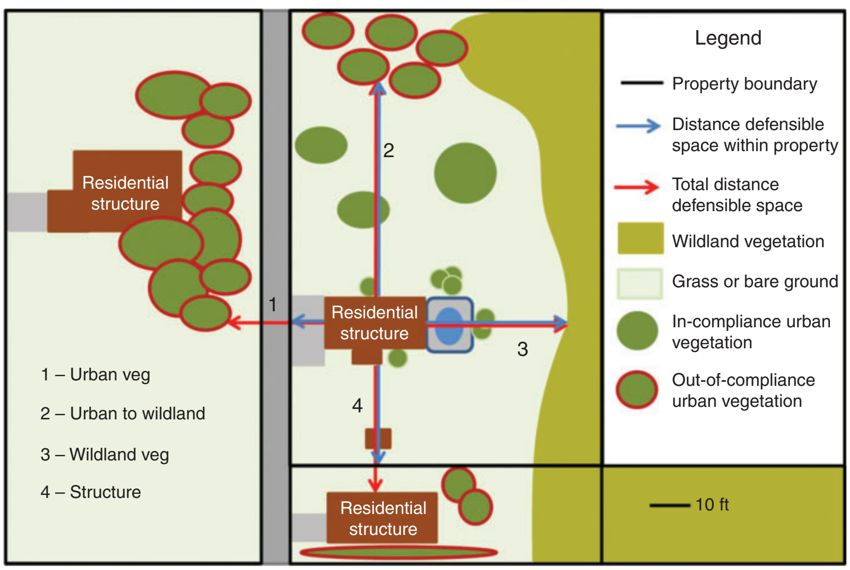

Fig. 2. Illustration of defensible space measurements. See Table 1 for full definition of terms.

owners usually can only clear vegetation on their own land, it is possible that the effectiveness of defensible space partly depends upon the actions of neighbouring homeowners. Therefore, we also recorded whether or not any neighbours' un-cleared vegetation was located within 30 m (100 ft) of the structure.

To assess the total amount of woody vegetation that can safely remain on a property and still receive significant benefits of defensible space, we calculated the total percentage of cleared land, woody vegetation and structure area across every property. This was accomplished by overlaying a grid on each property and determining the proportion of squares falling into each class. Preliminary results showed these three measurements to be highly correlated, so we only retained percentage clearance for further analysis. To evaluate the relative effect of woody vegetation directly adjacent to structures, we also calculated the number of sides of the structure with vegetation touching and recorded whether any trees were overhanging structures' roofs.

In addition to defensible space measurements, we evaluated other factors known to influence the likelihood of housing loss to fire in the region (Syphard *et al.* 2012, 2013). Using the same data as in Syphard *et al.* (2012, 2013), we extracted spatial information from continuous grids of explanatory variables for the locations of all structures in our analysis. Variables included interpolated housing density based on a 1-km search radius; percentage slope derived from a 30-m digital elevation model (DEM); Euclidean distance to nearest major and minor road and fuel type, which was based on a simple classification of US Forest Service data (Syphard *et al.* 2012), including urban, grass, shrubland and forest & woodland.

Analysis

We performed several analyses to determine whether relative differences in home protection are provided by different distances and amounts of defensible space, particularly beyond the legally required 30 m (100 ft), and to identify the effective treatment distance for homes on low and steep slopes.

Categorical analysis

For the first analysis, we divided our data into several groups to identify potential differences among specific categories of defensible space distance around structures located on shallow and steep slopes. We first sorted the full dataset of 2000 structures by slope and then split the data in the middle to create groups of homes with shallow slope and steep slope. We divided the data in half to keep the number of structures even within both groups and to avoid specifying an arbitrary number to define what constitutes shallow or steep slope. The two equal-sized subsets of data ranged from 0 to 9%, with a mean of 8% for shallow slope, and from 9 to 40%, with a mean of 27% for steep slope. Within these data subsets, we next created groups reflecting different mean distances of defensible space around structures. We also performed separate analyses based on whether defensible space measurements were calculated within the property boundary or whether measurements accounted for the total distance of defensible space.

Within all groups, we calculated the proportion of homes that were destroyed by wildfire. We performed Pearson's Chi-square tests of independence to determine whether or not the proportion of destroyed structures within groups was significantly different (Agresti 2007). We based one test on four equal-interval groups within the legally required distance of 30 m (100 ft): 0–7 m (0–25 ft), 8–15 m (26–50 ft), 16–23 m (51–75 ft) and 24–30 m (76–100 ft). A second test was based on three groups (24–30 m (75–100 ft), 31–90 m (101–300 ft) and >90 m (>300 ft) or >60 m (>200 ft)) to evaluate whether groups with mean defensible space distances >30 m (>100 ft) were significantly different from groups with <30 m (<100 ft). When defensible space distances were only measured to the property boundary, few structures had mean defensible space >90 m (>300 ft). Therefore, we used a cut-off of 60 m (200 ft) to increase the sample size in the Chi-square analysis. In addition to the Chi-square analysis, we calculated the relative risk among every successive pair of categories (Sheskin 2004). The relative risk was calculated as the ratio of proportions of burned homes within two groups of homes that had different defensible space distances.

Effective treatment analysis

In addition to comparing the relative effect of defensible space among different groups of mean distances, as described above, we also considered that the protective effect of defensible space for structures exposed to wildfire is conceptually similar to the effect of medication in producing a therapeutic response in people who are sick. In addition to pharmacological applications, treatment–response relationships have been used for radiation, herbicide, drought tolerance and ecotoxicological studies (e.g. Streibig *et al.* 1993; Cedergreen *et al.* 2005; Knezevic *et al.* 2007; Kursar *et al.* 2009). The effect produced by a drug or treatment typically varies according to the concentration or amount, often up to a point at which further increase provides no additional response. The effective treatment (ET50), therefore, is a specific concentration or exposure that produces a therapeutic response or desired effect. Here we considered the treatment to be the distance or amount of defensible space.

Using the software package DRC in R (Knezevic *et al.* 2007; Ritz and Streibig 2013), we evaluated the treatment–response relationship of defensible space in survival of structures during wildfire. To calculate the effective treatment, we fit a log-logistic model with logistic regression because we had a binary dependent variable (burned or unburned). We specified a 2-parameter model where the lower limit was fixed at 0 and the upper limit was fixed at 1. We again performed separate analyses for data subsets reflecting shallow and steep slope, as well as from measurements of defensible space taken within, or regardless of, property boundaries. We also performed analyses to find the effective treatment of percentage clearance of trees and shrubs within the property.

Multiple regression analysis

To evaluate the role of defensible space relative to other variables, we developed multiple generalised linear regression models (GLMs) (Venables and Ripley 1994). We again had a binary dependent variable (burned versus unburned), so we specified a logit link and binomial response. Although the proportion of 0s and 1s in the response may be important to consider for true prediction (King and Zeng 2001; Syphard *et al.* 2008), our objective here was solely to evaluate variable importance. We developed multiple regression models for all possible combinations of the predictor variables and used the corrected Akaike's Information Criterion (AICc) to rank models and select the best ones for each region using package MuMIn in R (R Development Core Team 2012; Burnham and Anderson 2002). We recorded all top-ranked models that had an AICc value within 2 of that of the model with lowest AICc to identify all models with empirical support. To assess variable importance, we calculated the sum of Akaike weights for all models that contained each variable. On a scale of 0–1, this metric represents the weight of evidence that models containing the variable in question are the best model (Burnham and Anderson 2002). The distance of defensible space measured within property boundaries was highly correlated with the distance of defensible space measured beyond property boundaries ($r = 0.82$), so we developed two separate analyses – one using variables measured only within the property boundary and the other using variables that accounted for defensible space outside of the property boundary as well as the potential effect of neighbours having uncleared vegetation within 30 m (100 ft) of the structure. A test to avoid multicollinearity showed all other variables within each multiple regression analysis to be uncorrelated ($r < 0.5$).

Surrounding matrix

To assess whether the proportion of destroyed structures varied according to their surrounding matrix, we summarised the most common cover type at the end of defensible space measurements (descriptions in Table 1) for all structures. These summaries

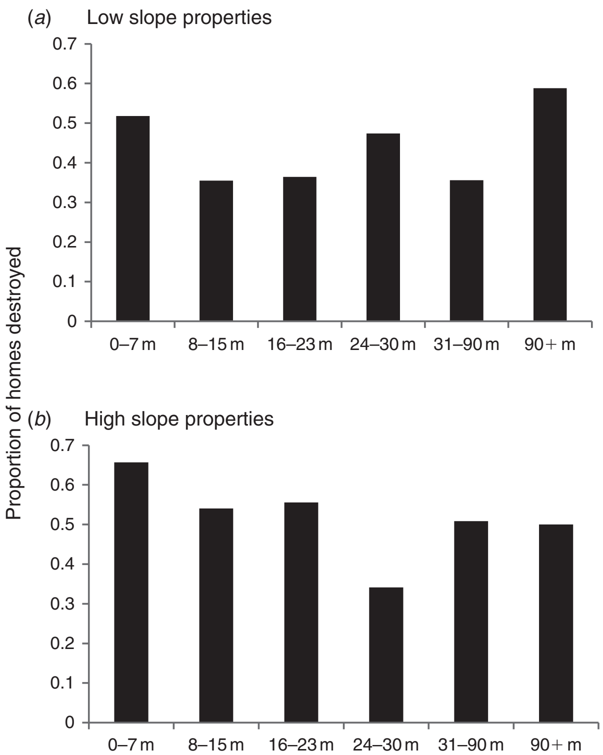

Fig. 3. Proportion of destroyed homes grouped by distances of defensible space based upon total distance of clearance within property boundary, for structures on (*a*) shallow slopes (mean 8%) and (*b*) steep slopes (mean 27%).

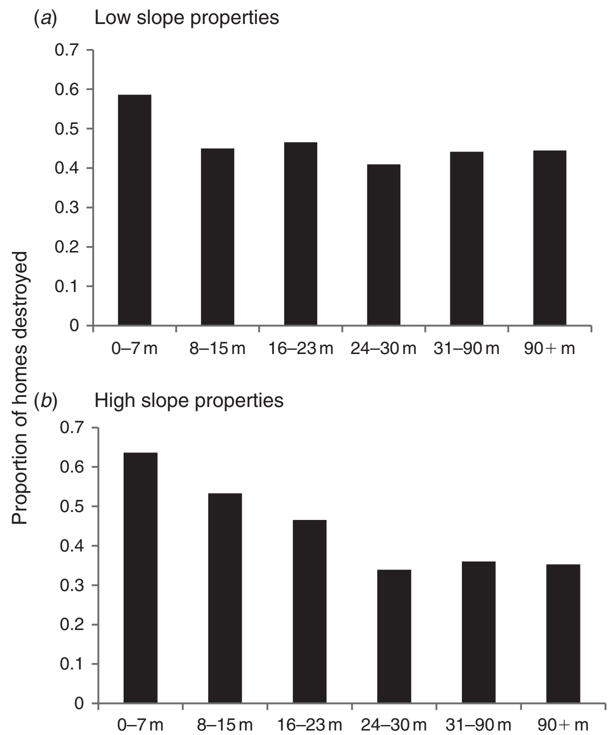

Fig. 4. Proportion of destroyed homes grouped by distances of defensible space based upon total distance of clearance regardless of property boundary, for structures on (*a*) shallow slopes (mean 8%) and (*b*) steep slopes (mean 27%).

were based on the majority surrounding cover type from the four orthogonal sides of the structure. We also noted cases in which there was a tie (e.g. two sides were urban vegetation and two sides were structures).

Results

Categorical analysis

When the distance of defensible space was measured both 'only within property boundaries' (Fig. 3) and 'regardless of property boundaries' (Fig. 4), the Chi-square test showed a significant difference ($P < 0.001$) in the proportion of destroyed structures among the four equal-interval groups of distance ranging from 0 to 30 m (0–100 ft). This relationship was consistent on both shallow-slope and steep-slope properties, although the relative risk analysis showed considerable variation among classes (Table 2) There was a steadily decreasing proportion of destroyed structures at greater distances of defensible space up to 30 m (100 ft) on the steep-slope structures with defensible space measured regardless of property boundaries (Fig. 4*b*). Otherwise, the biggest difference in proportion of destroyed structures occurred between 0 and 7 m (0–25 ft) and 8–15 m (26–50 ft) (Figs 3*a–b*, 4*a*).

When the distance of defensible space was measured in intervals from 24 m (75 ft) and beyond, the Chi-square test showed no significant difference among groups ($P = 0.96$ for shallow-slope properties and $P = 0.74$ for steep-slope properties) (Figs 3, 4), although again, the relative risk analysis showed considerable variation (Table 2).There was a slight increase in the proportion of homes destroyed at longer distance intervals when the defensible space was measured only to the property boundaries (Fig. 3*a–b*). This slight increase is less apparent when distances were measured regardless of boundaries (Fig. 4*a–b*).

The relative risk calculations showed that the ratio of proportions was generally more variable among successive pairs when the distances were measured within property boundaries (Table 2). For these calculations, the risk of a structure being destroyed was significantly lower when the defensible space distance was 8–15 m (25–50 ft) compared to 0–7 m (0–25 ft) on both shallow- and steep-slope properties. On the steep-slope properties, there was an additional reduction of risk when comparing 24–30 m (75–100 ft) to 16–23 m (50–75 ft). However, the risk of a home being destroyed was slightly significantly higher when there was 31–90 m (101–225 ft) compared to 16–23 m (50–75 ft). For distances that were measured regardless of property boundary (total clearance), the only significant differences in risk of burning were a reduction in risk for 8–15 m (25–50 ft) compared to 0–7 m (0–25 ft).

Table 2. Number of burned and unburned structures within defensible space distance categories (m), their relative risk and significance
A relative risk of 1 indicates no difference; <1 means the chance of a structure burning is less than the other group; >1 means the chance is higher than the other group. The relative risk is calculated for pairs that include the existing row and the row above. Confidence intervals are in parentheses

	Distance within property				Total distance			
	Burned	Unburned	Relative risk	*P*	Burned	Unburned	Relative risk	*P*
Shallow slope								
0–7	200	186			162	114		
8–15	109	198	0.69 (0.12)	<0.001	108	132	0.77	0.002
16–23	51	89	1.03 (0.30)	0.850	78	90	1.03	0.770

24–30	29	56	0.61 (0.17)	0.004	26	50	0.73	0.080
31–	29	28	1.49 (0.48)	0.050	39	68	1.06	0.760
60 or 90+	5	5	0.98 (0.47)	0.950	4	8	0.91	0.830

Table 3. Effective treatment results reflecting the distance (in metres, with feet in parentheses) and percentage clearance within properties that provided significant improvement in structure survival during wildfires
The property mean is the average distance of defensible space or percentage clearance that was calculated on the properties before the wildfires and provides a means to compare the effective treatment result to the actual amount on the properties

	All parcels effective treatment ($n = 2000$)	Parcel mean	Shallow slope (mean 8%) effective treatment ($n = 1000$)	Parcel mean	Steep slope (mean 27%) effective treatment ($n = 1000$)	Parcel mean
Defensible space within parcel	10 (33)	13 (44)	4 (13)	14 (45)	25 (82)	11 (35)
Total distance defensible space	10 (32)	19 (63)	5 (16)	20 (67)	20 (65)	18 (58)
Mean percentage clearance on property	36	48	31	51	37	35

Effective treatment analysis

Analysis of the treatment–response relationships among defensible space and structures that survived wildfire showed that, when all structures are considered together, the mean actual defensible space that existed around structures before the fires was longer than the calculated effective treatment (Table 3). Regardless of whether the defensible space was measured within or beyond property boundaries, the estimated effective treatment of defensible space was nearly the same at 10 m (32–33 ft).

The effective treatment distance was much shorter for structures on shallow slopes (4–5 m (13–16 ft)) than for structures on steep slopes (20–25 m (65–82 ft)), but in all cases was <30 m (<100 ft). Although longer distances of defensible space were calculated as effective on steeper slopes, these structures actually had shorter mean distances of defensible space around their properties than structures on low slopes (Table 3).

The calculated effective treatment of the mean percentage clearance on properties was 36% for all properties, 31% for structures on shallow slopes and 37% for structures on steep slopes (Table 3). In total, the properties all had higher actual percentage clearance on their property than was calculated to be effective. However, this mainly reflects the shallow-slope properties, as those structures on steep slopes had less clearance than the effective treatment.

Multiple regression analysis

When defensible space was measured only to the property boundaries, it was not included in the best model, according to the all-subsets multiple regression analysis (Table 4). However, it was included in the best model when factoring in the distance of defensible space measured beyond property boundaries (Table 5). In both multiple regression analyses, low housing density and shorter distances to major roads were ranked as the most important variables according to their Akaike weights. Slope and surrounding fuel type were also in both of the best models as well as other measures of defensible space, including the percentage clearance on property and whether vegetation was overhanging the structure's roof. The number of sides in which vegetation was touching the structure was included in the best model when defensible space was only measured to the property boundary. The total explained deviance for the multiple regression models was low (12–13%) for both analyses.

Table 4. Results of multiple regression models of destroyed homes using all possible variable combinations and corrected Akaike's Information Criterion (AICc)

Includes variables measured within property boundary only. Top-ranked models include all those ($n = 12$) with AICc within 2 of the model with the lowest AICc. Relative variable importance is the sum of 'Akaike weights' over all models including the explanatory variable

Variable in order of importance	Relative variable importance	Model-averaged coefficient	Number inclusions in top-ranked models
Housing density	1	−0.003	12
Distance to major road	1	−0.0005	12
Percentage clearance	1	−0.02	12
Slope	1	0.03	12

Fuel type	0.67	Factor	9
Vegetation touch structure	0.49	0.07	6
Distance defensible space within property	0.45	−0.0002	5
South-westness	0.36	−0.0007	3
Distance to minor road	0.28	−0.0002	1
D^2 of top-ranked model			0.123

Table 5. Results of multiple regression models of destroyed homes using all possible variable combinations and corrected Akaike's Information Criterion (AICc)

Includes variables measured beyond property boundary. Top-ranked models include all those ($n = 6$) with AICc within 2 of the model with the lowest AICc. Relative variable importance is the sum of 'Akaike weights' over all models including the explanatory variable

Variable in order of importance	Relative variable importance	Model-averaged coefficient	Number inclusions in top-ranked models
Housing density	1	−0.003	6
Distance to major road	1	−0.0005	6
Total distance defensible space	1	−0.004	6
Percentage clearance	1	−0.01	6
Vegetation overhang roof	0.99	0.4	6
Slope	0.99	0.03	6
Fuel type	0.86	Factor	4
South-westness	0.42	−0.0009	2
Distance to minor road	0.36	−0.0009	2
Neighbours' vegetation	0.27	0.08	1
Vegetation touch structure	0.27	0.18	1
D^2 of top-ranked model			0.125

Surrounding matrix

The cover type that most frequently surrounded the structures at the end of the defensible space measurements was urban vegetation, followed by urban vegetation leading into wildland vegetation, and wildland vegetation (Fig. 5). Many structures were equally surrounded by different cover types. There were no significant differences in the proportion of structures destroyed depending on the surrounding cover type. However, a disproportionately large proportion of structures burned (28 *v.* 9% unburned) when they were surrounded by urban vegetation that extended straight into wildland vegetation.

Discussion

For homes that burned in southern Californian urban areas adjacent to non-forested ecosystems, most burned in high-intensity Santa Ana wind-driven wildfires and defensible space increased the likelihood of structure survival during wildfire. The most effective treatment distance varied between 5 and 20 m (16–58 ft), depending on slope and how the defensible space was measured, but distances longer than 30 m (100 ft) provided no significant additional benefit. Structures on steeper slopes benefited from more defensible space than structures on shallow slopes, but the effective treatment was still less than 30 m (100 ft). The steepest overall decline in destroyed structures occurred when mean defensible space increased from 0–7 m (0–25 ft) to 8–15 m (26–50 ft). That, along with the multiple regression results showing the significance of vegetation touching or overhanging the structure, suggests it is most critical to modify vegetation immediately adjacent to the house, and to move outward from there. Similarly, vegetation overhanging the structure was also strongly correlated with structure loss in Australia (Leonard *et al.* 2009).

In terms of fuel modification, the multiple regression models also showed that the percentage of clearance was just as, or more important than, the linear distance of defensible space.

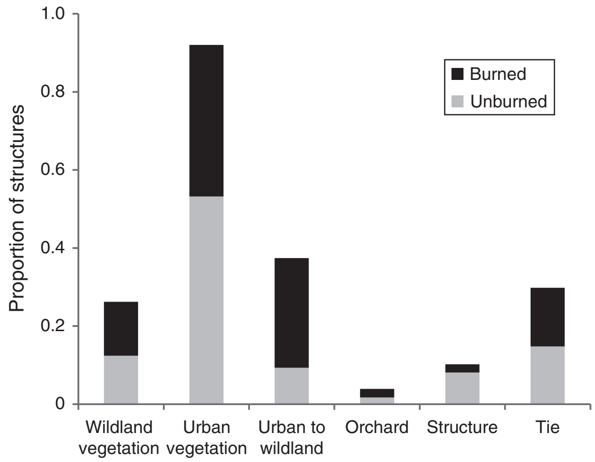

Fig. 5. Proportion of destroyed and unburned structures based on the primary surrounding cover type at the end of defensible space measurements. There were no significant differences in the proportion of burned and unburned structures within cover types ($P = 0.14$). Cover types are defined in Table 1.

However, as with defensible space, percentage clearance did not need to be draconian to be effective. Even on steep slopes, the effective percentage clearance needed on the property was <40%, with no significant advantage beyond that. Although these steep-slope structures benefited more from clearance, they tended to have less clearance than the effective amount, which may be why slope was such an important variable in the multiple regression models. Shallow-slope structures, in contrast, had more clearance on average than was calculated to be effective, suggesting these property owners do not need to modify their behaviours as much relative to people living on steep slopes.

Although the term 'clearance' is often used interchangeably with defensible space, this term is incorrect when misinterpreted to mean clearing all vegetation, and our results underline this difference. The idea behind defensible space is to reduce the continuity of fuels through maintenance of certain distances among trees and shrubs. Although we could not identify the vertical profile of fuels through Google Earth imagery, the fact that at least 60% of the horizontal woody vegetative cover can remain on the property with significant protective effects demonstrates the importance of distinguishing defensible space from complete vegetation removal. Thus, we suggest the term 'clearance' be replaced with 'fuel treatment' as a better way of communicating fire hazard reduction needs to home owners.

The percentage cover of woody shrubs and trees was not evenly distributed across properties, and we did not collect data describing how the cover was distributed. Considering the importance of defensible space and vegetation modification immediately adjacent to the structure, it should follow that actions to reduce cover should also be focussed in close proximity to the structure. The hazard of vegetation near the structure has apparently been recognised for some time (Foote *et al.* 1991; Ramsey and McArthur 1994), but it is not stressed enough, and rarely falls within the scope of defensible space guidelines or ordinances.

In addition to the importance of vegetation overhanging or touching the structure, it is important to understand that ornamental vegetation may be just as, if not more, dangerous than native vegetation in southern California. Although the results showed no significant differences in the cover types in the surrounding matrix, there was a disproportionately large number of structures destroyed (28% burned *v.* 9% unburned) when ornamental vegetation on the property led directly into the wildland. Ornamental vegetation may produce highly flammable litter (Ganteaume *et al.* 2013) or may be particularly dangerous after a drought when it is dry, or has not been maintained, and species of conifer, juniper, cypress, eucalypt, *Acacia* and palm have been present in the properties of many structures that have been destroyed (Franklin 1996). Nevertheless, ornamental vegetation is allowed to be included as defensible space in many codes and ordinances (Haines *et al.* 2008).

One reason that longer defensible space distances did not significantly increase structure protection may be that most homes are not destroyed by the direct ignition of the fire front but rather due to ember-ignited spot fires, sometimes from fire brands carried as far as several km away. Although embers decay with distance, the difference between 30 and 90 m (100 and 300 ft) may be small relative to the distance embers travel under the severe wind conditions that were present at the time of the fires. The ignitability of whatever the embers land on, particularly adjacent to the house, is therefore most critical for propagating the fire within the property or igniting the home (Cohen 1999; Maranghides and Mell 2009).

Aside from roofing or home construction materials and vegetation immediately adjacent to structures (Quarles *et al.* 2010; Keeley *et al.* 2013), the flammability of the vegetation in the property may also play a role. Large, cleared swaths of land are likely occupied at least in part by exotic annual grasses that are highly ignitable for much of the year. Conversion of woody shrubs with higher moisture content into low-fuel-volume grasslands could potentially increase fire risk in some situations by increasing the ignitability of the fuel; and if the vegetation between a structure and a fire is not readily combustible, it could protect the structure by absorbing heat flux and filtering fire brands (Wilson and Ferguson 1986).

The slight increase in proportion of structures destroyed with longer distances of defensible space within parcel boundaries was surprising. However, that increase was not significant in the Chi-square analysis, although there were some significant differences in the pairwise relative risk analysis. Nevertheless, the largest significant effect of defensible space was between the categories of 0–7 m (0–25 ft) to 8–15 m (26–50 ft), and it may be that differences in categories beyond these distances are not highly meaningful or reflect an artefact of the definition of distance categories. These relationships at longer distances are likely also weak compared to the effect of other variables operating at a landscape scale. Although the categorical analysis allowed us to answer questions relative to legal requirements and specific distances, the effective treatment analysis was important for identifying thresholds in the continuous variable.

The multiple regression models showed that landscape factors such as low housing density and longer distances to major roads were more important than distance of defensible space for explaining structure destruction, and the importance of

these variables is consistent with previous studies (Syphard *et al.* 2012, 2013), despite the smaller spatial extent studied here. Whereas this study used an unburned control group exposed to the same fires as the destroyed structures, previous studies accounted for structures across entire landscapes. The likelihood of a fire destroying a home is actually a result of two major components: the first is the likelihood that there will be a fire, and the second is the likelihood that a structure will burn in that fire. In this study, we only focussed on structure loss given the presence of a fire, and the total explained variation for the multiple regression models was quite low at ~12%. However, when the entire landscape was accounted for in the total likelihood of structure destruction, the explained variation of housing density alone was >30% (Syphard *et al.* 2012). One reason for the relationship between low housing density and structure destruction is that structures are embedded within a matrix of wildland fuel that leads to greater overall exposure, which is consistent with Australian research that showed a linear decrease of structure loss with increased distance to forest (Chen and McAneney 2004). That research, however, only focussed on distance to wildland boundaries and did not quantify variability in defensible space or ornamental vegetation immediately surrounding structures. Thus, fire safety is important to consider at multiple scales and for multiple variables, which will ultimately require the cooperation of multiple stakeholders.

Conclusions

Structure loss to wildfire is clearly a complicated function of many biophysical, human and spatial factors (Keeley *et al.* 2009; Syphard *et al.* 2012). For such a large sample size, we were unable to account for home construction materials, but this is also well understood to be a major factor, with older homes and wooden roofs being most vulnerable (Franklin 1996; Cohen 1999, 2000). In terms of actionable measures to reduce fire risk, this study shows a clear role for defensible space up to 30 m (100 ft). Although the effective distances were on average much shorter than 30 m (100 ft), we recognise that additional distance may be necessary to provide sufficient protection to firefighters, which we did not address in this study (Cheney *et al.* 2001). In contrast, the data in this study do not support defensible space beyond 30 m (100 ft), even for structures on steep slopes. In addition to the fact that longer distances did not contribute significant additional benefit, excessive vegetation clearance presents a clear detriment to natural habitat and ecological resources. Results here suggest the best actions a homeowner can take are to reduce percentage cover up to 40% immediately adjacent to the structure and to ensure that vegetation does not overhang or touch the structure.

In addition to defensible space, this study also underlines the potential importance of land use planning to develop communities that are fire safe in the long term, in particular through their reduction to exposure to wildfire in the first place. Localised subdivision decisions emphasising infill-type development patterns may significantly reduce fire risk in the future, in addition to minimising habitat loss and fragmentation (Syphard *et al.* 2013). This study was conducted in southern California, which has some of the worst fire weather in the world and many properties surrounded by large, flammable exotic trees. Therefore, recommendations here should apply to other non-forested ecosystems as well as many forested regions.

Abstract. Recent regional mountain pine beetle (MPB) outbreaks have generated unprecedented tree mortality across the fire-prone landscapes of western North American forests and could potentially modify fire severity and postfire ecological effects. In 2012, 2013, and 2014, three fires burned through high mortality, gray-phase lodgepole pine-dominated forests in the plateau regions of central interior British Columbia, Canada, providing an opportunity to test for interactions between MPB outbreaks and wildfires. We inventoried 63 plots that spanned gradients of outbreak severity, fire severity, and burning conditions in a wilderness setting. Our objective was to evaluate the influence of outbreak severity on fire severity by assessing typical first-order fire effects as well as legacy structure related to the consumption of woody biomass on snags/trees. We found no evidence of a relationship between outbreak severity and fire severity for six of seven first-order fire effects, with the exception of deep charring. We found evidence that legacy structure in the form of consumed branch structure and deep char development had greater odds of occurrence on MPB-killed snags compared to trees killed during wildfire. Our results indicate two key findings. First, fire severity as it relates to most first-order fire effects measures is not influenced by outbreak severity, instead it is more strongly influenced by the interaction of fuels, weather, and topography during fire events. Second, our results highlight how the interaction between outbreak severity and fire severity alters postfire structural legacies and their functional attributes, which could have important ecosystem implications.

Key words: deep char; *Dendroctonous ponderosae*; legacy structure; mountain pine beetle; *Pinus contorta* var. *latifolia*; short-interval disturbances; snags; sub-boreal; wildfire.

Introduction

Forest ecosystems across western North America are increasingly experiencing ecological disturbances from wildfires burning through landscapes with abundant tree mortality from insect outbreaks. The recent mountain pine beetle (*Dendroctonous ponderosae*, hereafter MPB) outbreaks circa the 1990s and 2000s are responsible for tree mortality in forests that span over 25 million hectares across the western United States and Canada (Raffa et al. 2008, Bentz et al. 2010, Meddens et al. 2012), and British Columbia (BC) houses nearly 20 million of those hectares (Axelson et al. 2009, Perrakis et al. 2014). The spatial extent and high mortality rates associated with recent outbreaks alter standing woody fuels in affected forests from mostly alive to mostly dead, which changes the composition of the fuel profile and raises concerns for increased fire severity (Hicke et al. 2012, Jenkins et al. 2012). The overlap between MPB outbreak and wildfire disturbances that recur within a short time interval may lead to linked effects in which the first event alters the extent, severity, or probability of occurrence for the second event (Kulakowski and Veblen 2007, Simard et al. 2011). Previous field-based studies have investigated interactions of short-interval MPB-fire disturbances with variable levels of lodgepole pine (*Pinus contorta* var. *latifolia*) mortality in montane regions of the western United States (Harvey et al. 2014*a*, *b*, Agne et al. 2016) and found fire severity to be either weakly linked or unrelated to outbreak severity. However, the magnitude of the MPB outbreaks in BC far exceeds the conditions seen in the western United States (Raffa et al. 2008) and the biophysical environment differs from earlier studies (Harvey et al. 2014*b*, Agne et al. 2016), such that further investigation is required to understand the implications of fire burning through BC's MPB-affected forests.

The changes in fuel profiles from MPB outbreaks and subsequent stand breakdown have raised concerns among land managers for altered fire behavior and potential changes in subsequent fire severity that could generate burning conditions that are more hazardous and more severe than from fire burning through stands of live trees. Severe tree mortality alters the configuration, continuity, and moisture content of fuels over time as stands break down (i.e., needle loss, branch breakage, sloughing bark, snag fall), all of which may influence fire behavior (Page and Jenkins 2007, Hicke et al. 2012). Dry, dead fuels ignite more quickly (Stockstad 1979) and at lower temperatures (Stockstad 1975) compared to live fuels. When these dead fuels are coarse, they are prone to smoldering (Brown et al. 2003), which often extends burning time beyond the initial flaming front (Alexander 1982), thus allowing for dry dead fuels to burn longer and have more biomass consumed (Brown et al. 2003, Hyde et al. 2011) that could alter the structural legacies that persist postfire. The only known empirical study examining the effects of altered fuel profiles on fire behavior found that spread rates increased through red-phase outbreak conditions in lodgepole pine forests in BC (Perrakis et al. 2014). Simulation models posit crown fire to increase during the red phase of the outbreaks, 1–3 years postattack, and then decline as needles are dropped from the canopy and snags transition to the gray-phase of the outbreaks, 3–10 years postattack (Hicke et al. 2012). Alternative models suggest a shift from active crown fire during the red phase to passive crown fire in the gray phase (Klutsch et al. 2011, Simard et al. 2011, Schoennagel et al. 2012) that could result in more biomass consumption and simplification of the legacy structure of snags.

Retrospective data that evaluate fire effects to characterize fire severity provide a complement to measures of fire behavior for understanding interactions between MPB outbreak and wildfire. Fire severity is often characterized by measurements of first-order fire effects (Reinhardt et al. 2001, Ryan and Elliot 2005) and refers to the amount of immediate ecological change associated with vegetation mortality and biomass loss from fire (Keeley 2009). Retrospective studies on MPB-fire interactions are two pronged either using remotely sensed data (e.g., satellite imagery) to quantify the amount of change between prefire and postfire conditions at coarser resolutions, or field studies that measure fire effects on the ground to characterize fire severity at finer scale resolutions. Existing remote sensing studies have shown that outbreak severity does not increase fire likelihood (Meigs et al. 2015), fire severity (Meigs et al. 2016), or area burned (Hart et al. 2015) for forests in the western United States.

Field studies can capture subtleties that may be absent in remote sensing studies and have found that the relationship between outbreak severity and fire severity varies across the western United States. These studies have focused on subalpine lodgepole pine forests (Harvey et al. 2014*a*, Agne et al. 2016) and forests dominated by subalpine fir (*Abies lasiocarpa*) but with substantial basal area of lodgepole pine (Harvey et al. 2014*b*) across topographically complex landscapes. Generally, these studies have suggested that gray-phase outbreak severity results in decreased fire severity (Harvey et al. 2014*a*, Agne et al. 2016), or limited to no change in fire severity (Harvey et al. 2014*b*, Agne et al. 2016)—with the exception of deep char, a metric of fire severity that showed a consistently positive relationship with severity of MPB outbreaks (Harvey et al. 2014*b*). Some measures of fire severity increased under extreme fire weather and were attributed to burning conditions, including deep char (Harvey et al. 2014*b*), suggesting that prefire beetle outbreak and burning conditions contribute to deep charring on wood. Deep char is generated through incomplete combustion of deadwood often from long, smoldering burns (Bird et al. 2015) that result in more biomass consumption and is visually distinct compared to scorch that is generated from flaming combustion and typically occurs on trees that are alive at the time of fire (Campbell et al. 2007). Deep char is distinguished by its iridescent black with patterning like the scales of alligator skin in contrast to the matte black, dusty appearance of scorch. Deep charring on trees changes the structure and function of the postfire landscape (Campbell et al. 2007, Donato et al. 2016) by altering structural legacies and has been clearly recognized as an important severity metric when examined in areas of high-severity reburns (fire + fire; Donato et al. 2016). However, the deep char effect, and the altered structural legacy it contributes to the postfire landscape, has largely been ignored in the context of insect outbreak and wildfire interactions.

Here, we examine the effect of gray-phase outbreak severity on fire severity for lodgepole pine-dominated forests with high prefire mortality rates, in central interior BC. Our objective was to evaluate the influence of outbreak severity on fire severity by assessing first-order fire effects after three recent wildfires that burned in 2012, 2013, and 2014. We wanted to (1) ascertain whether the extensive MPB-induced tree mortality that spans the sub-boreal forests of BC responds similarly in terms of first-order fire effects to forests that have burned and been studied in the western conterminous United States and (2) expand understanding and recognition of how postfire legacies (e.g., snags) can be affected by MPB outbreaks. We anticipated first-order fire effects (e.g., scorch/char height and area on trees, surface char, exposed mineral soil) would be unaffected by the severity of the outbreaks and primarily driven by fire weather, based on previous findings (Harvey et al. 2014*a*, *b*, Agne et al. 2016). In the context of structural legacies, we anticipated that snags killed by the MPB outbreak a decade prior to fire would burn longer, through smoldering combustion that would consume more wood biomass and lead to consistent development of deep char. We also predicted the interaction between outbreak severity and fire would reduce the structural complexity on snags, due to the potential extended duration of smoldering combustion in addition to prefire stand breakdown where MPB-killed trees experience needle loss, branch breakage, and shedding of bark. In contrast, the legacies of trees that were alive at time of fire and then killed by the wildfire (i.e., fire-killed) would have less deep char and retain much more structural complexity.

Methods

Study area

We conducted our field sampling across three fires that burned in 2012, 2013, and 2014 in Tweedsmuir and Entiako Provincial Parks, which are situated in the sub-boreal forests on the southern portion of the Nechako Plateau in BC (Fig. 1). The study area has a mean monthly maximum temperature of 8.5°C (range −3.3 to 19.8°C), a mean monthly nighttime temperature of −2.8°C (range −11.9 to 6.7°C), and total annual precipitation of 507.6 mm with a monthly mean of 42.3 mm (range 22.7–60.8 mm), based on the monthly means from the 1981–2010 climate normals (Abatzoglou et al. 2018). Precipitation accumulates as snow in the winter and rain during the remainder of the year. Although it rains through the summer (Abatzoglou et al. 2018), there are weeks with no rain that are associated with persistent high-pressure ridges (Nash and Johnson 1996). Within the fire perimeters, landscapes are associated with the Sub-Boreal Pine Spruce and Sub-Boreal Spruce biogeoclimatic zones (Meidinger and Pojar 1991), and lodgepole pine is the dominant canopy species (Fig. 1; BCMFLNRO 2012). Moisture gradients dictate composition, structure, and disturbance history, based on historical reconstructions from surrounding areas (Steventon 2001, Francis et al. 2002) and stand age distributions (Delong 1998). Within our fire perimeters, climax lodgepole pine inhabits the driest end of the moisture gradient, seral lodgepole pine persists with mean fire returns of 100–175 years, and climax spruce (*Picea engelmannii* × *glauca*) occupies pockets with high moisture levels such as riparian zones or through succession with long intervals of no fire (Parminter 1992). The landscape is gently rolling with low topographic relief, minimizing the topographic influence on fire behavior. Elevation ranges from 850 to 1300 m, in the region.

Field sampling occurred within three wildfire perimeters (Fig. 1). All fires were lightning ignited and received minimal to no suppression activities due to wilderness management

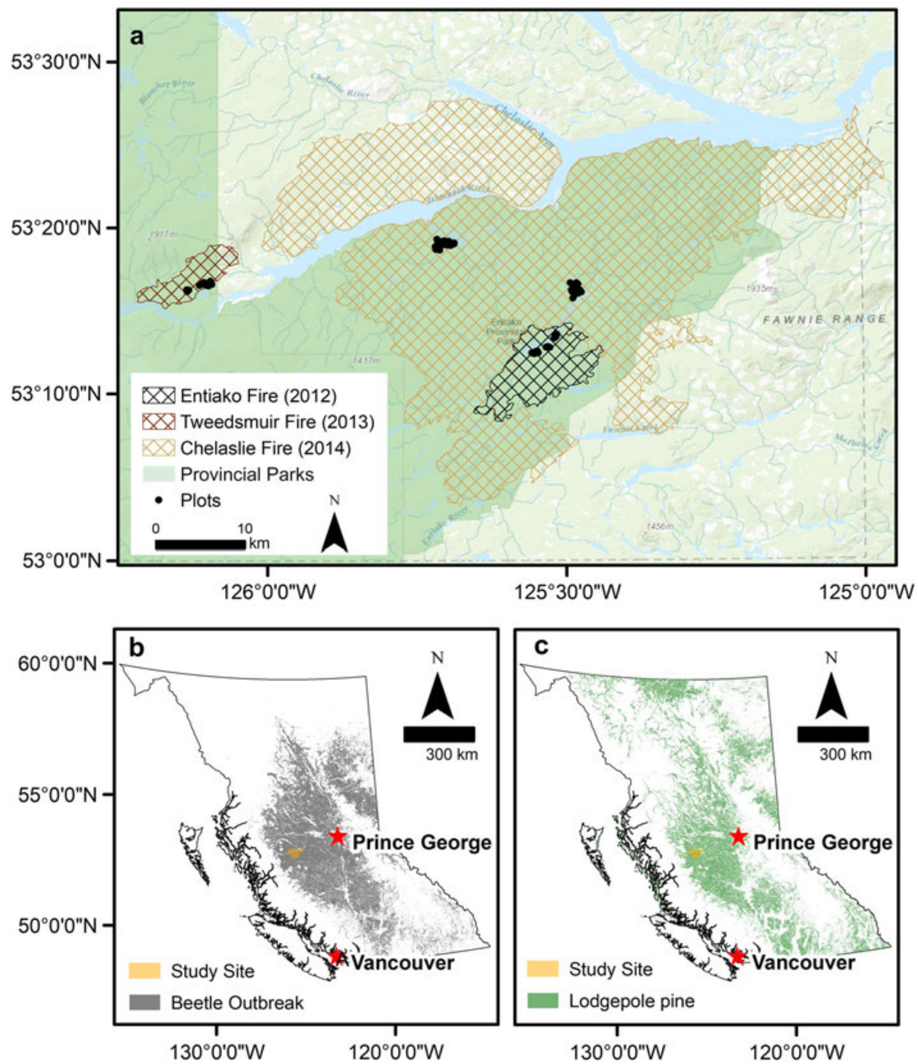

Fig. 1. Maps of the study area, MPB outbreak extent, and lodgepole pine range. Fire perimeters for three study fires that burned in 2012 (Entiako Fire; 7459 ha), 2013 (Tweedsmuir Fire; 3354 ha), and 2014 (Chelaslie Fire; 133,000 ha). (a) Provincial park boundaries are displayed as protected areas and overlaid with fire perimeters. Panel (b) shows the extent of the MPB outbreak across British Columbia based on aerial survey data from 2000 to 2011 (BCMFLNRO 2016). Panel (c) shows the estimated range of lodgepole pine across British Columbia.

objectives for the parks (Rob Krause and Mike Pritchard, *personal communication*). The Entiako Lake fire (R10171) burned 7450 ha from 3 August 2012 to 22 September 2012 (BCWS 2016). The Tweedsmuir fire (R10252) burned 3600 ha from 9 September 2013 to 16 September 2013 (BCWS 2016). The Chelaslie River fire (R10070) burned 133,100 ha from 8 July 2014 to 26 October 2014 (BCWS 2016). All fires burned through gray-phase outbreak conditions of varying severity. The recent MPB outbreaks, circa 1990s and 2000s, peaked in the region around 2003/2004 and have affected forests across much of the province (Fig. 1). MPB activity has declined since 2006 (Wulder et al. 2009). The lag between peak outbreak and the three wildfires was about a decade, with standing dead trees (snags) beginning to transition to coarse woody debris in some outbreak-affected stands. The location of fires within parks provided a rare opportunity to study MPB-fire interactions without the interference of active management (i.e., harvest/salvage activity, fire management/suppression).

Sampling design

Field sampling occurred from late June through August 2016, allowing us to characterize a snapshot of early successional forest communities from two to four years postfire. The study area has no road access, and sampling was limited by hiking and boating distances from three remote cabins within the parks (Fig. 1). Study plots were distributed through forest dominated by lodgepole pine. We selected plots based on a two-pronged approach including an a priori site selection using digital data, followed by verification and final selection in the field. A priori digital data included aerial survey data of MPB outbreak severity (BCMFLNRO 2016), burn severity maps generated from the differenced normalized burn ratio (dNBR; Eidenshink et al. 2007), and vegetation maps from the province's Vegetation Resource Inventory (VRI) to target areas of pure lodgepole pine (BCMFLNRO 2012). Aerial survey data for MPB outbreaks were a coarse resolution (400 m raster data products) and indicated areas within and around our study sites ranged between 50% and 100% canopy mortality (BCMFLNRO 2016). We selected from 12 to 39 plots in each study fire, depending on accessibility, for a total of 63 plots (Appendix S1: Table S1). We distributed plots across a gradient of fire severity within each fire class based on dNBR maps as low (n = 22), moderate (n = 18), and high (n = 23) that equated to light surface, severe surface, and crown fire based on our field measurements.

We visited plots on the ground for data collection. We verified canopy trees were predominantly lodgepole pine and were representative of the fire severity in the surrounding area. From the plot center location, we recorded GPS coordinates using a Garmin hand-held unit (GPSMAP 78s) and established a ten-by-ten-meter (100 m^2; 0.01 ha) survey plot, and divided it into four quadrants along the north–south and east–west axes, identified as NE, SE, SW, and NW. Within each quadrant, we placed a one-by-one-meter (1 m^2) subplot at increasing distances from the center of the plot (NE-1 m, SE-2 m, SW-3 m, and NW-4 m). Within plots, we recorded information for each live or dead tree: species, live/dead, evidence of MPB activity including exit holes and j-shaped galleries, diameter at breast height, and measures of first-order fire effects to characterize fire severity (including legacy structures) described in detail below. Within subplots, we recorded surface fire severity as first-order fire effects including duff depth, exposed mineral soil, terrestrial surface char, and litter. Measured variables at the plot and subplot resolution were used to characterize stand structure, MPB outbreak severity, fire severity and to analyze the relationship between MPB outbreaks and fire severity.

Mortality status of canopy trees and outbreak severity

We identified trees as live or dead at time of sampling and assigned a cause of death to each dead tree. We used these data to quantify MPB outbreak severity, mortality from fire, and cumulative mortality for each plot. We identified a tree's cause of death based on protocols adapted from Harvey et al. (2013, 2014*a*). We attributed each tree as most likely to have been (1) killed prefire by MPB (i.e., MPB-killed), (2) killed prefire by another agent (i.e., other-killed), (3) killed by fire (i.e., fire-killed), or (4) live postfire with no evidence of MPB activity (Table 1). We evaluated snags for MPB activity unless they were alive at time of sampling. We assessed each dead canopy tree for presence or absence of exit holes associated with adult beetles emerging from the tree (Harvey et al. 2013, 2014*a*). Then, we removed bark from each dead tree to identify galleries specific to MPB or other bark beetle species (Harvey et al. 2013, 2014*a*). We classified a tree as MPB-killed if it had the requisite exit holes and j-shaped galleries specific to MPB. While much of the prefire tree mortality present was linked to MPB, we also observed significant Ips beetle (*Ips pini*) activity, which we included as other-killed if there was no evidence of MPB. We classified a tree as other-killed if it was lacking evidence of exit holes and j-shaped galleries, but other evidence suggested death prior to fire such as no needle retention in the canopy, sloughing bark, other insect activity, and decay at the base, which is common in this system due to the moist climate (Table 1); this was a small portion of the total trees sampled (7%). We classified a tree as

Table 1. The criteria and classes used to identify a tree's cause of death for the study region in BC.

Cause of death	Description	Trees sampled (%)
Live tree	Live when sampled; green canopy; no visible beetle activity	4.67
Fire-killed	Dead when sampled; scorched bark, branches, and/or outer sapwood; no evidence of galleries or exit holes from MPB or other bark beetle activity; not highly decayed/weathered particularly at the base and in the canopy	28.95
MPB-killed	Dead when sampled; no needles remaining in the canopy; vacated mountain pine beetle (MPB) galleries in cambium with exit holes in remaining bark	59.38
Other-killed	Dead when sampled; highly decayed/weathered, no bark, missing branches; more advanced decay then MPB-killed trees; full deep char with no identifiable vacated MPB galleries	7.00
Prefire-killed: MPB-killed + Other-killed	All prefire-killed from both MPB-killed and other-killed	66.38

Notes: Methods adapted from Harvey et al. (2014*a*). Trees sampled summarize observed data from field collections.

fire-killed if it had red needles in the canopy or postfire needle drop, and no evidence of prefire MPB or other beetle activity. We estimated a general metric of prefire-killed trees as the combination of MPB-killed and other-killed (Table 1). We calculated plot-level metrics for outbreak severity as the proportion of MPB-killed trees per plot and prefire mortality as the proportion of all prefire-killed trees per plot. Pre-outbreak stand estimates were based on all trees in the plot, regardless of status.

Fire severity recorded as first-order fire effects at the plot level

We characterized fire severity with seven measures of first-order fire effects that were scaled to a plot-level metric. We measured fire effects on standing trees/snags and the terrestrial surface including: height of scorch and/or char on trees, percent cover of scorch and/or char on trees, percent deep charring on trees, litter/duff depth, proportion of remaining litter, proportion of terrestrial surface char, and proportion of exposed mineral soil. Scorch and deep char are visually distinct, scorch with a dusty, matte black appearance and deep char with an iridescent black, scale-like appearance. In some cases, snags had both areas of scorch and deep char. The height of scorch and/or deep char (hereafter scorch/char) was measured to the nearest 0.5 m on each tree with four-meter measuring sticks and converted to mean scorch height per plot. We estimated the percent area covered, as height and circumference, of scorch and/or deep char (hereafter scorch/char) and calculated a mean proportional area per plot. We inverted the mean proportion of area per plot to the proportion of unscorched area per plot for analysis. We recorded deep char for each tree as no deep char, <50% deep char, or 50–100% deep char coverage on the snag and calculated the proportion of snags with deep char for a plot-level variable. The four terrestrial surface fire effects metrics were measured in each subplot in the four quadrants of the plot. Litter/duff depth was measured as the combination of litter plus duff to the nearest millimeter in two opposing corners of each subplot and averaged to a plot-level variable. We recorded the percent of remaining litter, terrestrial surface char, and exposed mineral soil and calculated a mean for each variable from the four subplots to generate plot-level metric. Remaining litter, terrestrial surface char, and exposed mineral soil were converted to proportions for analysis purposes. Because we surveyed plots between two and four years postfire, we captured various early successional stages in postfire litter accumulation and vegetative regrowth.

Fire severity recorded as biomass consumption of legacy structure at the tree level

To characterize the effect of outbreaks and wildfires on postfire legacy structure, we categorized biomass loss on each tree based on the remaining branch structure and deep char. The remaining branch structure refers to the fine, moderate, and coarse branch structure, and it was quantified as presence or absence. A classification of absence meant that there was no remaining branch structure on the tree and no associated branches on the ground in the area of the tree/snag, which indicated that branches were consumed by fire. As described above, deep char was visually distinct from scorch and recorded as absent, <50%, or 50–100% deep char coverage on each snag. We retained these categories to assess the relationship between deep char and remaining branch structure and converted the categories to presence or absence of deep char for each tree/snag to evaluate the relationship between a tree's cause of death and deep char development.

Fire weather and topography

The Entiako, Tweedsmuir, and Chelaslie fires that provided the footprint for our study burned during three different fire seasons (2012, 2013, and 2014) across a landscape with low topographic complexity. Fires burned over a relatively long duration within each season, which allowed us to account for variability in fire weather and day-of-burn conditions (Appendix S1: Table S1). Each plot was assigned a day of burn from day-of-burn progression maps estimated from MODIS hotspot data (Parks 2014), which allowed us to assign the daily fire weather index (FWI) to each plot that was generated from the nearest weather station (Appendix S1: Table S1). The calculated FWI is a metric from the Canadian Forest Fire Weather Index System (Van Wagner 1987) that integrates temperature, relative humidity, and wind speed. We used the FWI to assign each plot a burning condition category of moderate (>13–29) or extreme (>29), based on breakpoints outlined by Alexander and De Groot (1988). All fires experienced moderate burning conditions within a portion of their perimeter; however, extreme burning conditions (FWI $\geq$ 29) only occurred in two of the three fires (2012 Entiako and 2014 Chelaslie fires; Appendix S1: Table S1). For plots, elevation fluctuated between 873 and 1043 m. Plots were relatively flat with a mean slope of 2.6° (range 0–20°). We did not pursue topography as an explanatory variable of fire severity due to the low topographic variability at our study plots.

Statistical analysis

We tested for relationships between each of the seven fire effects metrics and MPB outbreak severity at the plot level, while accounting for burning conditions. Our seven fire effects metrics served as response variables: average scorch/char height, average proportion of unscorched/uncharred area on trees, proportion of trees with deep char, litter/duff depth, proportion of remaining litter, proportion of terrestrial surface char, and proportion of exposed mineral soil. We tested the relationship of each response variable against the proportion of MPB-killed trees (our index of MPB severity) and burning conditions, which was included as a categorical variable of moderate or extreme FWI (Appendix S1: Table S1). An interaction term between burning conditions and proportion of MPB-killed trees was included in all models to assess whether observed relationships changed under different fire weather conditions. Relationships with scorch/char height and litter/duff depth were fit using linear models. The proportion of terrestrial surface char was logit-transformed and fit with a linear model. All other models in which the response variable was a proportion were analyzed with generalized linear models, and each response variable was fit with a distribution appropriate for the type and distribution of the response variable (see Appendix S1: Table S3 for distributions associated with each analysis). We also ran each model and replaced the proportion of MPB-killed trees with the proportion of prefire-killed trees, since dead trees would all be similar in terms of conditions and moisture content regardless of what killed them. The models with the proportion of prefire-killed trees demonstrated similar statistical relations to the proportion of MPB-killed trees. We report all models that were statistically significant, and we kept all fire effects models that were run with the proportion of MPB-killed trees as an explanatory variable, since these models were a more conservative estimate of MPB caused mortality.

We evaluated the effect of outbreak severity and wildfire on postfire legacy structure from tree-level fire effects of deep char and branch structure loss. We analyzed data at the tree level using two different response variables: (1) presence/absence (1/0) of branch structure on individual trees and (2) presence/absence (1/0) of deep char on individual trees. We accounted for burning conditions as a categorical variable of moderate or extreme FWI (Appendix S1: Table S1). An interaction term between burning conditions and cause of death was included in all models. We used generalized linear mixed models with a binomial distribution for presence/absence data using a logit link, and each model included the plot as a random effect and the interaction term between cause of death and burning conditions. Results are reported as probability of occurrence, and the comparison between mortality types (e.g., MPB-killed versus fire-killed) is reported as the odds ratio. Additionally, we determined whether the presence/absence of branch structure was related to the coverage of deep char on the tree. Our explanatory variable of deep char was treated as a three-level categorical variable of no deep char, <50% coverage of deep char, or 50–100% coverage of deep char on the tree, while accounting for burning conditions.

We assessed fit for all models by visually inspecting the residuals, which appeared to be adequately met. We evaluated and corrected for overdispersion in all generalized linear models and generalized linear mixed models when necessary. For our two linear models, assumptions of normality and constant variance of the residuals were checked graphically and appeared to be adequately met. We assessed the interaction term with a drop-in-deviance test. The interaction term was retained in each model regardless of statistical significance, because of the known interaction between fire weather and fuels. All statistical analyses were conducted in R statistical computing software version 3.4.4 with the stats package (R Development Team 2018). For generalized linear models, we used the function glm in the MASS package (Venables and Ripley 2002). For generalized linear mixed models, we used the function glmer in the lme4 package (Bates et al. 2015). We considered $p < 0.05$ as convincing evidence of a relationship and $P < 0.10$ as suggestive of a relationship to minimize the potential of a type II error. Data and code for analyses are available online (Talucci 2019).

Results

We collected data from 943 trees across 63 field plots with 910 lodgepole pine trees/snags and 33 spruce trees/snags. Canopy tree species were predominantly lodgepole pine with a plot mean of 96% (range across plots 63–100%; Appendix S1: Table S2). Estimated mortality from MPB was 59% of all trees sampled, and estimated prefire mortality (i.e., MPB-killed plus other-killed) was 66% of all trees sampled (Table 1). When we evaluated just lodgepole pine mortality across all 63 plots, the estimated mean for lodgepole pine killed by MPB was 63% and the estimated mean for lodgepole pine killed by all agents prior to fire (all prefire) was 70% (Appendix S1: Table S2). Cumulative mortality was estimated at 93% for lodgepole pine as a combination of prefire and fire mortality (Appendix S1: Table S2).

Effect of outbreak severity on first-order fire effects at the plot level

The effect of outbreak severity on fire severity was limited, with six of seven fire effects showing no evidence of an effect (Fig. 2, Appendix S1: Table S3). average scorch/char height, average proportion of unscorched/uncharred area on trees, litter/duff depth, proportion of remaining litter, proportion of terrestrial surface char, and proportion of exposed mineral soil showed no evidence of an effect of outbreak severity (Fig. 2, Appendix S1: Table S3). Outbreak severity did show evidence of an effect on proportion of trees with deep char. Under moderate burning conditions, the proportion of trees with deep char increased with increasing outbreak severity (Fig. 2, Appendix S1: Table S3), which held true when we substituted the proportion of prefire-killed trees for MPB-killed trees (Fig. 2, Appendix S1: Table S3). Under extreme burning conditions, the relationship between the proportion of MPB-killed trees and deep char was not statistically significant, however when we substituted the proportion of prefire-killed trees for MPB-killed trees that relationship was statistically significant (Fig. 2, Appendix S1: Table S3).

Effect of outbreak and wildfire on legacy structure

Outbreak severity and wildfire showed distinct evidence of an effect on the legacy structure of the forest, measured by biomass consumption as deep char and branch structure loss on individual trees. Both deep char development and branch structure loss had greater odds of occurrence when a tree was dead prior to fire (i.e., MPB-killed or prefire-killed) compared to being

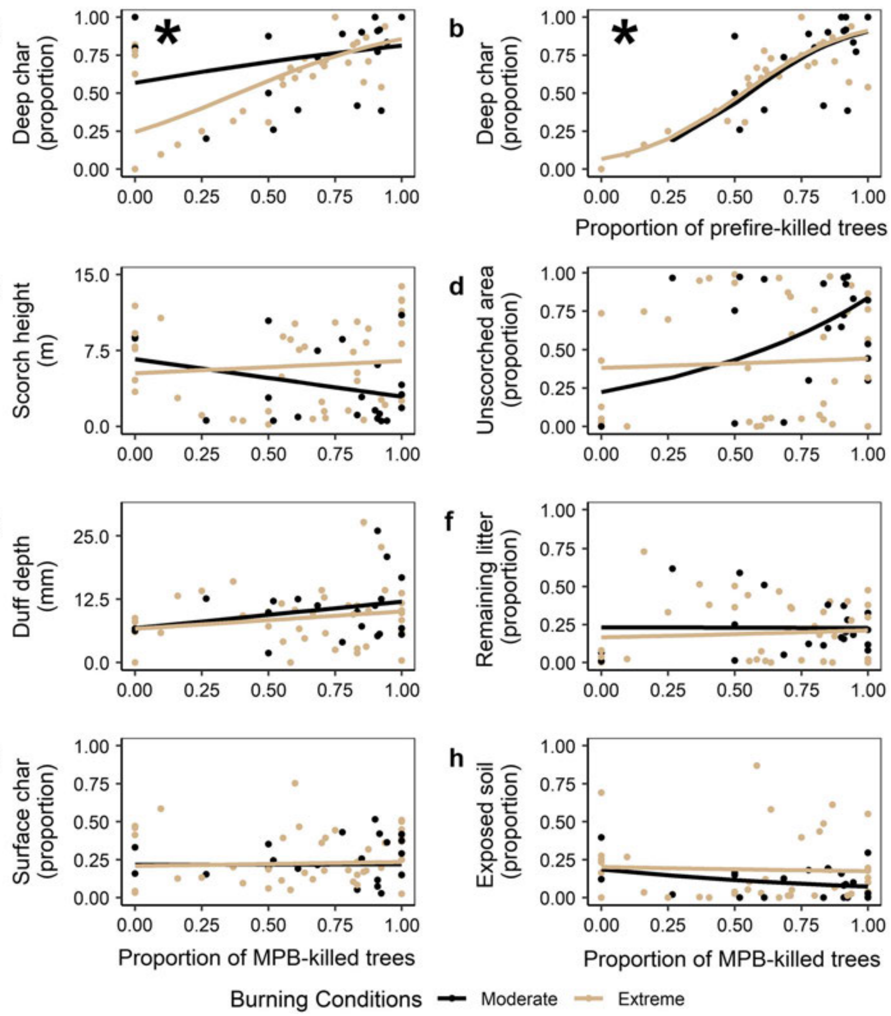

Fig. 2. The relationships between outbreak severity and seven first-order fire effects measured at the plot level: proportion of trees with deep char (a–b), average scorch/char height (c), average proportion of unscorched/uncharred area on trees (d), litter/duff depth (e), proportion of remaining litter (f), proportion of terrestrial surface char (g), and proportion of exposed mineral soil (h). Response variables are along the *y*-axis with the explanatory variable of the proportion of mountain pine beetle (MPB) killed trees or prefire-killed trees (only panel b) along the *x*-axis. Points are the raw data (n = 63 plots), and fitted lines show the estimated statistical relationship. The response variable of deep char is shown in panels a and b, and they were the only two models that indicated a strong statistical relationship (*). Response variables c–h were unrelated to outbreak severity. See Appendix S1: Table S3 for model estimates and confidence intervals.

alive at time of fire, which was consistent across both moderate and extreme burning conditions (Figs. 3, 4, Appendix S1: Table S4). Under both moderate and extreme burning conditions, a MPB-killed and prefire-killed snag had greater odds of developing deep char compared to a fire-killed tree (Figs. 3, 4, Appendix S1: Table S4). There were greater odds of branch structure being consumed on a MPB-killed and prefire-killed snag compared to a fire-killed tree under moderate conditions, and the size of that effect was slightly smaller under extreme conditions but still significant (Figs. 3, 4, Appendix S1: Table S4). We found that branch structure had greater odds of being consumed when deep char exceeded 50% coverage on the tree for both

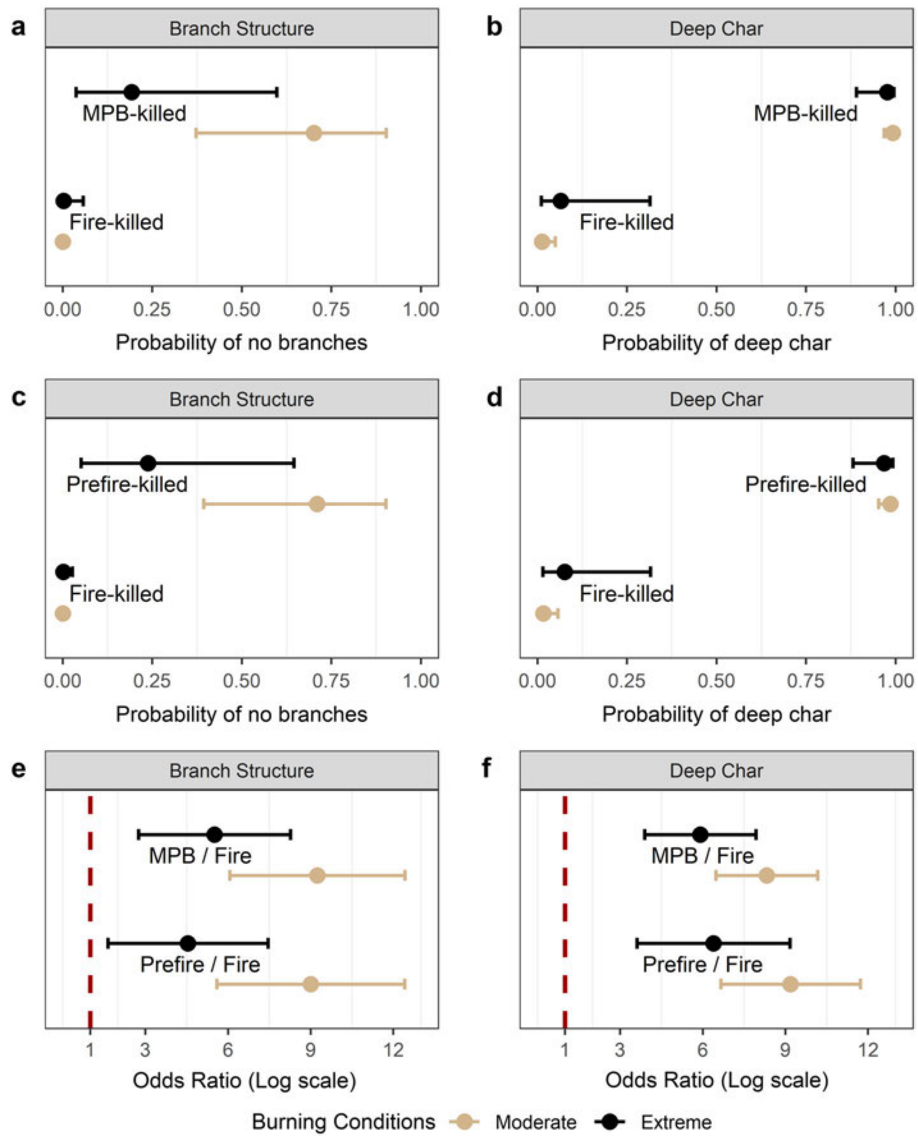

Fig. 3. The effect of outbreak severity and wildfire on legacy structure measured at the tree level. Tree-level fire effects show the role of mountain pine beetle (MPB) outbreak severity (MPB-killed and prefire-killed) on consumption of woody material and simplification of structural legacies in the form of branch loss and deep char development (a–d). Comparison between groups (i.e., MPB-killed versus fire-killed) is shown in (e) and (f) as odds ratios with the red dashed line marking no difference at one. The model estimates are listed in Appendix S1: Table S4.

moderate and extreme burning conditions (Fig. 5, Appendix S1: Table S5).

Discussion

We found that fire severity as measured by scorch/char height and area, and surface fire metrics, is not influenced by MPB outbreak severity but that fire severity measured as biomass loss and legacy structure was consistently influenced by the outbreak history. These findings from BC align with previous field research that evaluated the influence of outbreak severity on fire severity in the western United States

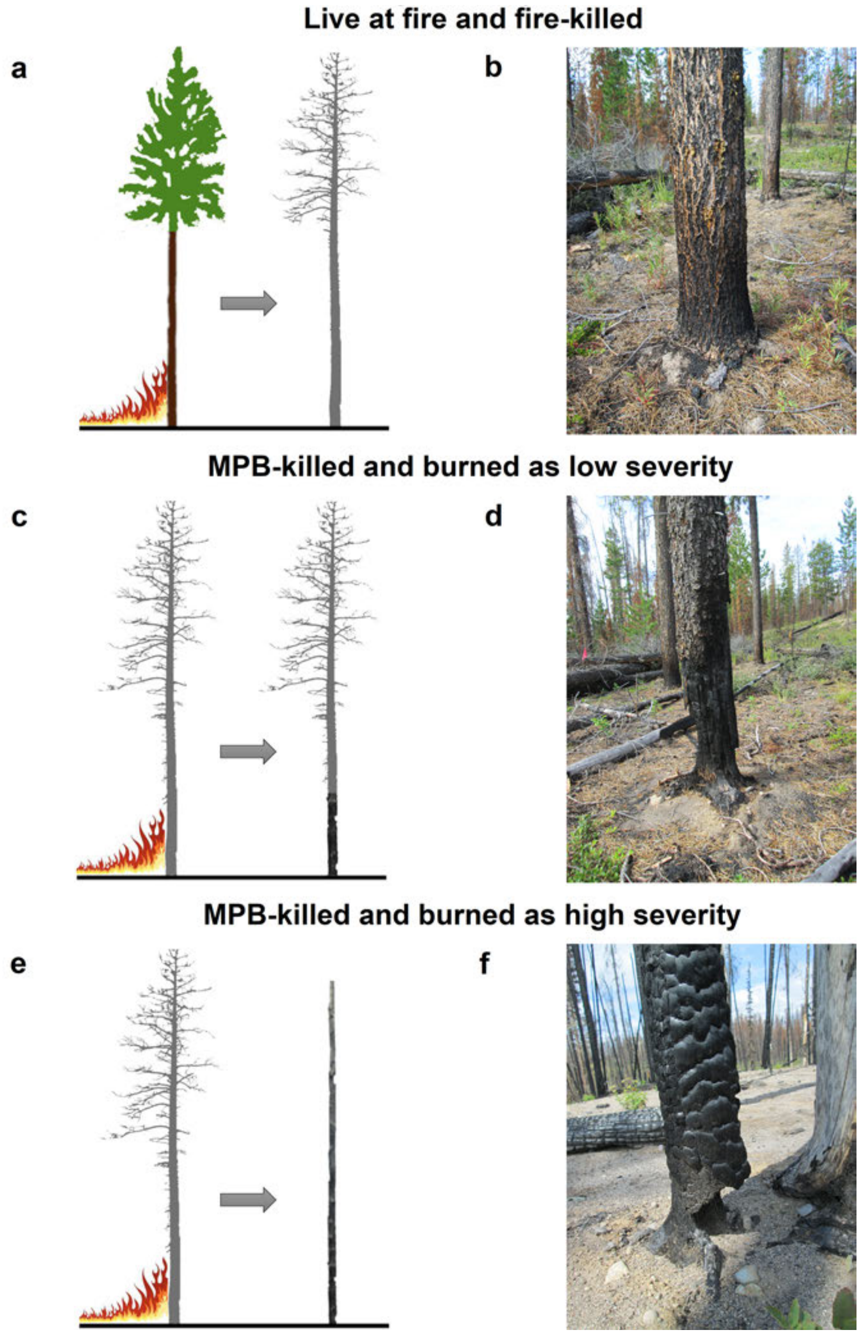

Fig. 4. Tree-level fire effects are dependent on whether a tree is alive or dead at time of fire. Panel (a) illustrates a tree that is live at time of fire and killed by fire, with the adjacent panel (b) showing a photo of a tree live at time of fire and killed by fire with scorched bark but no consumption of the tree. Panel (c) illustrates a MPB-killed tree that burns under low severity conditions, with the adjacent panel (d) showing a photo of deep char development and consumption at the base of the tree, which is attributed to fungal development (Donato et al. 2009). Panel (e) illustrates a MPB-killed tree that burns under high-severity conditions, with the adjacent panel (f) showing a photo of deep char that covers the entire tree in a plot that burned as high severity.

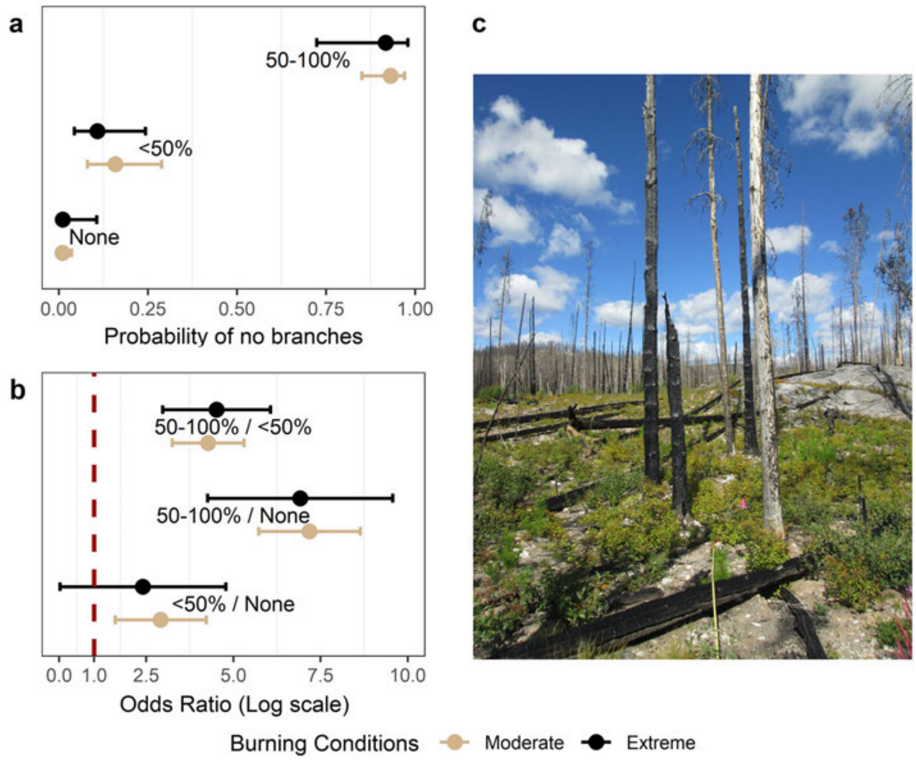

Fig. 5. Deep char coverage influences the consumption of branch structure on a tree. The probability of branch loss from deep char development is shown in (a). Comparisons between groups are shown in (b) with a red dashed line demarcating no difference at one. In (c), a photo of a snag with deep char and no branches adjacent to a snag with branches still intact and no deep char. Model estimates are list in Appendix S1: Table S5.

(Harvey et al. 2014*a*, *b*, Agne et al. 2016), but extends our understanding of these short-interval disturbances by highlighting the synergistic effect on postfire structural legacies. Prefire mortality had a greater likelihood for increased biomass consumption and deep char, which aligns with findings on reburns, where wildfires recur in short intervals (Donato et al. 2016). Prefire mortality, regardless of the mechanism of death, results in an altered legacy structure that is more simplistic and has more deep char. While this effect on structural legacies is generally accepted in the field, it has been broadly overlooked and unquantified in assessments of how outbreak affects fire severity. When asking the question "does MPB outbreak affect fire severity, are they linked disturbances," the answer is yes—specifically through the deadwood structure that remains in these ecosystems.

Effect of outbreak severity on first-order fire effects at the plot level

Outbreak severity did not show evidence of an effect on fire severity for six out of seven measured first-order fire effects; the exception was deep char. This reflects similar findings in gray-phase outbreak conditions found by Harvey et al. (2014*b*) and extends our understanding to the geography of BC's sub-boreal forests. Our finding indicates some inherent noise and uncertainty in our data as well as the influence of fire weather. The six fire effects—scorch/char height and area, duff depth, litter, surface char, and exposed soil, are likely controlled by the combined factors of the fire environment, that is, the interaction of fuels, weather, and topography (Countryman 1972, Krawchuk and Moritz 2011, Whitman et al. 2015) but without a strong signal from outbreak fuel structure, which aligns with previous research evaluating interactions between outbreak severity and fire severity (Harvey et al. 2014*a*, *b*, Agne et al. 2016). Scorch on trees is naturally variable and can be driven by multiple factors including the composition of fuel structures, crown and/or surface fire spread, burning conditions, slope steepness, and ignition patterns (Alexander and Cruz 2012*a*). Our results show no evidence of a relationship between terrestrial surface fire effects and outbreak severity, which was also consistent with findings in previous retrospective studies with gray-phase outbreak conditions (Harvey et al. 2014*b*, Agne et al. 2016). The lag time between needle drop and our study fires would have allowed for the decomposition of fine fuels (Simard et al. 2011, Harvey et al. 2013) thus minimizing the effect of outbreak on surface fuels. Most snags were still standing at time of fire, so that the concern of increased surface fire severity from abundant coarse woody debris was not observed. These findings support the general narrative that low-frequency and high-severity fire regimes associated with lodgepole pine in sub-boreal forests are strongly driven by climate systems of high-pressure, creating dry-hot conditions conducive for burning such that variability in fuel structure/vegetation plays a secondary role (Bessie and Johnson 1995, Nash and Johnson 1996, Whitman et al. 2015).

Effect of outbreak and wildfire on structural legacies

Our findings support the notion that dead wood, which in our landscapes is predominantly snags generated by MPB outbreaks, burns differently than live wood and indicates an important MPB-fire connection. Live trees rarely experience significant combustion, and therefore, little to no consumption occurs on the tree (Campbell et al. 2007), which is attributed to higher moisture content compared to their dead counterparts (Brown et al. 1985). Extended periods of smoldering and glowing combustion (Brown et al. 1985, Page and Jenkins 2007, Hyde et al. 2011) are facilitated by lower moisture content in snags and coarse wood (Stockstad 1979). Lower moisture content in snags could enable passive crown fire or torching of snags (Wenger 1984), which may be the primary mechanism for consumption of branch structure. Some simplification of branch structure may also occur on gray-phase MPB-killed trees prior to fire. The torching of snags and extended periods of smoldering have been demonstrated in areas that experience reburn, wildfires that recur in short intervals (Donato et al. 2016). High-severity reburns have shown there is an eightfold increase in deep char development on snags and the retention of woody biomass is half the amount of once burned areas, in the Klamath Mountains of southwestern Oregon (Donato et al. 2016). Where wind-throw is followed by wildfire in short intervals, snags and coarse wood have been shown to be reduced with a marginal increase in charred material (Buma et al. 2014). In lodgepole pine/Douglas-fir (*Pseudotsuga menziesii*) forests on the Chilcotin Plateau of BC south of our study sites, areas of high prefire mortality from MPB outbreak experienced 13% more consumption of dead wood and the variability in canopy consumption was attributed to mortality status with dead prefire snags having more of their branch structure consumed (Brad Hawkes, *personal communication*). This evidence indicates that it is not necessarily the mechanism of prefire mortality, for example, MPB outbreak, wind-throw, or prior wildfire, but the fact that there is an abundance of deadwood with altered moisture levels and fuel structures compared to live wood, which alters postfire ecological and structural legacies as they relate to standing snags and coarse woody debris.

The consumption of branches and deep char development on snags alters the structural legacies that endure through fire. These altered legacies may introduce long-term implications for ecosystem structure and function including availability of canopy seedbank, accumulation of coarse woody debris, and early seral structure and resources for early seral species (Franklin et al. 2000, Swanson et al. 2011, Johnstone et al. 2016). After MPB outbreak, lodgepole pine snags continue to retain some of their aerial seedbank in the canopy postmortem while some cones fall to the forest floor (Teste et al. 2011). Cones in snags or on the forest floor can be exposed to extended heating from a snag smoldering or slower moving surface fire (Alexander and Cruz 2012*b*), which could reduce seedbanks and influence postfire resilience (Johnstone et al. 2016). The loss in snag biomass and branch structure alters the accumulation of coarse wood that may influence short- and long-term carbon and nutrient cycles (Harmon 2001), structure of habitat for wildlife (Fontaine et al. 2009, House 2014) including nesting and perching habitat, and both structure and function of early seral ecosystems (Swanson et al. 2011). More charring on trees reduces the quality of the snag for saproxylic insects thereby affecting foraging woodpeckers (Saint-Germain et al. 2004, Nappi et al. 2010), which could influence trophic webs. Deep char development can encapsulate the remaining wood, which may limit decomposition, slow decay, and extend long-term carbon storage (Preston 2009, Bird et al. 2015). Together, these changes to dead wood that may alter the long-term structure and function in the postfire forest are considered compound disturbance effects, where the outbreak severity and fire severity work in combination to create unique post-disturbance conditions that are different than the outcomes of the singular disturbance of wildfire (Paine et al. 1998). Further research is needed to determine the long-term implications of compound disturbance effects related to legacy structure, coarse wood recruitment, carbon storage, pyrogenic carbon, habitat structures, trophic webs, and early seral ecosystems in forests where fires are increasingly burning through stands with high volumes of snags from insects, windthrow, drought, and prior fire.

Conclusion

Sub-boreal forest ecosystems of BC have experienced widespread tree mortality from the MPB outbreaks, generating a fuel structure characterized by an abundance of deadwood that is now interacting with wildfires. The contiguous landscape of lodgepole pine-dominated forests situated at the epicenter of the outbreak in western North America allowed us to assess interacting, or linked, effects between outbreak and fire severity. Our results suggest that while many first-order fire effects are not influenced by outbreak severity, legacy structure related to the degree of biomass consumption is strongly influenced by the interaction of outbreak severity and fire severity. These findings are especially important to consider after the 2017 and 2018 fire seasons in BC wherein a record number of hectares burned, with many of the fires burning through snag forests affected by MPB outbreaks.

Acknowledgments

We thank Kirsten Calder for her tireless work as a field assistant. We thank Mark Parminter, the Cheslatta Carrier Nation, Elizabeth, and Joe Doerig at Nechako Lodge, Katharina and Theodor Temperli at Tetachuck Lodge, Miles Fuller, John Blackwell, and the Lawrence Family for their logistical support. We thank the Landscape Fire and Conservation Science Research Group—specifically Marc Edwards, Kim House, Kurt Frei, Philip Camp, Garrett Meigs, Andrew Merschel, Will Downing, Claire Tortorelli, and Ana Barros—for their thoughtful insight and expertise throughout this project. Xianli Wang and Steve Taylor at the Canadian Forest Service provided day-of-burn maps and fire weather data, respectively. Ariel Muldoon provided statistical advice in the analysis for this project. We thank Chris Dunn, Dave Shaw, and Lauren Matosziuk for insightful conversations. Thank you to two anonymous reviewers who provided valuable comments that improved this manuscript. Funding was provided by Simon Fraser University, Oregon State University, and Natural Sciences and Engineering Research Council NSERC Discovery Grant 418376-2012 to MAK.

Chapter 13

Perspectives on LANDFIRE Prototype Project Accuracy Assessment

James Vogelmann, Zhiliang Zhu, Jay Kost, Brian Tolk, and Donald Ohlen

Introduction

The purpose of this chapter is to provide a general overview of the many aspects of accuracy assessment pertinent to the Landscape Fire and Resource Management Planning Tools Prototype Project (LANDFIRE Prototype Project). The LANDFIRE Prototype formed a large and complex research and development project with many broad-scale data sets and products developed throughout its various stages. The scope of the project was defined as mapping and modeling vegetation, wildland fuel, and fire regime characteristics (Rollins and others, Ch. 2). Because of the breadth of the investigation, it is important to base our expectations for accuracy on a clear understanding of the intricacies, interdependencies, and scope of mapping and modeling LANDFIRE products. Our goals in this chapter are to: 1) provide relevant background information regarding accuracies and what was realistically achievable in the LANDFIRE Prototype, 2) provide background regarding our strategies for LANDFIRE National, 3) describe our actual LANDFIRE Prototype accuracy results in broad terms, and 4) provide recommendations for the national implementation of LANDFIRE. This chapter is not intended to provide an exhaustive list and description of all of the various accuracy-related issues and conclusions resulting from the LANDFIRE Prototype (for specific details, the reader will be referred to the appropriate chapters). Rather, this chapter is intended to be broad in scope and to place the many accuracy components within the context of the LANDFIRE Prototype and LANDFIRE National projects. Please note that Lunetta and Lyon (2004) provide an in-depth discussion of the current state of accuracy assessment within the science community.

Background

General Accuracy Tenets and Philosophy

First we will provide the reader with several broad tenets used in defining accuracy assessment for the LANDFIRE Prototype Project and thereby lay the foundation for the more in-depth discussion following.

Tenet 1: Assuming that thematic detail and spatial scale are constant, product accuracy is generally inversely correlated with the size of the region being assessed.

Within the remote sensing literature, there are many references to accuracy levels, and many of the reported values are quite high. These high levels may lead to inflated expectations regarding what types of accuracies will be achievable from LANDFIRE. Many previous studies were conducted within relatively small study

In: Rollins, M.G.; Frame, C.K., tech. eds. 2006. The LANDFIRE Prototype Project: nationally consistent and locally relevant geospatial data for wildland fire management. Gen. Tech. Rep. RMRS-GTR-175. Fort Collins: U.S. Department of Agriculture, Forest Service, Rocky Mountain Research Station.

areas, often aided by high levels of "hand crafting" during the mapping process and/or in-depth knowledge of the particular study area. We do not have the luxury of spending a great amount of time and effort on any one particular region mapped through the LANDFIRE Project, and the mapping and modeling tasks need to be accomplished through largely automated processes. These limitations do not by any means reduce the value of the products being created through LANDFIRE; however, it should be stated that LANDFIRE products will likely have lower overall accuracies than do data sets derived from more localized studies characterized by large amounts of field data, increased processing effort that may include on-screen digitizing and recoding, and/or iterative refinement of modeled results.

Tenet 2: The higher the thematic detail, the lower the accuracy.

A relatively large number of vegetation classes were mapped for the LANDFIRE Prototype (Long and others, Ch. 6). While the chosen map unit classification system made sense on many levels for the LANDFIRE Prototype, it must be recognized that the proliferation of classes in this or similarly complex systems will imply a relative decrease in accuracy levels. This does not in any way diminish the value of the vegetation products, but is rather simply a result of a more complex map unit classification design. For example, a two-category classification of water and uplands is likely to result in high accuracy, with expected accuracies above 99 percent. This high accuracy does not mean that the *value* of the product is particularly high, but simply reflects that the accuracy for depicting these two classes is high. Additionally, there are difficulties that arise when categorizing continuous phenomena into rigid and discrete classes. For instance, a more detailed map unit classification system might treat juniper and pinyon – juniper ecosystems as several discrete classes even though the boundaries between them are relatively arbitrary and difficult to delineate both in the field as well as within the imagery. With complex vegetation map unit legends, such as that used in the LANDFIRE Prototype, vegetation class accuracy levels can be expected to drop. Nevertheless, LANDFIRE products reliably and consistently describe the distribution of vegetation composition, condition, and structure and associated wildland fuel and fire regimes across broad landscapes. These mapped data are useful for hazardous fuel reduction projects, for a variety of resource management projects, and for both strategic and tactical wildland fire management.

Tenet 3: Field information used for assessing accuracy is not perfect.

As mentioned under Tenet 2, the LANDFIRE Prototype vegetation map unit legends are relatively complex (Long and others, Ch. 6). The map unit classifications are developed using large quantities of field data, and all of the field plots are assigned to one of the many possible classes. Most of these plots are used to generate maps, but some are reserved for use in the accuracy assessment phase of the investigation. We recognize four major potential sources of error associated with field plot data:

- Errors occur frequently in the identification of species and measurement of vegetation structure in the field (for example, in the data for one prototype field plot, a misplaced decimal point indicated a shrub height of 60 feet).
- The vegetation on some field plots has undoubtedly changed between the time the field data were collected and when the imagery was acquired.
- Geo-location errors in plot and imagery data result in inaccurate characterization of some imagery pixels.
- The assignment of plots to specific vegetation classes will have errors associated with the wide array of opinions among professional field ecologists regarding the field classification of any given field plot.

Tenet 4: The modeled results of complex ecological systems will be characterized by ambiguity and controversy.

The products generated from the LANDFIRE Prototype represent our best approximations in depicting the current status of very complex natural phenomena. The information used in our modeling efforts is based on the best available input data and assumptions. However, although our output products represent reasonable and robust depictions of current conditions, we recognize that, due to lack of baseline research, our knowledge of certain ecological systems is imprecise. Use of such information in the modeling process may result in potential flaws in the products, and hence not all of the core LANDFIRE deliverables will be free of error and ambiguity. Nevertheless, the LANDFIRE Project represents an integration of the best available science in remote sensing, ecosystem simulation, landscape fire and succession modeling, predictive landscape mapping, and wildland fire behavior and effects prediction.

We are therefore confident that the products generated represent the best current assessments of the status of these ecosystems with regard to wildland fire and will be of great value to natural resource managers.

Accuracy Assessment Considerations for LANDFIRE

The need for conducting accuracy assessments of the spatial products created from mapping projects has been well documented (Congalton 1991; Foody 2002). Factors that influence map accuracy include (but are not limited to) the remote sensing platform, the quality of ancillary sources of information, the quality of field data, the floristic complexity of the map unit classification system used, and the sampling design. Traditional first-order map accuracy estimates involve generating an error matrix, computing overall accuracy, and estimating "producer's accuracy" and "user's accuracy" (Congalton 1991). In the past, assessment of map accuracy has involved much post-mapping fieldwork in order to develop error matrices. These formal, traditional accuracy assessments involving field campaigns can be labor-intensive, time-consuming, and cost-prohibitive, especially when dealing with projects that cover large regions of diverse and overlapping vegetation composition and conditions (Stehman and others 2000). For this reason, only a few efforts have conducted accuracy assessments across broad expanses such as the entire United States (Stehman and others 2003; Wickham and others 2004).

Techniques that worked well in assessing mapping accuracy across large regions for the 1990s National Land Cover Database (NLCD; Vogelmann and others 2001) employed modifications of traditional accuracy assessment methodologies (Stehman and others 2003; Wickham and others 2004). As background, the 1990s NLCD database was developed using Landsat satellite imagery acquired for the Multi-Resolution Land Characteristics (MRLC) 2001 consortium using methods previously described (Vogelmann and others 1998). During development of the database, it was determined that an accuracy assessment for the large area product was required, and that such an effort would have to be modified from more traditional assessments. The modifications were necessary in part due to the scarcity of field data across the mapped regions, the large size of the area being assessed (and associated high costs of collecting data from a statistically valid number of field locations across the entire conterminous United States), difficulties in assigning unambiguous map unit labels to many field plots, and geolocational errors associated with field plot and satellite-derived mapping information.

Three important lessons learned from the accuracy assessments of the 1990s NLCD effort pertain directly to the accuracy assessment methods used during the LANDFIRE Prototype Project:

- Collecting data for and compiling custom field databases is time consuming and expensive. Similarly, combining data from disparate sources and distilling them into a training database for mapping purposes is time consuming, expensive, and can result in data inconsistencies unless special effort is made to crosswalk and/or standardize input data. On the other hand, using existing field data, rather than collecting custom field data, saves both time and money. In short, for large-area projects, it makes sense to use existing field data for conducting accuracy assessments.
- Determining accuracy values for different subregions is acceptable when mapping large regions. Accuracies are likely to vary across large mapped areas due to region-specific heterogeneity in landscape composition and structure, and it was advantageous to derive an understanding of the geographic variability of accuracies of the products developed for LANDFIRE. To this end, use of a systematic random sampling design can provide optimal results. Such a design ensures that all geographic regions are adequately sampled and thereby ensures that at least some estimates of accuracies exist throughout the entire study region.
- Some errors are more "wrong" than others. For instance, for the LANDFIRE effort, misclassification of a pinyon – juniper stand as a riparian woodland stand will likely have a greater negative impact on the predicted fire behavior than misclassification of a pinyon – juniper stand as a juniper stand. Furthermore, some vegetation types are spectrally and biogeographically very similar to other vegetation types, and even with "perfect" source material, it is difficult to adequately distinguish some of these classes. For example, Douglas-fir and white fir are spectrally very close (fig. 1), and both species inhabit similar ecological niches. In regions where both Douglas-fir and white fir occur, we can expect significant confusion between the two classes. For instance, in central Utah, cross validation accuracies for these two classes were quite low, as anticipated. Nonetheless, we suspect that the errors related to misclassifying similar vegetation types will only minimally impact predicted fire behavior, whereas

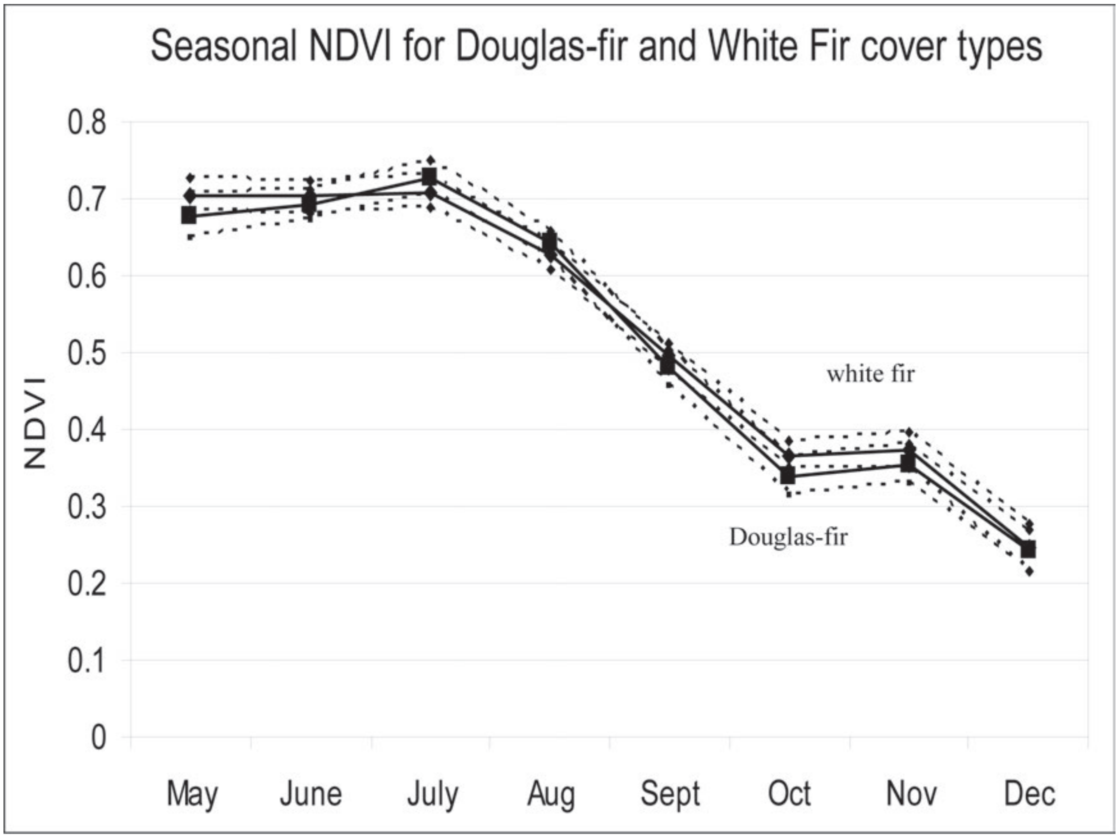

Figure 1—Seasonal normalized difference vegetation index (NDVI) spectral profiles for Douglas-fir and White Fir cover types.

errors related to misclassifications of more dissimilar vegetation types lead to greater negative impact. For this reason, both ecologists and image analysts need to critically analyze error matrices in order to fully understand and characterize the ways in which product errors may affect project objectives.

We took these lessons into consideration in the design of our LANDFIRE accuracy assessment protocol:

- Because LANDFIRE is a large-region project, we tapped into a variety of data sources and made use of existing field data to assess the accuracy of LANDFIRE Prototype products (rather than wasting time and money collecting data for and compiling a custom field database). See Caratti, Ch. 4 for details on the acquisition of data for and compilation of the LANDFIRE reference database.
- Cross-validation error matrices were generated and examined separately for both LANDFIRE Prototype regions.
- For the LANDFIRE Prototype, mappers, ecologists, and wildland fire scientists critically evaluated errors at several stages in prototype product development. These evaluations resulted in aggregation and disaggregation of classes based on the “mappability” and “model-ability” of the vegetation classes. See Keane and Rollins, Ch. 3 and Long and others, Ch. 6 for detailed descriptions of the creation of the final vegetation legends for the LANDFIRE Prototype. This expert-based process for map unit classification refinement is built into the accuracy assessment system for LANDFIRE National.

Overview of Accuracy Assessment Conducted for the LANDFIRE Prototype Project

The LANDFIRE Prototype Project involved many sequential steps, intermediate products, and interdependent processes, each involving evaluations of the accuracy of intermediate and final products. Please see appendix 2-A in Rollins and others, Ch. 2 for a detailed outline of the procedures followed to create the entire suite of LANDFIRE Prototype products.

Role of Input Data

Field data accuracy issues—Field data played a critical role in many stages of the LANDFIRE Prototype. These data were essential inputs for developing the vegetation products, percent canopy cover and height data layers, and potential vegetation data layers. See Caratti, Ch. 4 for detailed information on data acquisition for and compilation of the LANDFIRE reference database.

Described below are a number of data quality issues that needed to be addressed in the LANDFIRE Prototype.

- *Number of field plots*: For the LANDFIRE Prototype accuracy assessment, we used all field plot data that met the stringent quality-control criteria (Caratti, Ch. 4) and represented the large number of classes mapped during the vegetation mapping tasks (for details about the vegetation mapping procedures, see Frescino and Rollins, Ch. 7 and Zhu and others, Ch. 8) We used literally thousands of points for each of the two prototype regions. During this process, we recognized that some vegetation classes had limited numbers of field plots. Short of gathering additional plot information (see Keane and Rollins, Ch. 3 for LANDFIRE Prototype design criteria), there was no obvious solution to this problem. We attempted to map these rarely sampled vegetation types, even when we had limited numbers of field plots for those classes. We believe that most of these rare classes were under-represented in the resultant products.

- *Field plot geolocational accuracy*: Field plots must have accurate geolocational coordinates to geographically rectify with the many spatial databases involved in the LANDFIRE process. This was especially important during the vegetation cover and structure characterization phase of the LANDFIRE Prototype, wherein each field plot was matched with a single Landsat pixel and used in the mapping process. Any significant error in the field location coordinates has the potential to match the wrong spectral information with that particular field plot, thereby resulting in mapping error. For the prototype effort, we overlaid plot locations onto satellite imagery to determine whether there were plots that obviously did not match the imagery. While most plot locations appeared to be reasonable, we observed that many plots representing natural vegetation were actually located on major roads. When plot information was originally acquired for these sites, the actual Global Positioning System (GPS) measurements were apparently made at the road locations adjacent to the field plots, rather than within the field plots. Thus, the GPS locations did not exactly match the locations where the field measurements were made. For these sites in the LANDFIRE Prototype, a new set of geolocations was derived to better represent actual field plot locations.

  In another case, we noted (also based upon imagery assessment) that many putative shrub sites were located in obviously forested areas. We later discovered that those plots corresponded to a particular project in which the main focus was to describe shrub vegetation regardless of whether or not it represented the dominant vegetation type. These plots were consequently discarded from the prototype accuracy assessment. Both cases illustrate the need for assessing field plot information in conjunction with satellite imagery to ensure that the field information is accurately recorded.

  Moreover, it should be recognized that satellite imagery can have georeferencing errors as well. As a general rule, the coordinates of most pixels in the imagery used for the LANDFIRE Prototype are within 30 meters of the actual location – but exceptions occur. Even in the case where a pixel has slightly greater than a 15-meter error associated with it, this may be large enough to create a slight yet definite mismatch between the imagery and field information. While there is little that we can do about this problem, we at least need to recognize that some of the error term associated with the products generated will be attributable to this issue.

- *Assignment of field data into discrete vegetation classes*: One of the challenges in generating land cover maps is the stratification into discrete classes of a very complex natural world composed of multiple continuums. Regardless of which vegetation map unit system is used, many vegetation plots will represent elements of two or even more classes, and thus some plots will defy unambiguous categorization. As an example of one such problem, we mapped Juniper and Pinyon – Juniper (PJ) as two distinct classes. In nature, pinyon pine and juniper often coexist, but sometimes juniper occurs as more-or-less pure stands. We used 25 percent juniper composition as the threshold separating Juniper from Pinyon – Juniper (in other words, if a stand had 75 percent or greater basal area juniper in a stand comprised of both pinyon pine and juniper, it was called "Juniper"; whereas, if it had less than 75 percent juniper, it was called "PJ"). Analysis of seasonal spectral data indicated that many juniper stands were spectrally distinct from many of the PJ stands (fig. 2); however, significant spectral overlap existed between the two classes, as well. After decision tree classification, cross-validation accuracies indicated significant error in the classification of these two cover types (fig. 3). We believe that much of this error is attributable to the artificial boundaries imposed by the classification of a continuum.

- *Temporal correlation between field data and satellite imagery*: Disturbance such as that caused by fire, insects, or logging can alter the sites enough to cause the temporal mismatches between field data and satellite imagery that result in classification problems. For the prototype, we made use of a large volume of existing field data acquired from disparate sources (Caratti, Ch. 4), and much of the field information was acquired over a long period of time. Although information from many plots was relatively old (for example, field data acquired over a 10-year time period prior to imagery acquisition), we determined that many of these plots still contained information that was useful and relevant to the LANDFIRE Prototype. For example, plots located within reasonably intact and undisturbed forests or sagebrush lands, under normal circumstances, do not change much over a 10-year span. After completing the first prototype study in Utah, we recognized the importance of using a change-detection approach and employed such an approach in the northern Rockies prototype region to discard plot information derived from areas that changed between the times when the field information was obtained and when the imagery was acquired.

Geospatial data issues—Landsat imagery data from the MRLC 2001 consortium served as the primary source of spatial data for developing the vegetation and structure products (Homer and others 2004) (refer to

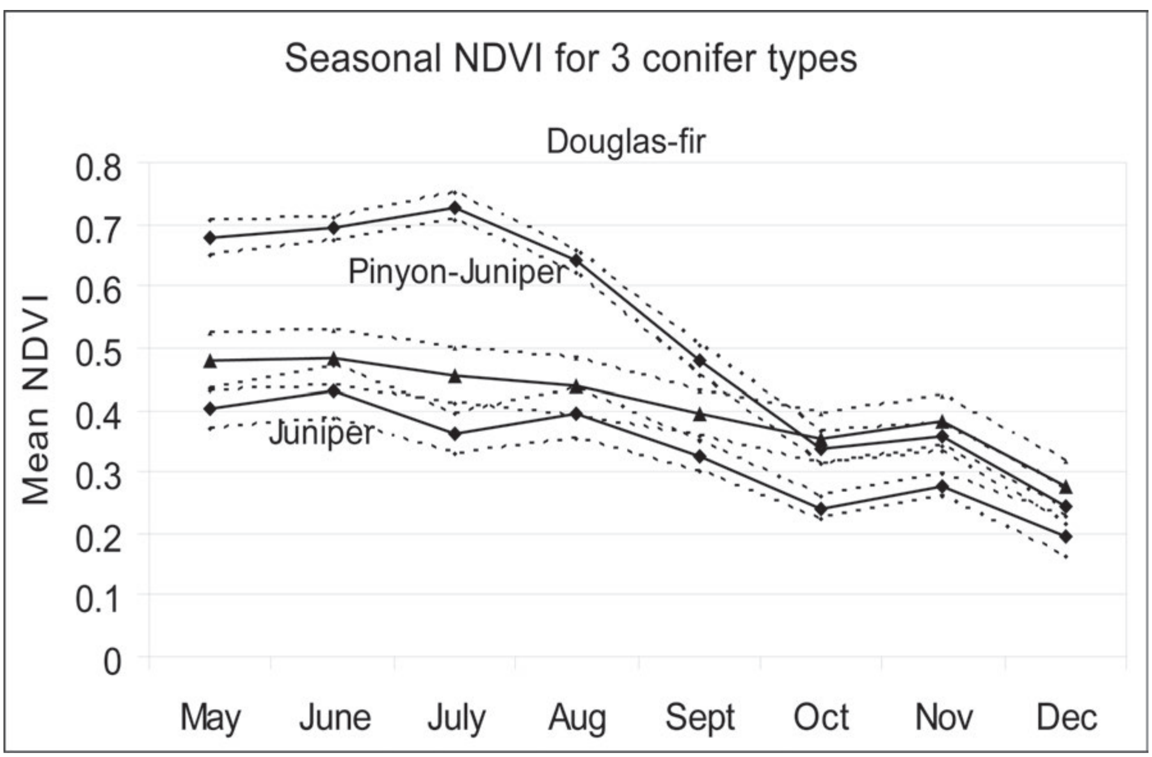

Figure 2—Seasonal normalized difference vegetation index (NDVI) spectral profiles for Douglas-fir, Pinyon – Juniper, and Juniper cover types.

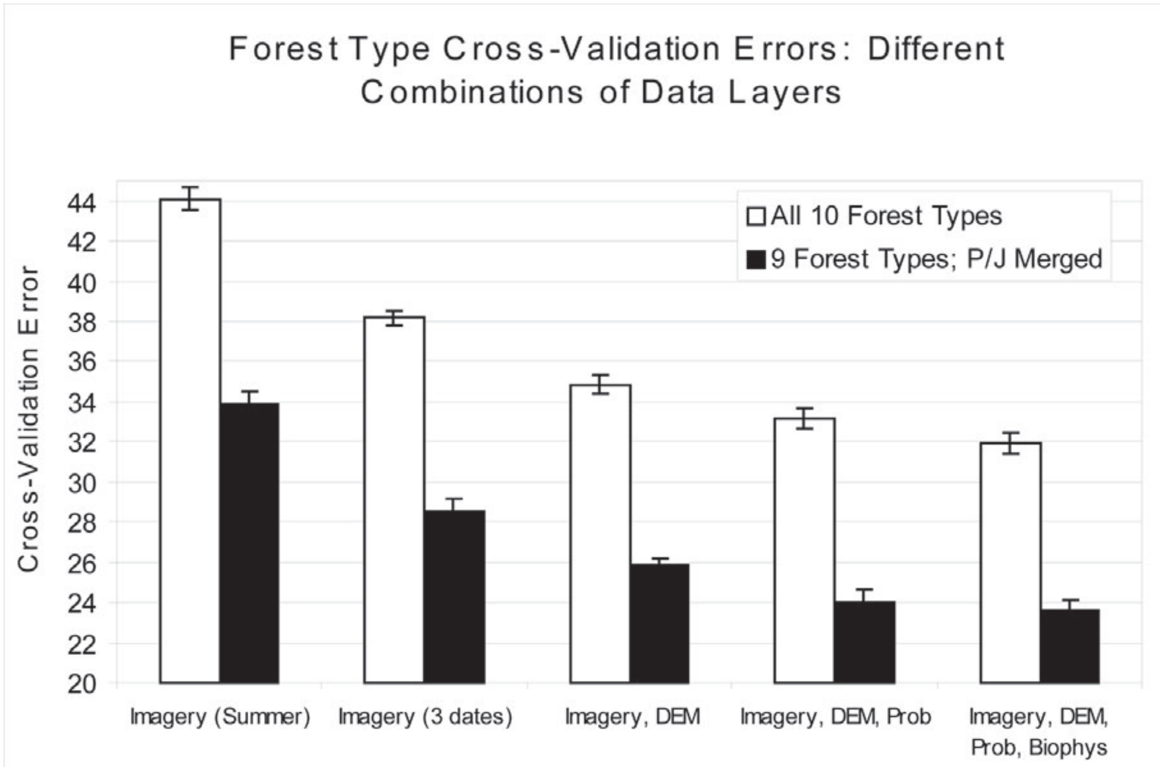

Figure 3—Cross-validation errors for forest types in the Zone 16 prototype study area as a function of different amounts of input source material. Black bars depict the effects of merging the Pinyon – Juniper and Juniper classes.

Zhu and others, Ch. 8 for further discussion regarding the imagery and ancillary data sources used for vegetation mapping in the LANDFIRE Prototype). In general, the images used for the prototype effort were the best data available during the LANDFIRE Prototype and represented three seasonal time periods (leaf-off spring, leaf-on summer, and leaf-on fall). Although the MRLC 2001 data used are of high quality, problems can arise when using any source of remotely sensed information. The foremost imagery-related problems affecting the LANDFIRE Prototype included atmospheric issues, disparate imagery acquisition dates, and geolocational problems.

- *Atmospheric issues*: Most of the acquired image scenes used in the prototype effort were of excellent quality. Even the best scenes, however, have occasional cloud and/or haze problems, which can either totally obstruct the view of portions of landscape or change the digital values enough to impact the mapping process. While not a large problem in the prototype areas, there were a few locations for which imagery quality was sub-par. These issues are inevitable and are likely to be a bigger problem in cloudier locations of the country such as the eastern United States and the upper Midwest.
- *Disparate imagery acquisition dates*: We attempted to use imagery from similar time periods as much as possible; however, due to cloud issues, optimal imagery data were not always available. Using scenes from different dates of the same year, such as using July and September data in the same "leaf-on" mosaic, resulted in problems resulting from phenological differences. Using scenes from different years, such as using one scene from 2002 and an adjacent scene from 2003, resulted in problems related to different weather patterns (for example, vegetation spectral response can be very different during wet versus dry years) and to occasional land cover changes that occurred between years. For the LANDFIRE Prototype, we attempted to minimize these problems through careful selection of scenes and use of spatial "date of acquisition" information in our decision tree and regression tree classifications.

- *Geolocational problems*: Images used in this investigation were processed using the National Landsat Archive Production System methods (USGS Landsat Website 2004). Data were corrected for terrain and projected to a standard projection (Albers Equal Area) using automated software processing. Individual pixel coordinate information was approximately 30 meters from actuality. Thus, even when field information had precise GPS coordinates, the field data were sometimes linked to the wrong pixel due to imagery registration errors. Because of technological, time, and budget constraints, we could not circumvent this problem. Registration methods needed to be consistent and automated to ensure that the process was feasible for application over the entire United States. We simply had to assume that the field data adequately characterized an area broader than the precise location of the plot and that the image pixel used was spectrally representative of its surrounding pixels. Note that in many cases, the quality-control checks performed on the field data mitigated some of these problems.

Ancillary data issues—Other sources of input information for the LANDFIRE Prototype included Digital Elevation Model (DEM) data and derivative products, 1990s NLCD land cover data (Vogelmann and others 2001), 2000s NLCD land cover data (Homer and others 2004), a suite of biophysical gradient data layers (Holsinger and others, Ch. 11; Keane and others 2001; Rollins and others 2004), and potential vegetation information (Frescino and Rollins, Ch. 7). Error terms are associated with each data type. While it is beyond the scope of this chapter to describe in detail all of the sources of errors associated with the many data layers, a few specific points should be made:

- Although not flawless, each data source used in the LANDFIRE Prototype represented the best available science and data quality.
- The source of the DEM data was the National Elevation Dataset (NED) (Gesch and others 2002). Although NED is an excellent source of digital elevation data, it came to our attention during the final stages of the prototype effort that another data source would have been more appropriate: the Elevation Derivatives for National Applications (EDNA) data set (http://edna.usgs.gov). The EDNA data represent a set of data layers derived from an earlier version of the NED. To create the EDNA data layers, the NED data were "smoothed" so that they would be better suited for hydrological modeling purposes. It should also be noted that, regardless of the source of the digital elevation model information, there are horizontal and vertical error terms associated with these data sets tracing back to the original source material. These digital elevation model data sets are regularly improved and updated.
- The 1990s and 2000s NLCD data sets were used for stratification purposes at various stages in the prototype effort, and both data sets have known error terms associated with them. See Yang and others (2001) and Homer and others (2004) for details regarding the accuracies of these products.

Accuracy of Thematic Maps

Cross-validation and points for independent validation—Accuracy assessment is an integral component of land cover mapping work. When a large number of field points are available, a reasonable alternative to generating traditional first-order accuracy estimates (see the above section *Accuracy Assessment Considerations for LANDFIRE*) is cross-validation. To create the LANDFIRE vegetation products, we employed decision tree analysis implemented within the See5 program (Quinlan 1993) using Landsat, DEM, slope, aspect, biophysical gradient, and potential vegetation data layers. The program enables cross-validation, which consists of repeated experiments in which a subset of the sample is used to train a classification model and an unseen subset is used to evaluate the model. In model runs for the prototype effort, we found that a five-fold cross-validation was appropriate. In each model run, the original field point data sets were divided into five subsets of equal size, and each subset was used to evaluate the algorithm trained using the remaining four subsets. Theoretically, this approach is not as thorough as a rigorous, statistically designed post-mapping field accuracy assessment campaign. It has been shown, however, that cross-validation can provide accuracy estimates comparable to these time-consuming and expensive methods (Huang and others 2003). See Frescino and Rollins, Ch. 7 and Zhu and others, Ch. 8 for actual accuracy results and cross-validation error matrices for the vegetation products derived for the LANDFIRE Prototype. For LANDFIRE National, we recommend reserving a set percentage of plots from the decision and regression tree analyses for independent accuracy assessment. See the *Recommendations for National Implementation* section below for details.

Field verification—Although it is not always feasible to conduct a detailed field verification and validation campaign, when possible, field visits at various stages of product development can be highly useful. Field visits, both during and after the product generation phase, provide the technical teams conducting the mapping work with a good basic understanding of the natural vegetation and ecology of the regions in which they are working. Further, field checks of particular sites to determine if they match the modeled results can be very instructive and useful for improving mapping accuracies. For the LANDFIRE Prototype, we made three separate field visits of approximately five days each. We traveled to the central Utah highlands region twice (once before mapping and once after the products were created), and we traveled once to the western Montana region (post-mapping). In all cases, images and/or maps were evaluated in the field, and actual plot measurements were made. Although not statistically rigorous, such efforts provided a better understanding of potential problem areas for future methods improvement. For example, an area of western hemlock was overestimated in the map products, and we were able to trace the overestimation back to problems in the original field sampling methods used to help generate the training data in the mapping process. Although no obvious solution to the problem was apparent, the case illustrates the importance of field visits in methods improvement. In another field activity, spectral measurements of shrub and herbaceous vegetation density were made by one team in the western Montana region to help refine shrub and herbaceous canopy cover methodology. This activity was undertaken in an attempt to improve canopy cover mapping and is being considered for the National Implementation of LANDFIRE.

Consistency checks with data from other sources—Related data sets, generated by other projects and for other applications, are often available and can be used for comparison purposes. The USGS Gap Analysis Program (GAP), for example, generates detailed vegetation maps for conservation management and planning (http://www.gap.uidaho.edu). We compared the GAP products created for the central Utah highlands prototype area with the cover type maps created for the LANDFIRE Prototype. The two sources of data compared reasonably well in some cases and less so in others (see figs. 4 and 5). It should be noted that the GAP products were created using different field databases than those used for the LANDFIRE Prototype. In addition, the vegetation map unit classification systems used were different, which limited the utility of direct, parallel comparison between the GAP products and LANDFIRE products. Although such comparisons may lack statistical rigor, they indicate where major qualitative similarities and differences exist between products and in turn may indicate which classes and regions are the most suspect. In addition, vegetation and structure products should be reviewed by regional experts whenever possible to determine whether noteworthy mapping problems exist and whether additional work is warranted. Such a review is recommended for national implementation of LANDFIRE.

Accuracy of Potential Vegetation Type and Canopy Fuel Maps

We generated potential vegetation type (PVT) data sets using decision tree software and cross-validation routines very similar to those used for generating vegetation maps. We also produced coinciding maps of confidence, which depict the relative prediction errors representing a spatial and visual representation of PVT map accuracy. See Frescino and Rollins, Ch. 7 for detailed descriptions and results of these activities. We estimated the accuracy of canopy fuel layers using regression tree procedures in which correlation coefficients were generated to measure the agreement between the predicted values and actual values. Additionally, we compared with predicted values a set of points randomly selected from the LANDFIRE reference database from each prototype zone. As in the case of PVT, we also produced coinciding maps of confidence. See Keane and others, Ch. 12 for a detailed description of canopy fuel accuracy.

Accuracy of Maps Based on Landscape Simulation Models

Accuracy evaluation of vegetation maps created from satellite imagery and ancillary data is straightforward and is based on a foundation of scientific literature (Foody 2002; Lunetta and Lyon 2004). In contrast, it is often conceptually very difficult to ascertain the quantitative accuracy of many of the products that are generated through complex modeling efforts, such as those employed to create the historical reference conditions for quantifying ecological departure in LANDFIRE. Moreover, it is difficult — if not impossible — to assign an absolute measure of accuracy to an ecological departure product because such a product represents deviation from conditions modeled under a variety of limitations in terms of baseline ecological data. Modeling assumptions, while based on the best available disturbance ecology science, may or may not be completely valid. Without the luxury of time-travel, it is very difficult to validate what the "normal" or historical vegetation condition actually was.

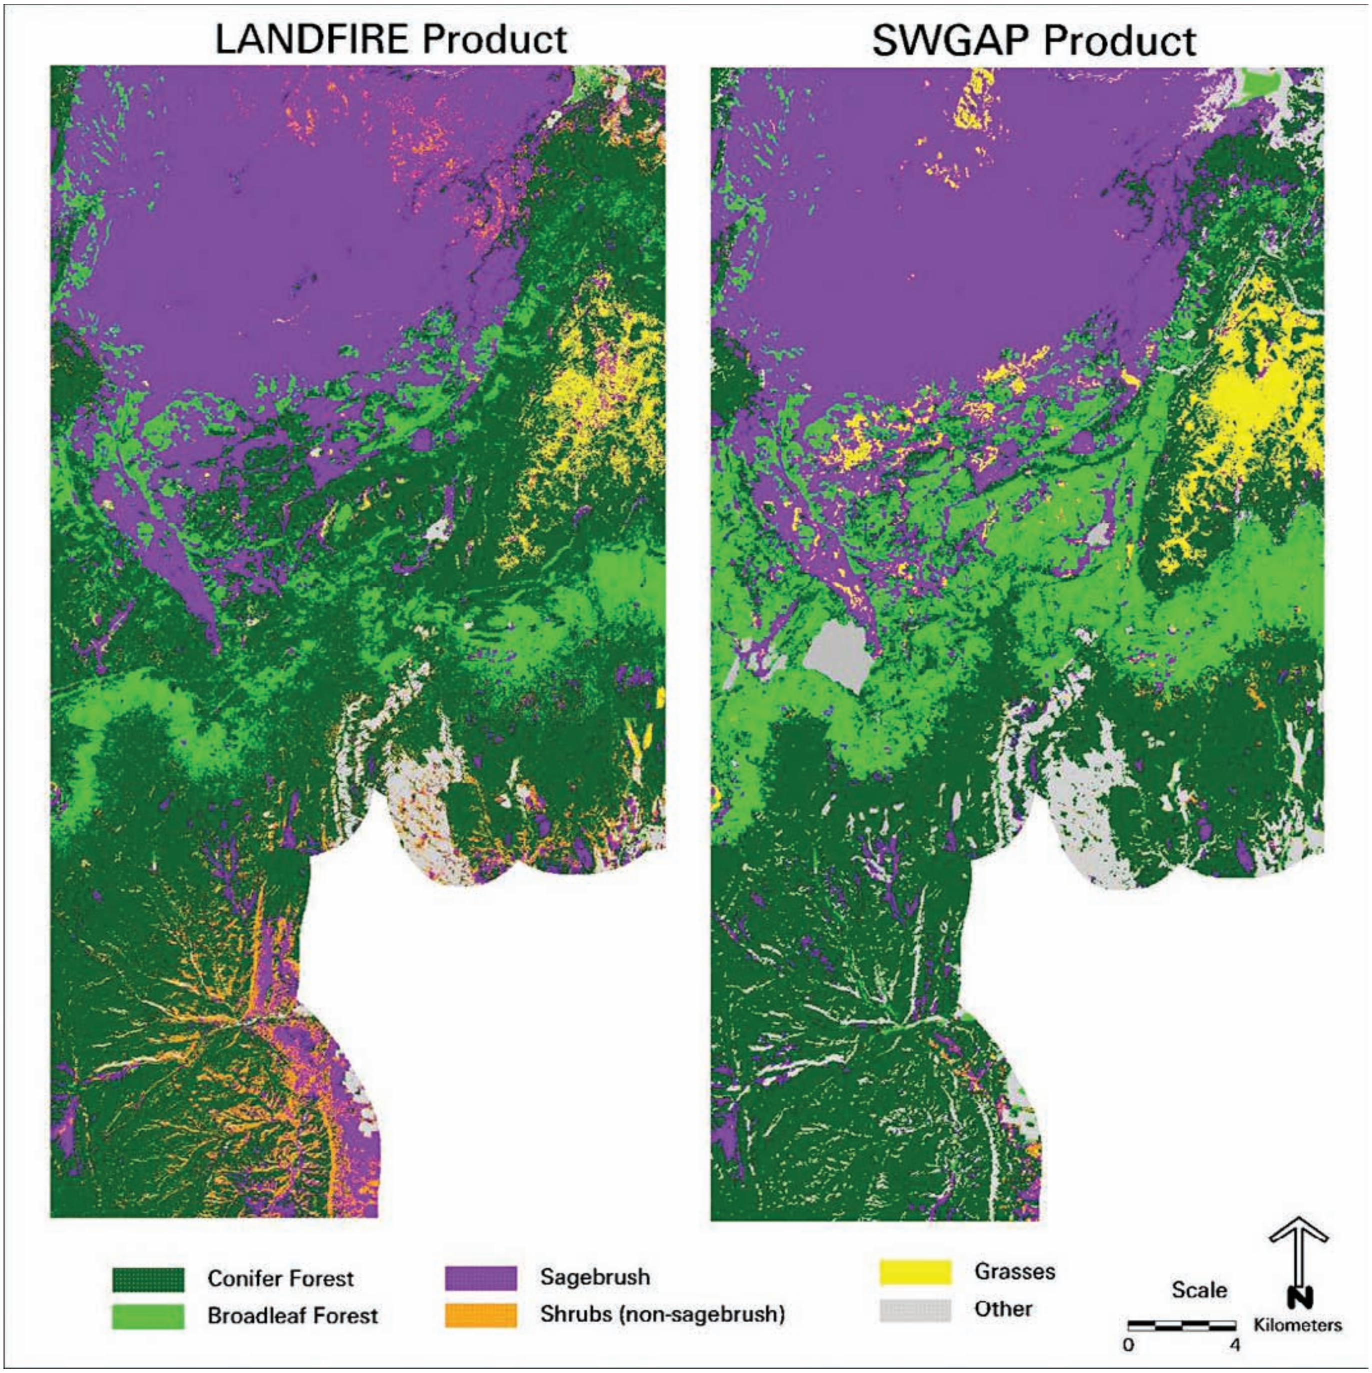

Figure 4—Comparison between a LANDFIRE vegetation type product and a product developed by the Southwest GAP Project in southern Utah. Multiple thematic classes have been combined to facilitate visual comparisons.

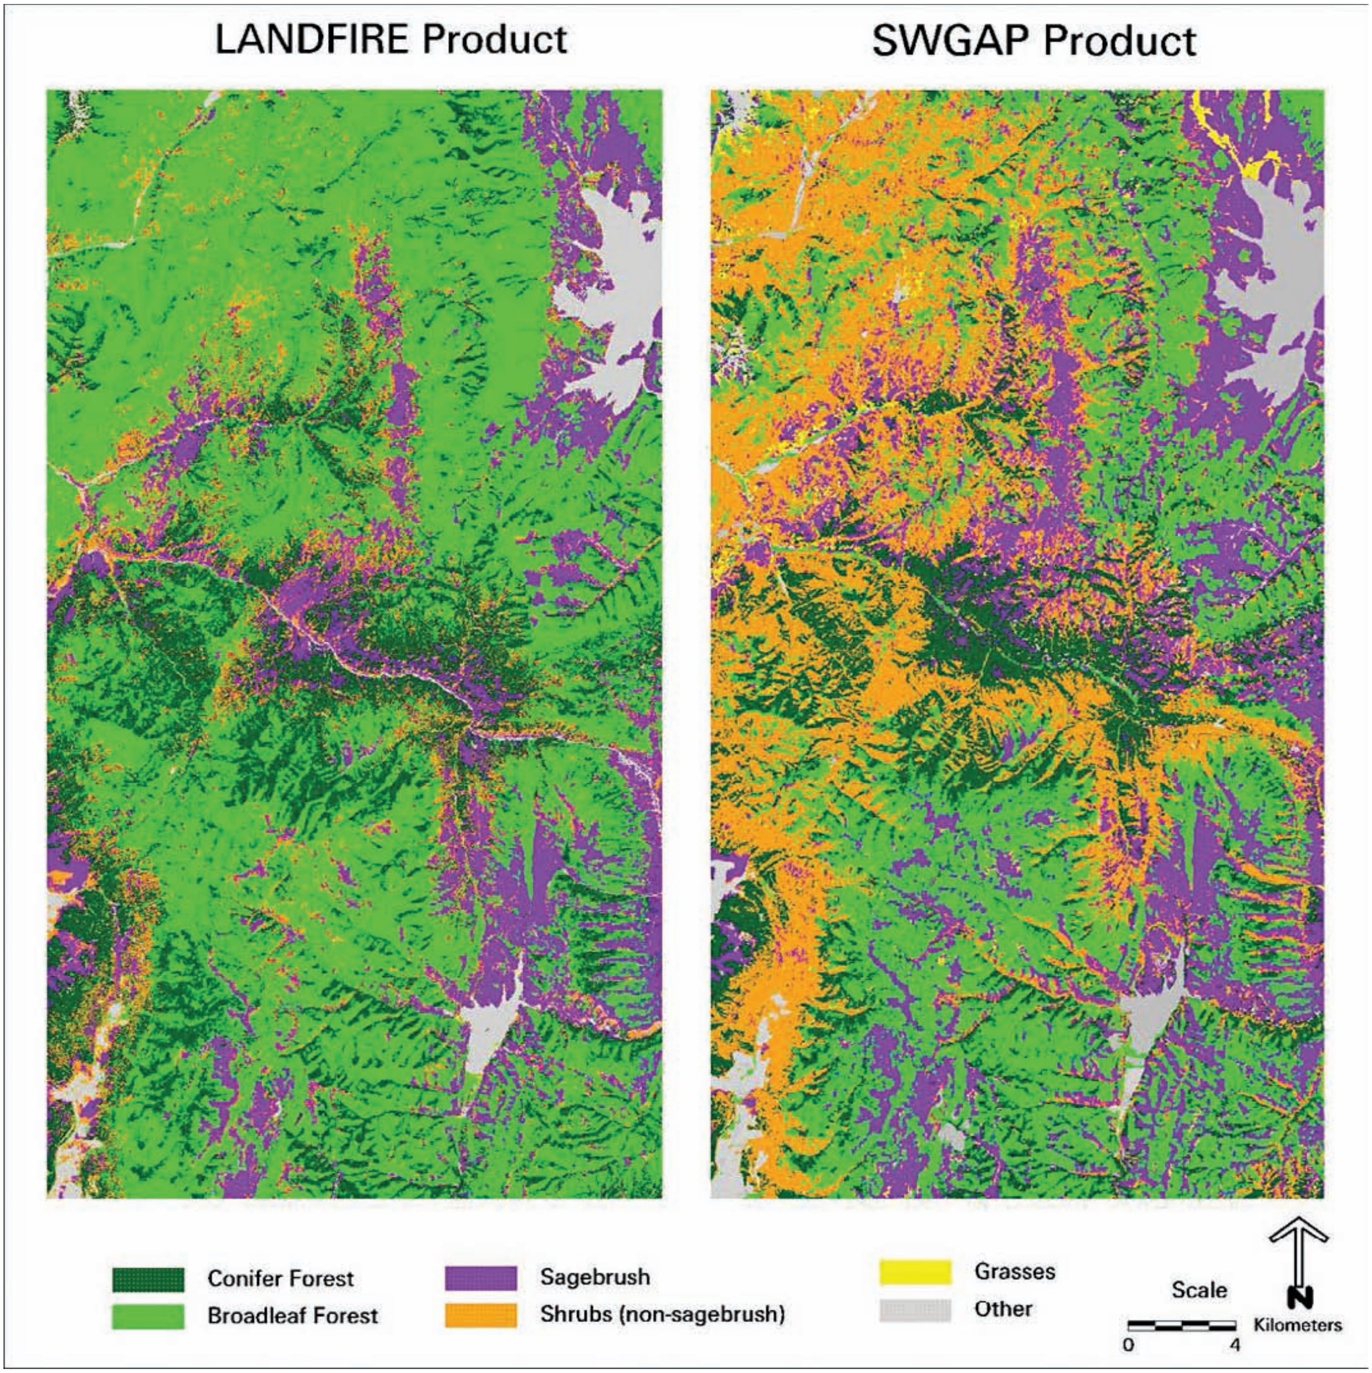

Figure 5—Additional comparison between a LANDFIRE vegetation type product and a product developed by the Southwest GAP Project in southern Utah. Multiple thematic classes have been combined to facilitate visual comparisons. Major differences between shrub and broadleaf forest classes can be traced back to differences in classification systems (Gambel oak and bigtooth maple were categorized as trees in the LANDFIRE map unit classification and as shrubs by GAP).

For accuracy assessment approaches used to evaluate LANDFIRE products based on landscape simulation models, see Pratt and others, Ch. 10 and Holsinger and others, Ch. 11. In addition, see the *Recommendations for National Implementation* section below for suggestions on improving the accuracy assessment of LANDFIRE products based on landscape simulation models.

Recommendations for National Implementation

Source Data

All source data need to be inspected carefully. This is especially true for field data and imagery, which form important foundations for much of the ensuing LANDFIRE tasks. As a matter of course, if field data used for training are inaccurate, then the resulting products will likely have lower levels of accuracy. Imagery quality can also greatly affect accuracy levels of derived products. Although optimal imagery data sets are not always available for a given location, there are usually several excellent options. It is important to ensure that the best possible imagery data sets are used. Below are some specific recommendations regarding the selection of source data.

Number of field plots—As general rule, the more field reference plots, the better. For each LANDFIRE National mapping zone, we anticipate using literally thousands of field plots in order to develop adequate characterizations. These must represent the entire range of conditions that occur throughout the mapping zones. For vegetation map unit classification development, for example, we have a target number of at least 100 plots per class. Fewer plots per class would diminish our confidence in our ability to map that class accurately and would likely result in the inadequate mapping of that particular feature. Rare classes (land cover features limited in occurrence across the landscape) are notoriously difficult to map accurately, largely because there are relatively few field plots representing these classes that can be used for training data. For national implementation of LANDFIRE, we recommend 1) generating vegetation products using all plots, 2) evaluating results, 3) determining which vegetation classes were represented by too few plots, and 4) re-running the map unit classification without these rare classes.

Field plot geolocational accuracy—Field plots with inaccurate coordinates have the potential to cause significant error in mapping results. We recommend that field plot locations be overlaid onto the imagery and that the plot locations be visually inspected to determine if attribute data for each plot are consistent with the imagery. Points located on roads or other locations clearly not characterized by the reference plot should be either omitted or shifted to the appropriate location.

Field data temporal issues—Much of the field information available for the national implementation of LANDFIRE is likely to have been acquired by various organizations over a relatively long period of time. As discussed above, inclusion of plots located in areas where the vegetation has changed between the time the field information was collected and when the imagery was acquired can cause significant mapping problems. The ideal situation is for field data and imagery to be acquired at approximately the same time, but this is impractical due to the large volume of field data necessary for product generation. One option is to discard plots with relatively old information (by imposing an arbitrary cutoff of five or more years); however, including as many plots as possible, even if some include older information, is preferable because even old plots can contain useful information. For this reason, for national implementation, we recommend using the change-detection approach developed for the western Montana prototype area. We recommend using normalized difference vegetation index (NDVI) change between 1990s and 2000s NLCD imagery to locate and isolate plots that have changed markedly over the last 10 years. If a plot is located within a region of high spectral change (based upon imagery analysis) and if the change appears to be related to a land cover change event (such as fire, logging, or insect disease) as opposed to a cloud or cloud shadow, the plot should be flagged and omitted from further analyses.

Imagery data—Imagery acquired by Landsat will likely continue to be the primary source of spatial data for developing vegetation and structure products for LANDFIRE National. The MRLC 2001 consortium, of which the LANDFIRE Project is a partner, is the best source for imagery in part because it is readily obtained and has been consistently pre-processed. Although this imagery represents the best data available, we do anticipate some issues that will need to be addressed. As with the prototype effort, we anticipate the primary imagery-related problems impacting LANDFIRE National to include atmospheric issues, disparate imagery acquisition dates, and geolocational issues (see above section *Geospatial data issues*). It is anticipated that haze and cloud problems will be especially prevalent in the eastern U.S., upper Midwest, and in the Pacific Northwest. Imagery differences related to phenological variables are also likely to impact mapping on a grander scale than was experienced in the prototype effort. When current MRLC data are deemed insufficient for LANDFIRE purposes (based upon visual inspection), additional scenes should be purchased and processed and incorporated into the mosaicking process.

Ancillary data—LANDFIRE will continue to use the best available source data for national implementation. One change that we recommend is using the EDNA data set (USGS EDNA website 2004) as the primary source of digital elevation data. These data are more refined than the data used in the prototype effort. The 1990s and 2000s NLCD data sets will continue to be used for stratification purposes at various stages of LANDFIRE National.

Accuracy of Output Products

Output product inspection—All LANDFIRE products must initially undergo an inspection phase during which the following question is asked: “Do these products make sense?” Although admittedly subjective, many errors will be caught early in the process through such inspections. If performed properly, such an initial evaluation provides a valuable safeguard that can save time and prevent the need to recreate the products.

Cross-validation and error matrices—As in the LANDFIRE Prototype, we recommend the use of cross-validation for approximating accuracies, especially for existing vegetation type and potential vegetation type. Correlation coefficients derived from regression tree analyses should be used when generating continuous variable data sets. Error matrices should be evaluated to facilitate better understanding of the strengths and weaknesses of the vegetation products. Regarding creation of the mapping models, we recommend using 5- or 10-fold cross-validation for each of the individual LANDFIRE mapping zones.

Points for independent validation—For national implementation of LANDFIRE, we recommend reserving a set percentage of plots from the decision tree and regression tree analyses solely for assessing accuracy. Note, however, that the field-referenced data used as input are collected from various projects and agencies, and thus the original source of field data cannot be considered a “random” sample of plots. Any sample of plots selected from a non-random set of points cannot be considered statistically random. Nonetheless, we have determined that withholding a limited number of points for validation purposes provides worthwhile accuracy information.

Nevertheless, we determined that it’s better to produce a more accurate set of products with imperfect accuracy information than a less accurate set of products with better known accuracy estimates. We do not want to withhold plots that would best be used for model and product development. As a compromise, we recommend that two percent of the plots be withheld from the modeling activities. These plots will then be used to estimate accuracies for aggregations of LANDFIRE mapping zones or “superzones”. We plan to merge data sets from three to four adjacent mapping zones and conduct validation activities for these regions. A target of at least 50 plots for each vegetation class per superzone provides useful information for estimating accuracies.

Stratification of accuracy assessment—In addition to providing general accuracy information at the superzone and individual mapping zone levels, we recommend providing more local estimates of accuracy nested within these other levels. This will be accomplished through spatial stratification of broad areas using biophysical gradient modeling information and other sources of spatial data and through thematic aggregation of similar vegetation types for localized regions. The process of stratifying mapping zones into zones based on the biophysical gradient layers developed for LANDFIRE (see Holsinger and others, Ch. 5) will be used as a basis to further our understanding of product errors, which in turn will enable refinement of future mapping procedures. This stratification process may facilitate the discrimination of different vegetation types with similar spectral signatures that occupy sites having very different environmental characteristics.

Field verification—As discussed above, we recommend conducting a modest level of field verification throughout LANDFIRE National. Field visits provide the technical teams with a basic understanding of the natural vegetation and ecology of the regions in which they are working, and field visits to particular sites serve to verify (or invalidate) the modeled results. Ideally, a field visit should take place at the beginning of each zone’s mapping activities for familiarization purposes, and an additional field visit should occur near the end of the mapping process to verify and refine the mapping process.

Consistency checks with data from other sources—Whenever possible, products should be compared with existing independently produced data sets. In some cases, products unrelated to LANDFIRE have been generated for certain local areas, and these can be used to help assess accuracies of LANDFIRE products. Spatial and tabular data potentially provide good general information. In addition, we recommend that LANDFIRE support the generation of local validation data sets, where appropriate.

Accuracy of Maps Based on Landscape Simulation Models

As discussed above, it is generally very difficult to ascertain the quantitative accuracy of products generated through complex landscape modeling efforts. Even so, there are some approaches suitable for assessing the validity of certain LANDFIRE modeled products, such as modeled historical fire regimes.

Although as of yet there are no examples of complete data sets representing historical vegetation conditions for the entire United States at the spatial grain of the LANDFIRE products, there are local historical data sets that can be used to “spot check” the validity of the products generated. For instance, historical aerial photographs and field-based data sets may provide useful information for assessing modeled historical fire regime products. Although not a true quantitative analysis, comparisons with historical data will likely provide information regarding the validity of the products.

As described above, it is important that the outputs from complex modeling activities be scrutinized carefully and checked for obvious flaws or deviations from expected results. As obvious as this seems, we are aware of numerous investigations in which this avenue has been neglected and in which spatial products were produced but not carefully examined. Although this type of evaluation does not yield quantitative error estimates, it can provide valuable insight regarding probable accuracies.

Finally, users of the LANDFIRE data sets should recognize that the inputs to the modeling process, while not always perfect, reflect the most accurate and current information available and are based upon ecologically sound assumptions. For these reasons, LANDFIRE products represent state-of-the-art modeling and technology and thus a significant improvement over other current options.

Conclusion

There is no single recommended procedure for deriving accuracy estimates for LANDFIRE products. Because time- and cost-related constraints, it will not be possible to conduct traditional accuracy assessments for the LANDFIRE mapping region (the entire U.S.). Yet at the same time, we recognize that evaluations of quality and accuracy increase the credibility of the final LANDFIRE products. Additionally, we can learn much by assessing error terms in the products, and this knowledge can be invaluable for future mapping and modeling endeavors. We suggest conducting a suite of accuracy assessment methods for LANDFIRE National, ranging from mostly qualitative assessments (such as the critical inspection of products, consultation with regional experts, and comparisons with existing data sets) to more quantitative analyses (such as cross-validation assessments, traditional accuracy assessments at the superzone level, and select evaluations at local levels). These combined approaches will provide LANDFIRE data users with the accuracy information necessary to facilitate the appropriate use of the data.

For further project information, please visit the LANDFIRE website at www.landfire.gov.

The Authors

James Vogelmann is a Principal Scientist with the Science Applications International Corporation (SAIC), contracting with the USDOI Geological Survey Center for Earth Resource Observation and Science (EROS). Vogelmann’s research focuses on large-region land cover characterization and change assessment using remote sensing and ancillary sources of spatial data. His role in the LANDFIRE Prototype Project has been to assess different methods for mapping vegetation types, serve on the LANDFIRE Vegetation Working Group, and help direct project research activities. He received his B.A. degree in Botany from the University of Vermont in 1978 and his Ph.D. degree in Plant Sciences from Indiana University in 1983.

Zhiliang Zhu is a Research Physical Scientist with the USDOI Geological Survey Center for Earth Resource Observation and Science (EROS). Zhu’s research focuses on mapping and characterizing large-area land and vegetation cover, studying land cover and land use change, and developing remote sensing methods for the characterization of fire fuel and burn severity. His role in the LANDFIRE Prototype Project has been to design and test a methodology for the mapping of existing vegetation cover types and vegetation structure and to direct research and problem-solving for all aspects of the methodology. He received his B.S. degree in Forestry in 1982 from the Nanjing Forestry University in China, his M.S. degree in Remote Sensing in 1985, and his Ph.D. degree in Natural Resources Management in 1989, both from the University of Michigan.

Jay Kost is a Research Physical Scientist with the Science Applications International Corporation (SAIC), contracting with the USDOI Geological Survey Center for Earth Resource Observation and Science (EROS). Kost's work focuses primarily on mapping existing vegetation and vegetation structure (percent canopy and height) for the LANDFIRE Project using decision and regression tree models. Optimization of these models and high map accuracy results are paramount in his work and improvements in methodology and results are continually pursued. He received his B.S. in Electronic Engineering Technology in 1987 from Minnesota State-Mankato and his M.S. degree in Space Studies from the University of North Dakota, Grand Forks. In addition, Kost has completed four years of post-graduate study in the Atmospheric, Environmental, and Water Resources Ph.D. program at South Dakota State University, Brookings.

Brian Tolk is a Research Scientist with the Science Applications International Corporation (SAIC), contracting with the USDOI Geological Survey Center for Earth Resources Observation and Science (EROS). Tolk's research focuses on the mapping and characterization of large-area land and vegetation cover, as well as on the use of close-range remote sensing methods to aid and improve LANDFIRE mapping techniques. His role in LANDFIRE has been to map land cover and structure variables for the prototype zones, implement a data management scheme, and produce promotional products for the project. He received his B.A. degree in Geography from Augustana College, Sioux Falls in 1990 and his M.A. degree in Geography from the University of Nebraska, Lincoln in 1996.

Donald Ohlen is an Environmental Scientist for the Science Applications International Corporation (SAIC) at the USDOI Geological Survey Center for Earth Resource Observation and Science (EROS). Ohlen's research and interest focus on land cover mapping for fire science applications, including the characterization of satellite data for fuel mapping and post-fire burn mapping. He earned his B.S. (1976) and M.S. (2000) degrees in Geography from South Dakota State University.

Acknowledgments

We wish to acknowledge the funding provided by the USDOI Office of Wildland Fire Coordination and the USFS Fire and Aviation Management. The cooperation of the USFS Forest Inventory Analysis office in Ogden, Utah, and the help and support provided by the staff at the USFS Fire Sciences Laboratory in Missoula, Montana, are gratefully acknowledged. We also thank Terry Sohl, Sherry Chen, Matt Rollins, and Christine Frame for helpful technical and editorial review through the creation of this manuscript. The research was performed, in part, by the Science Application International Corporation under U.S. Geological Survey Contract 1434-CR-97-40274 and 03CRCN0001.

Chapter 8

Mapping Existing Vegetation Composition and Structure for the LANDFIRE Prototype Project

Zhiliang Zhu, James Vogelmann, Donald Ohlen, Jay Kost, Xuexia Chen, and Brian Tolk

Introduction

Overview

The Landscape Fire and Resource Management Planning Tools Prototype Project, or LANDFIRE Prototype Project, required the mapping of existing vegetation composition (cover type) and structural stages at a 30-m spatial resolution to provide baseline vegetation data for the development of wildland fuel maps and for comparison to simulated historical vegetation reference conditions to develop indices of ecological departure. For the LANDFIRE Prototype Project, research was conducted to develop a vegetation mapping methodology that could meet the following general requirements:

- Cover types (species composition) must be characterized at a scale suitable for subsequent mapping of wildland fuel and fire regime condition class (FRCC). The vegetation map unit classification used for mapping cover types must be based on existing national systems, such as the United States National Vegetation Classification System (NVCS; Grossman and others 1998). The alliance (a community with multiple dominant species) or association (a community with a single dominant species) levels of this standard must provide a clearly defined list of map units that can be used as a basis for mapping vegetation classes that are both scaleable and representative of suitable units for modeling historical fire regimes (see Long and others, Ch. 6 for details on the LANDFIRE vegetation map units).
- The mapping of existing vegetation structure must be based on the relative composition of forest, shrub, and herbaceous canopy cover and average forest, shrub, and herbaceous canopy height. Although structural stages are discrete map units describing unique combinations of canopy cover and canopy height by life form, mapping individual canopy cover and height variables as continuous variables is desired to provide additional information for mapping and modeling vegetation and flexibility for setting threshold values.

The task of mapping existing vegetation is interconnected with several major tasks performed in the LANDFIRE Prototype Project. The mapping of existing vegetation requires attribute tables developed from the LANDFIRE reference database (LFRDB) (Caratti, Ch. 4), satellite imagery acquisition and processing, the development of a vegetation map unit classification system (see Long and others, Ch. 6), the development of a biophysical settings stratification (Frescino and Rollins, Ch. 7), and the modeling of environmental gradient layers (Holsinger and others, Ch. 5). The design and testing of the vegetation mapping methodology have substantial influences on the outcome of the overall project because accuracies of subsequent products (such as maps of wildland fuel) are a function of the accuracy of mapped vegetation types and structure. In this chapter, we discuss the design features of the existing vegetation mapping component of LANDFIRE and present

In: Rollins, M.G.; Frame, C.K., tech. eds. 2006. The LANDFIRE Prototype Project: nationally consistent and locally relevant geospatial data for wildland fire management. Gen. Tech. Rep. RMRS-GTR-175. Fort Collins: U.S. Department of Agriculture, Forest Service, Rocky Mountain Research Station.

results of the prototype. We conclude the chapter with recommendations for the national implementation of a consistent vegetation mapping effort.

Technical Problems

Significant technical limitations exist regarding achieving desired accuracies in the mapping of vegetation types and structure variables over broad areas. In the LANDFIRE Prototype, accuracies were affected by the spatial resolution, geographic extent, and information content defined by the project's objectives. The U.S. Geological Survey (USGS) Gap Analysis Program demonstrated the feasibility of mapping many existing vegetation cover types at the regional scale; however, methodologies have been inconsistent between regions (Eve and Merchant 1998). In addition, the mapping of forest canopy cover using imagery and regression techniques has been routinely performed for the operational mapping of vegetation structure variables (Huang and others 2001). Beyond that, however, literature reporting success stories regarding the mapping of vegetation structure using imagery is scant.

We conducted a prototype study to test a methodology for mapping vegetation cover types and structure variables. The three central objectives of the study were to:

- test an adaptable approach for mapping existing vegetation types and canopy structure at a 30-m resolution for the entire prototype area;
- develop digital maps of existing vegetation types and structural stages and conduct an accuracy assessment for the vegetation deliverables; and
- document research findings and limitations to the consistent mapping of existing vegetation composition and structure.

Specifically, this study tested a vegetation mapping protocol that met the design criteria and guidelines of the LANDFIRE Project (Keane and Rollins, Ch. 3). Further, this study investigated the limitations of using data contained within the LANDFIRE reference database (Carrati, Ch. 4) as training data and the applicability of satellite and ancillary data in meeting LANDFIRE's objectives. For vegetation modeling and wildland fuel mapping, the LANDFIRE Prototype Project required a structural stage map classified on the basis of mapped canopy cover (closed and open) and canopy height (high and low) by forest, shrub, and herbaceous life forms. We attempted to generate continuous maps of vegetation height and cover to maximize the utility of these products in a variety of applications.

As described in Rollins and others (Ch. 2), the LANDFIRE Prototype Project was conducted in two mapping zones: Zone 16, located in the central highlands of Utah and covering approximately 4 million ha of forest ecosystems (57 percent of the total land cover) and 2.5 million ha of shrub and herbaceous ecosystems (35 percent of the total land cover); and Zone 19, located in the northern Rocky Mountains of western Montana and northern Idaho and covering approximately 5.4 million ha of forest ecosystems (47 percent of the total land cover) and 5 million ha of shrub and herbaceous ecosystems (44 percent of the total land cover).

Literature Review of Vegetation Mapping

Similar to other natural science problems, the regional-scale mapping of vegetation types and structure variables carries unique technical and organizational challenges (Gemmell 1995). Spatial variations of vegetation types and structure are generally not characterized by unique spectral signatures, as captured by conventional broadband optical sensors (Kalliola and Syrjanen 1991; Keane and others 2001). Although significant improvements can be made by using specialized sensors, such as hyperspectral spectrometer or canopy lidar, data from such sensors having desired spatial resolutions are not available at national or regional scales. The associated enormous data volumes and high costs (in time and labor) make these technologies impractical for large-area applications at the present time.

Various techniques exist for modeling and estimating vegetation type and canopy structure (particularly percent forest cover); these include physics-based canopy reflectance models, empirical models linking ground-referenced data to satellite imagery, spectral mixture analysis, neural networks, and direct measurement using lidar and interferometric synthetic aperture radar. Each of these approaches has limitations in large-area applications, such as those related to cost and consistency. However, recent applications using the classification and regression tree (CART) approach (Breiman and others 1984) have been found to overcome many such limitations, provided sufficient amounts of field and geospatial data are available. Recent studies (Friedl and others 2002; Huang and Townshend 2003; Mahesh and Mather 2003; Yang and others 2003) have demonstrated the utility of CART techniques in mapping land cover, estimating species distribution, modeling percent forest canopy cover, and computing imperviousness at a 30-m grid resolution for large areas and even for the United States. Although CART techniques require relatively little human decision-making during algorithm executions, it is important to note that, ultimately, the knowledge scientists have acquired through studying vegetation patterns and attributes enhances the development mapping models to produce the most accurate results possible. Computer classifiers, regardless of their sophistication, are no substitute for scientists' understanding of the patterns, attributes, and conditions of existing vegetation and associated ecological processes.

Environmental data layers (such as elevation) are important predictor variables for characterizing vegetation patterns and attributes and for stratifying the distribution of vegetation along environmental gradient lines (Balice and others 2000). The use of spectral bands in combination with topographic data (for example, digital elevation models (DEM), slope, and aspect) is common in many land cover and vegetation mapping applications. However, topographic data capture only a part of the overall environmental factors that determine the establishment, growth, distribution, and succession of plant species and associations. The incorporation of a more complete set of environmental gradient layers into the mapping of existing vegetation should lead to increased predictive power and thematic accuracy (Keane and others 2002; Rollins and others 2004). Keane and others (2002) discuss techniques for deriving an entire set of climate, soil, and ecological gradient layers using interpolated weather observations in conjunction with topographic and soil databases and also describe the advantages of using such biophysical gradients in combination with remote sensing and field data to map vegetation, wildland fuel, and general ecosystem conditions.

In addition to the development and use of gradient variables, Keane and others (2001, 2002), Keane and Rollins, Ch. 3, and Rollins and others (2004) also suggest an approach for developing site-specific biophysical settings maps by mapping stable, late-seral communities as a function of certain climate, topographic, soil, and ecological gradients. This mapped "potential" vegetation can be used as a stratification tool in mapping actual vegetation distribution by constraining the distribution of cover types to those geographic strata where growth of the cover types' dominant species is ecologically possible.

Methods

The LANDFIRE Prototype Project involved many sequential steps, intermediate products, and interdependent processes. Please see appendix 2-A in Rollins and others, Ch. 2 for a detailed outline of the procedures followed to create the entire suite of LANDFIRE Prototype products. This chapter focuses specifically on maps of vegetation composition and structure, which served as important precursors to maps of wildland fuel and ecological departure in the LANDFIRE Prototype Project. Figure 1 outlines the technical approach used in LANDFIRE Prototype vegetation mapping and illustrates the data flow between several technically challenging tasks. Details of these tasks are described below.

Satellite Data Acquisition and Processing

The LANDFIRE Project partnered with the Multi-Resolution Land Characterization (MRLC) Consortium (Homer and others 2004) to facilitate the acquisition and processing of Landsat imagery. The consortium has completed the acquisition and processing of a full set of Landsat imagery for the United States with a minimum of three cloud-cover dates (circa 2001) for each pixel corresponding to phenological cycles of leaf-on, leaf-off, and spring green-up. Huang and others (2002) describe the steps involved in processing the MRLC satellite imagery, including terrain-corrected geometric registration and radiometric calibration using at-satellite reflectance models, calculations of normalized difference of vegetation index (NDVI), and tasseled cap transformations. The MRLC Consortium-sponsored development of the National Land Cover Dataset (NLCD) includes general land cover map units such as forest, agriculture, water, and urban areas mapped at a 30-m resolution (Homer and others 2004). The acquisition and processing of satellite imagery and the mapping of NLCD land cover map units were conducted for mapping zones, which were loosely delineated along major ecological regions. The LANDFIRE central Utah highlands and northern Rockies prototype areas were examples of these MRLC map zones.

The LANDFIRE Prototype Project had access to the following data layers from the MRLC catalogue for the Utah and northern Rockies prototype areas: 10 spectral bands for each of the 3 Landsat seasonal acquisitions (6 original spectral bands excluding the thermal band, 3 tasseled cap transformation bands, and 1 NDVI band) and land cover classes mapped to Anderson's Level 1 land cover classification (Anderson and others 1976). Using these data as a starting point, we mapped forest, shrub, and herbaceous cover types and structure attributes. These maps formed the foundation for mapping wildland fuel and fire regime characteristics (Holsinger and others, Ch. 11; Keane and others Ch. 12).

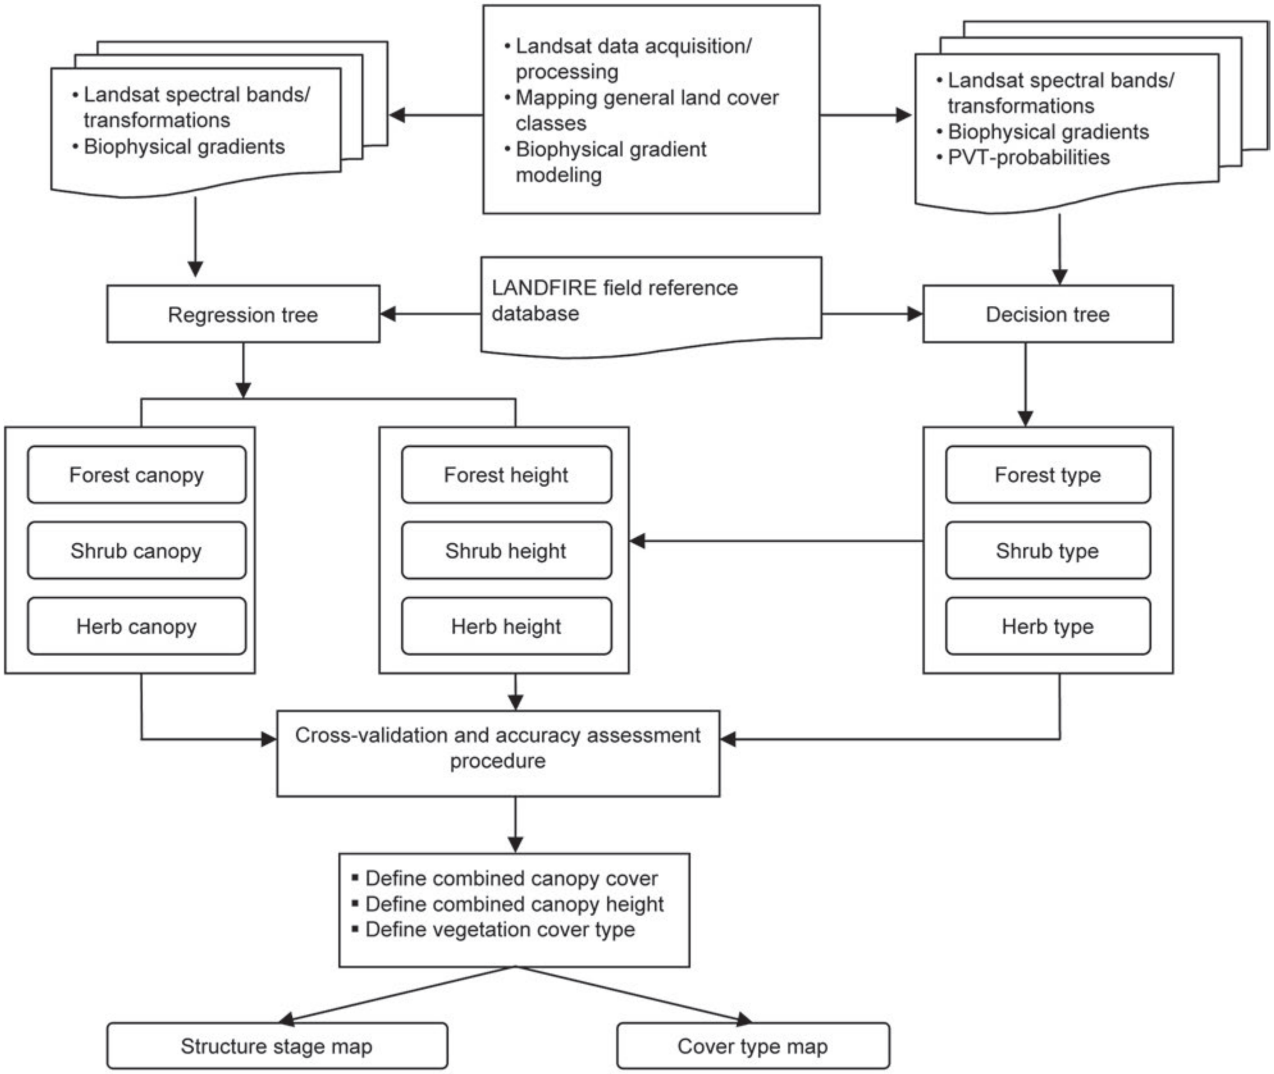

Figure 1—Flow diagram of the methodology used for mapping cover type and vegetation structure in the LANDFIRE Prototype Project.

Use of Biophysical Gradient Variables and Potential Vegetation Maps

In addition to the spectral predictor variables discussed above, the LANDFIRE existing vegetation mapping task incorporated two ancillary data sets that functioned differently in the mapping process. One was a suite of biophysical gradient layers developed as a set of intermediate LANDFIRE products with input from weather, topographic, and soil databases (Holsinger and others, Ch. 5: table 6). Table 1 lists the biophysical gradient variables used in the prototype for mapping existing vegetation; these represent a winnowed set of the entire suite of variables produced for the LANDFIRE Prototype. Biophysical gradients were used in the mapping process to provide a geographic context for the ecological processes that control establishment, growth, and distribution of vegetation communities.

The second data set was a potential vegetation type (PVT) map with attributes describing the probability of specific cover types existing in each PVT. This database was derived by calculating the distribution of cover types within individual PVTs by intersecting the plots contained in the LFRDB with the PVT map (Keane and Rollins, Ch. 3; Frescino and Rollins, Ch. 7). Conceptually, by using the PVT and cover type probability

Table 1—Biophysical and topographic layers used in the LANDFIRE vegetation mapping process.

Symbol	Description	Unit	Source data
SRAD	Daily solar radiation flux	$KW/m^2/Day$	Weather and topographic data
Tmin	Daily minimum temperature	C°	Weather and topographic data
Tmax	Daily maximum temperature	C°	Weather and topographic data
Tnight	Daily average nighttime temperature	C°	Weather and topographic data
Dday	Degree days	C°	Weather and topographic data
PPT	Daily precipitation	cm	Weather and topographic data
RH	Relative humidity	%	Weather and topographic data
PET	Potential evapotranspiration	kgH_2O/yr	Weather and topographic data
AET	Actual evapotranspiration	kgH_2O/yr	Weather, topographic, and soil data
GSWS	Growing season water stress	-Mpa	Weather, topographic, and soil data
PSI	Soil water potential	-Mpa	Weather, topographic, and soil data
KDBI	Keetch-Byram drought index	Index	Weather database
SWF	Soil water fraction	%	Weather, topographic, and soil data
Sdepth	Soil depth to bedrock	cm	Soil and topographic data
LAI	Potential leaf area index	Index	Landsat spectral data
DEM	Digital elevation model	m	National Elevation Database
Slope	Slope	%	National Elevation Database
Aspect	Aspect	Azimuth	National Elevation Database
POSIDX	Topographic position index	Index	National Elevation Database

information in the mapping of vegetation cover types, we implemented a stratification that constrained cover types to the geographic areas where cover types were ecologically possible. Sites (pixels) where certain cover types were not likely to occur would have low probabilities; therefore, these cover types were less likely to be predicted for these pixels. Each cover type was associated with a probability distribution map. The probability layers were implemented in the mapping process much in the same way as the biophysical gradient layers and satellite imagery.

Vegetation Map Unit Classification

Two different approaches were used in the development of the vegetation map unit classification systems for the prototype mapping zones. For the central Utah mapping zone, we formulated the map unit classificaton based on an overall understanding of the presence of vegetation alliances and associations (Long and others, Ch. 6). For the northern Rocky Mountains prototype area, we examined and summarized the LFRDB to form the basis for the vegetation map unit classification. Brohman and Bryant (2005) have described these approaches as the "top-down" and the "bottom-up" approaches, respectively. Long and others (Ch. 6) discuss the criteria and factors used in developing the LANDFIRE vegetation map unit classification systems, the lessons learned in applying them, and recommendations for a national approach to vegetation map unit development.

We were concerned with two technical issues when evaluating the map unit classifications of existing cover types for the prototype: 1) whether each cover type was sufficiently represented by an adequate number of field-referenced data from the LFRDB and, if not, how such "rare map units" should be treated and 2) whether some cover types (such as the Juniper cover type versus the Pinyon – Juniper cover type) would be floristically or ecologically difficult to separate in spectral, biophysical, and geographical domains. The technical issues were considered in the context of four guidelines defined at the beginning of the LANDFIRE Prototype Project: a map unit, whether it is a cover type or a fuel model, must be identifiable, scalable, mappable, and modelable (Keane and Rollins, Ch. 3). Because the prototype study areas were the first mapping zones to be mapped under the LANDFIRE design criteria and guidelines, we were unsure whether the map unit classification systems could perform consistently across different geographic areas.

Reference Data

Caratti (Ch. 4) describes in detail the compilation of the LFRDB for the prototype. The compilation of the LANDFIRE reference database relied on the coordination of three separate and independent efforts: 1) the cooperation and support from the U.S. Forest Service (USFS) Forest Inventory and Analysis (FIA) database collected nationwide on permanent inventory plots (Smith 2002); 2) the collection and processing of existing field data from all land management units such as Bureau of Land Management districts or national parks; and 3) the acquisition of new, supplementary field data from areas where there were no or not enough existing data (for example, various western rangelands in the United States do not currently have adequate field data collection programs).

Because the LFRDB was compiled from various sources collected for different purposes, information gleaned from the LFRDB was highly variable in terms of sampling design. The FIA data represented the most consistent information for forest cover types and canopy height. Rangeland field data usually contained cover type labels, but structure information was rare. In addition, reference data for mapping forest canopy cover were generated by calculating the number of forest cells within a 30-m cell using either high-resolution satellite data (spatial resolution of 1-m or better) or digital orthophotographs (Homer and others 2004).

Quality-control procedures were conducted as a part of the existing vegetation mapping process to detect problems and errors inherent in field-referenced data derived from disparate sources. We assumed that these procedures would identify most existing data problems but would not identify and eliminate all problems. These procedures were as follows:

Detecting outdated field data—Many field plots measured in years past were considered useful if the dominant species had not changed. A substantial number of plots, however, had undergone major disturbances such as fire or logging. We therefore computed the differences between the 1992 and 2001 Landsat NDVI values to flag field plots with conditions that had potentially changed during that 10-year period.

Detecting field data with erroneous geographic coordinates—We identified major geo-coding problems such as coordinates located on roads or located out of mapping areas. We visually examined plot locations overlaid with road networks and general land cover maps (such as NLCD maps).

Detecting field data with major coding errors—We detected such problems by overlaying field data on raw satellite imagery and by sorting variables according to major cover types. For example, if a field plot coded as *sagebrush* was located in the center of an otherwise intact *forest* polygon, or if a shrub plot had a height value taller than that of forest plots, such plots were flagged.

Reducing spatially clumped field plots—The LFRDB contains field data that come from different sources and are collected with different objectives, which occasionally results in spatially clumped plot information. In order to produce a spatially well-distributed and balanced data sample, we sub-sampled clumps of the available data to result in a more even distribution of field data.

The use of these quality-control procedures resulted in the exclusion of a number of available field plots from either the mapping or validation processes. This led to a total of 6,177 field plots (1,809 FIA forest plots and 4,368 non-FIA forest and rangeland plots) for Zone 16 and 7,735 field plots (1,993 FIA forest plots and 5,742 non-FIA forest and rangeland plots) for Zone 19 to be used for subsequent training or accuracy assessment. These numbers differ slightly from other applications of the LFRDB in LANDFRIE mapping because, based on objectives, each mapping effort implemented its own quality control procedure. Although all of the plots contained LANDFIRE cover type labels, only subsets of plots from the LFRDB had attributes of canopy height and canopy cover (table 2). In addition, ten percent of the field data points available for each of the cover type and structure mapping tasks were withheld from the mapping process for the purpose of accuracy assessment (Vogelmann and others, Ch. 13).

Mapping Algorithms

Classification and regression tree algorithms have demonstrated robust and consistent performance and advantages in integrating field data with geospatial data layers (Brown de Colstoun and others 2003; Friedl and Brodley 1997; Hansen and others 2000; Joy and others 2003; Moisen and others 2003, Moore and others 1991; Rollins and others 2004). Nonparametric CART approaches recursively divide feature space into many subsets in a hierarchical fashion to achieve the best overall model performance (lowest error and highest R^2, derived using a cross-validation technique). For this study, we adopted the classification tree algorithm to map vegetation types as discrete map units and the regression tree algorithm to map canopy cover and canopy height as continuous variables using two related

Table 2—Numbers of field reference plots in each mapping zone used in either mapping or accuracy assessment and corresponding to various map products. Forest canopy cover mapping relied on imagery of high spatial resolution instead of field reference plots.

	Mapping zone	Number of cover types	Cover type plots	Canopy cover plots	Canopy height plots
Forest	16	10	1,809	N/A	1,809
	19	14	1,993	N/A	1993
Shrub	16	14	1,595	2,120	1,698
	19	15	1,788	1,788	989
Herbaceous	16	7	300	2,263	1,311
	19	8	597	597	282

commercial applications: See5 (classification trees) and Cubist (regression trees) developed by Quinlan (1993). The mapping models were trained on the compiled data set of spectral bands and biophysical ancillary variables listed in table 1 and cover type and structure variables from the LFRDB.

Vegetation Database Development

Training vegetation mapping models—The creation of the CART-based algorithms for mapping existing vegetation involved several steps: 1) exploration of general data such as correlation analyses and plotting of cover types from the LFRDB against predictor layers, 2) iterations of CART algorithm runs to determine the adequacy of training data and other biophysical layers, 3) visual evaluation of classification and regression trees and final output maps, 4) generation of cross-validation statistics as an initial indicator of map accuracies, and 5) development of vegetation maps by applying the final mapping models. As mentioned above, we withheld data from 10 percent of available field reference plots for accuracy assessment and used the rest of the field plots for training the CART algorithms. We ran classification tree or regression tree classifiers, depending on whether the mapped theme was categorical or continuous, and generated 10-fold cross-validation statistics. Results of the cross-validation were used to determine the quality of training data and the performance of the predictor layers, but not to assess the final accuracy of resulting maps.

Determination of rare and similar map units—Although the LANDFIRE Prototype Project vegetation map unit classifications were developed to meet specific design criteria and guidelines (Keane and Rollins, Ch. 3; Long and others, Ch. 6), two technical questions arose during the mapping of existing vegetation: how to treat 1) rare cover types and 2) spectrally and biophysically similar cover types. We considered a cover type to be rare if it was supported with fewer than 30 reference plots, and those plots were not concentrated in one general location. We retained a rare map unit in the overall mapping process if the resulting spatial pattern made sense (such as when a riparian cover type followed river patterns) and if retaining the map unit did not result in a significant drop in accuracy. Otherwise, the rare map unit would be omitted. Additionally, we decided, based on differences in historical disturbance regimes, to keep cover types that were biophysically and spectrally similar (such as Pinyon – Juniper) separate, even though merging the cover types would significantly improve overall map accuracy.

Stratifications by life form—During the mapping of these vegetation attributes, the question arose as to whether the cover types and structural stages should be constrained by their respective forest, shrub, and herbaceous life forms; that is, we questioned whether a given pixel could be assigned more than one life form for cover type, height, and canopy designations. Multiple life form assignments provided flexibility for the characterization of wildland fuel. Such flexibility would also benefit other potential applications of LANDFIRE data, such as insect and disease or biomass studies. In the process of LANDFIRE vegetation mapping, we therefore modeled each pixel independently for each of the three life forms (forest, shrub, and herbaceous; fig. 1).

Product Validation Plan and Accuracy Assessment

The LANDFIRE accuracy assessment is described in detail in Vogelmann and others (Ch. 13). We tested the approach in which ten percent of the field data points available for cover type mapping were withheld from the mapping process for the purpose of accuracy assessment but found that the approach did not work well because of the uneven availability of field data in support of different cover types in the map unit classification. For several cover types in each of the mapping zones, the amount of data withheld in the 10 percent sample was too low to be statistically meaningful. As the result, we reported overall accuracies for cover types using the results of 10-fold cross-validations. For structure variables, we used a set of independent plots to assess statistical accuracy using regression techniques. This afforded us the opportunity to examine the behaviors of mapping structure variables versus those of categorical variables. Forest canopy cover, mapped with fine-resolution imagery as training data, would be assessed with both a sample of withheld reference points generated from the fine-resolution imagery as well as field estimates obtained from the use of digital cameras equipped with fisheye lenses.

Results

Maps of Cover Type and Structural Stage

We applied the vegetation mapping approach described above to the central Utah and northern Rockies prototype areas. Spectral imagery, biophysical gradients, PVTs, and probabilities were used together with field plot data to produce maps of forest, shrub, and herbaceous cover types, as well as canopy cover and canopy height by life form.

Accuracy of LANDFIRE Prototype Vegetation Mapping

We reported accuracy assessments using a cross-validation approach for cover types by life form (table 3) and by withholding field data for the structure variables by life form (table 4). For cover types, only overall accuracies were reported. For structural stages, R^2 values were variable and ranged from relatively consistent (for forest canopy cover and height) to relatively inconsistent (for shrub and herbaceous canopy cover and height). This variability indicates that forest structure may be mapped reasonably as a continuous variable, whereas consistency and accuracy would be questionable when mapping shrub and herbaceous structure as continuous variables. However, when evaluated as two-class variables (either as closed and open canopy cover or high and low canopy height), results showed that the same shrub and herbaceous structure can perform as consistently and accurately as categorical variables.

Discussion

Analysis of Mapping Consistency for Vegetation Types and Structure

In general, we found that the approach described above for mapping existing vegetation characteristics effectively met LANDFIRE requirements, which was a difficult objective to achieve due to the large number of vegetation map units, reliance on existing field-referenced data, the task of characterizing vegetation structure, and the requirement for a nationally consistent methodology. For the moderately detailed vegetation map unit classification, mapping accuracies of 60 percent or better were achieved at a 30-m spatial resolution.

We explored the mapping of more than two map units for structure variables. For example, we mapped herbaceous height to three map units (0 to 0.5 m, >0.5 to 1 m, and >1 m), shrub height to four map units (0 to 0.5 m, >0.5 to 1 m, >1 to 3 m, and >3 m), and forest height to four map units (0 to 5 m, >5 to 10 m, >10 to 25 m, and >25 m). The tests yielded independent overall accuracies of 73, 61, and 82 percent for herbaceous, shrub, and forest height, respectively. From these results, we concluded that grouping continuous values of the structure variables into several discrete map units would be an acceptable and rational alternative methodology for national implementation of the LANDFIRE methods. Use of this alternative methodology would require the development of a consistent national structural stage map unit classification.

Table 3—Cross validations (10 percent withheld, ten-fold repetitions) conducted separately by mapping zones and by forest, shrub, and herbaceous life forms.

Life form	Mapping zone	Number of classes	Cross validation
Forest	16	10	67
	19	14	64
Shrub	16	14	62
	19	15	68
Herbaceous	16	7	60
	19	8	56

Table 4—Accuracy assessments conducted separately for two structure variables by life forms and map zones. Overall accuracy (OA) was obtained by using holdout withheld field plots (n) that were set aside based on quality and distribution of the total available field plot data (N). Structure variables are treated as both continuous variables measured with the R2 statistic and two-class categorical variables for overall accuracy (OA). The Ttwo canopy cover classes of canopy cover are closed (≥40%) and open (<40%); for canopy height they classes are high (≥10m, 1m, 0.24m) and low (<10m, 1m, 0.24m) for forest, shrub, and herbaceous life forms, respectively.

	Map	Canopy cover			Canopy height		
Life form	zone	n/N	R^2	Overall accuracy	n/N	R^2	Overall accuracy
Forest	16	1,272/20,000	0.78	0.92	220/2204	0.58	0.88
	19	1,200/20,000	0.88	0.89	127/5,541	0.56	0.78
Shrub	16	125/1,253	0.41	0.74	107/1,073	0.36	0.85
	19	119/1,788	0.59	0.79	81/989	0.65	0.86
Herbaceous	16	18/182	0.37	0.71	15/280	0.04	0.86
	19	126/597	0.58	0.69	75/182	0.63	0.70

Consistency in field sampling and data collection affects the consistency of mapping vegetation characteristics. Of the three types of reference data used in mapping existing vegetation, cover type and canopy height values can generally be identified or measured consistently in the field. Canopy cover, on the other hand, can be difficult to measure in the field. This issue does not affect the measurement of forest canopy cover values because training data are derived from high-resolution (1 m or better) imagery by calculating numbers of high-resolution forest pixels within each 30-m Landsat pixel. The use of inconsistently estimated canopy cover values as training data, however, can potentially affect the mapping of shrub and herbaceous canopy percent cover (as happened during the prototype). Shrub and herbaceous canopy results from the two prototype mapping zones were reasonable (table 3), but difficulties in consistently estimating canopy cover in the field indicated that we needed to further research new or alternative methods for mapping shrub and herbaceous canopy cover.

The results of this study may be attributed, in part, to the use of ecologically significant ancillary data layers, which accounts for a moderate but nonetheless significant increase in accuracy (ranging from 1 to 9 percent). The development of biophysical gradient layers and PVT probabilities follows a standardized process for all mapping zones. However, for any given area, satellite reflectance can vary significantly for the same cover type with different canopy cover percentages (either due to land management practices or regeneration stages) or appear similar for different vegetation types or different structural stages during certain seasonal periods. Different cover types or structural stages, however, should respond consistently to the effects of biophysical gradient variables such as soil depth or potential evapotranspiration (PET); this addition of information from the biophysical gradient variables increases the likelihood that these map units will be discriminated by mapping algorithms. For example, one might expect Engelmann spruce (*picea engelmannii*) to grow in relatively deep soil on cool, north-facing sites with low PET, regardless of whether it is found in Zone 16 or Zone 19. Therefore, the incorporation of biophysical and PVT data in the mapping process should contribute to enhanced consistency and thematic accuracy in mapped existing vegetation across the United States.

Even though the existing vegetation maps shown in figures 2 and 3 characterize the vegetation composition of all life forms, it should be noted that each life form was mapped independently, by design, for cover type and structure. Modeling life forms independently preserves the possibility of more than one mapped life form per pixel (in other words, allows for probabilities of multiple canopy layers within a pixel) to improve fuel mapping and enhance the range of the data's ecological applications. However, mapping approaches should be carefully considered when comparing or merging these separate data sets. For example, a final map of cover types may look different depending on the order of precedence between forest, shrub, and herbaceous cover and the threshold values used in defining the life forms (for example, a pixel with 10 percent or greater forest canopy cover may be considered as forested land). It is important that precedence and thresholds be applied uniformly between mapping zones for consistency.

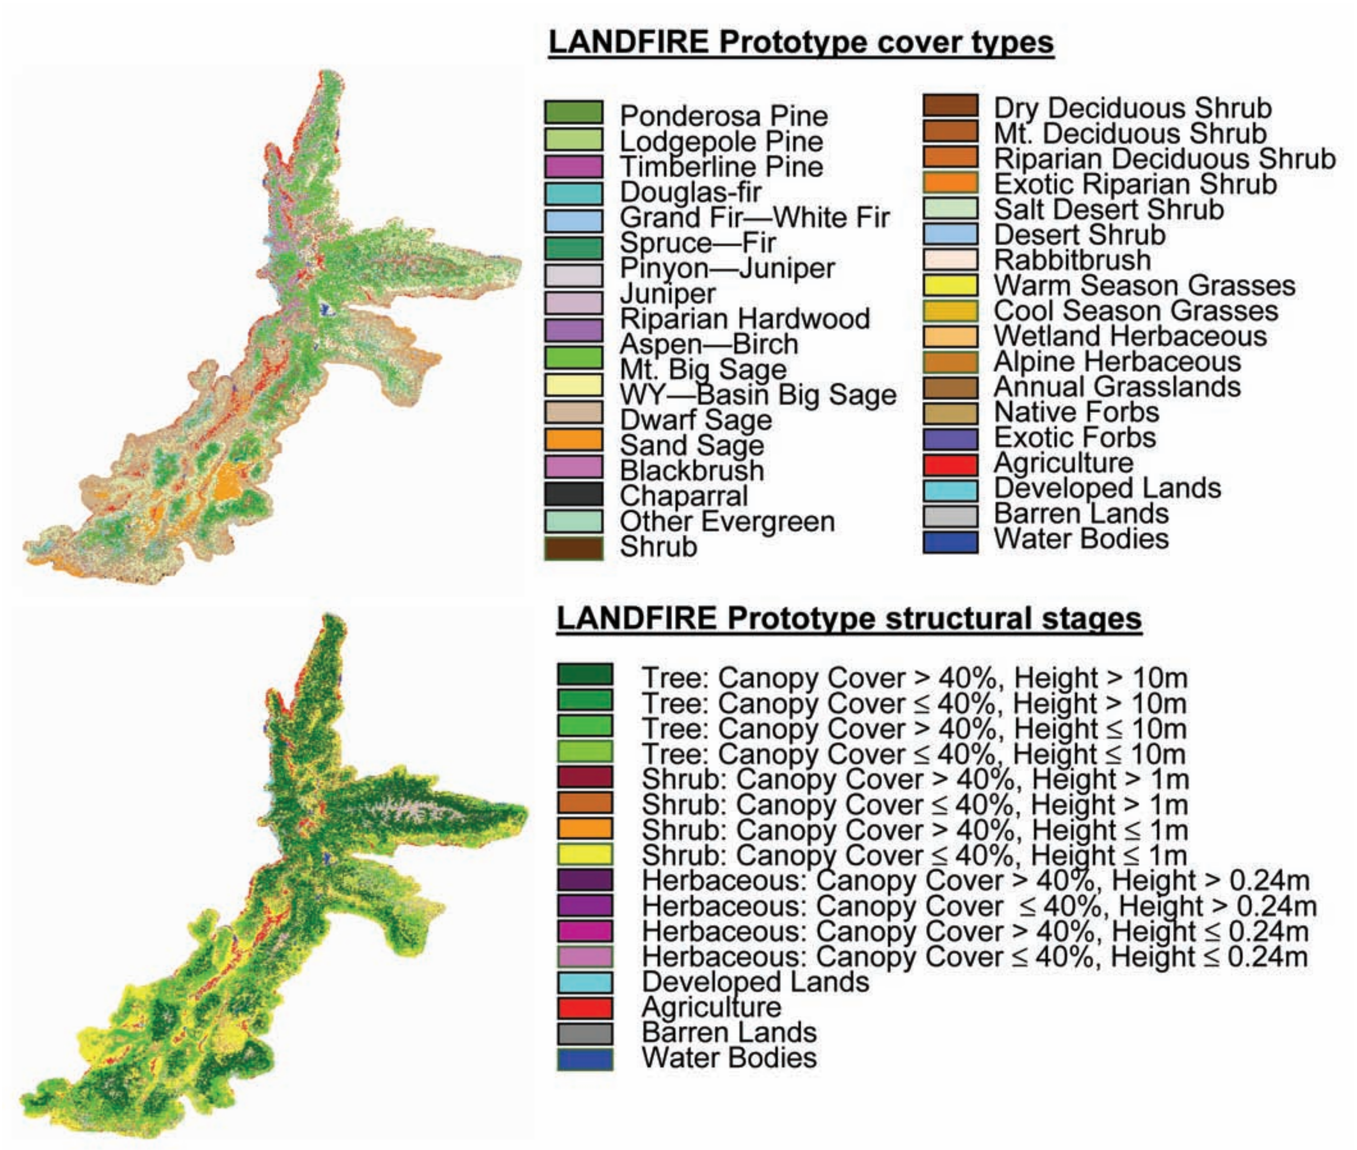

Figure 2—LANDFIRE Prototype cover type (top) and structural stage (bottom) maps for Zone 16. The cover type map is compiled from separate forest, shrub, and herbaceous cover type maps, whereas the structural stage map is grouped from continuous maps of height and cover for display purposes.

Factors that Affect Mapping Accuracies

Several factors should be considered when examining the accuracy estimates for maps of cover types and structure. First, the mapping and accuracy assessment of cover type and structure variables by life form were conducted based on field-referenced databases of different sizes and data collected throughout the study areas using a variety of sampling strategies. As would be expected, vegetation mapping was sensitive to the availability of field data. Test results showed that the number of field-referenced plots used for mapping and accuracy assessment affected not only the level but also the consistency of mapping accuracies, with fewer plots related to greater variability in accuracy estimates and more plots to more robust accuracy estimates (fig. 4). Data for herbaceous vegetation were limited in availability relative to the overall size of the field-referenced data set and hence affected herbaceous mapping accuracy. To improve uncertainties related to shrub and herbaceous cover and height, we determined that these variables should be mapped as categorical map units.

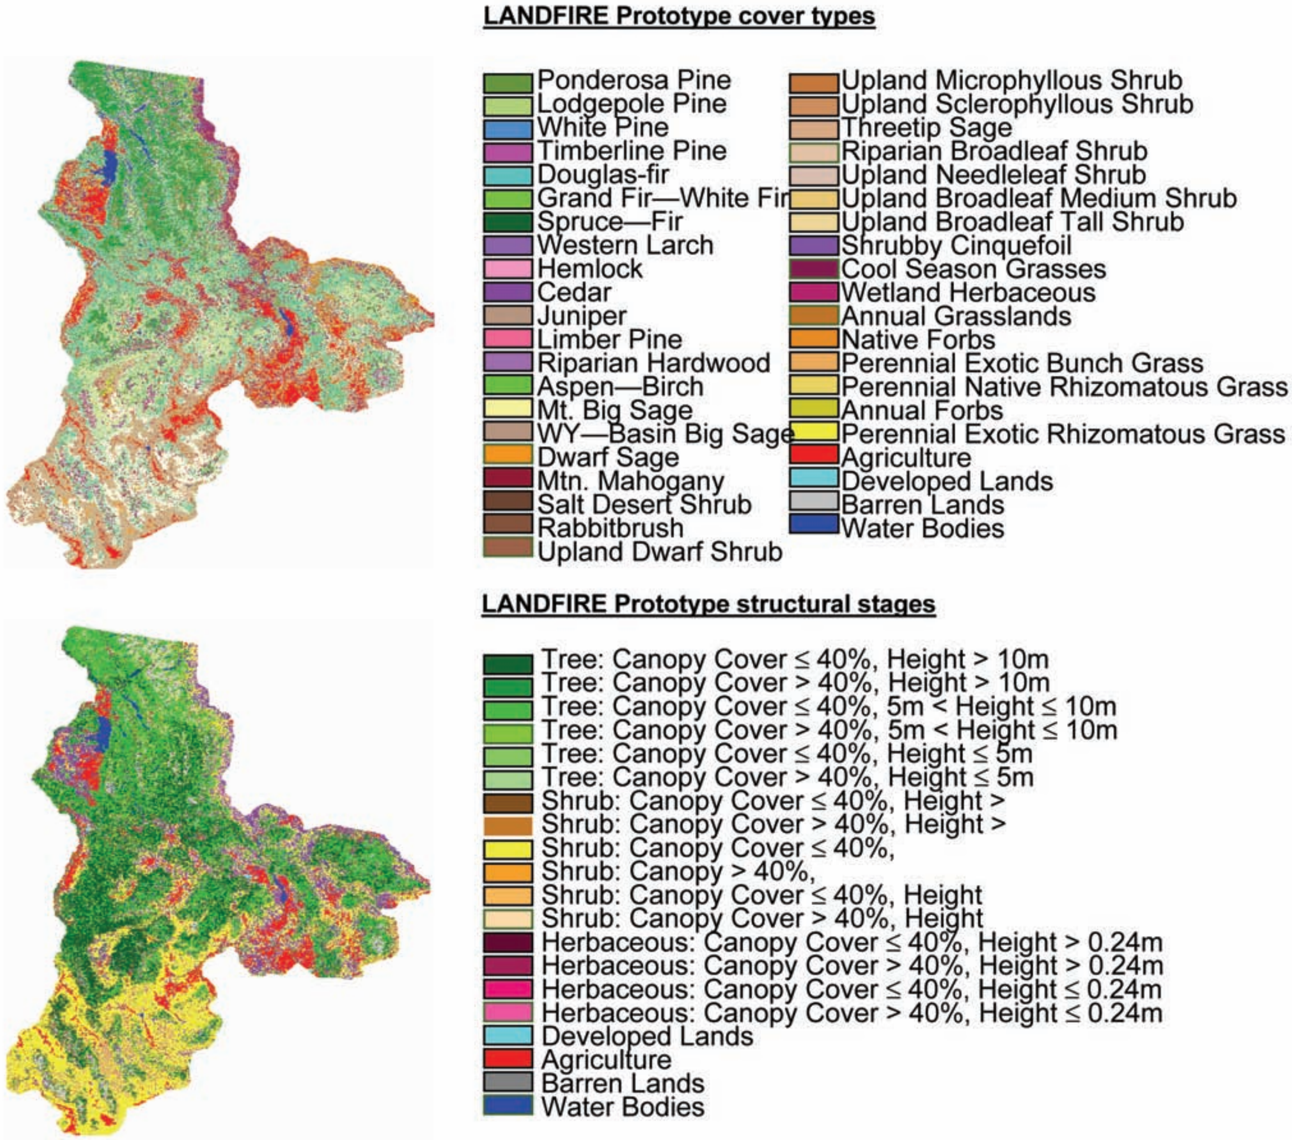

Figure 3—LANDFIRE Prototype cover type (top) and structural stage (bottom) maps for Zone 19. The cover type map is compiled from separate forest, shrub, and herbaceous cover type maps, whereas the structural stage map is grouped from continuous maps of height and cover for display purposes.

Second, field-referenced data, with which mapping models were trained and accuracy assessed, were collected from different sources, for different objectives, and with different techniques. Even though these plot data were quality-screened and standardized through an extensive effort (Caratti and others, Ch. 4), it was inevitable that the differences and errors in field data carried over into map quality and accuracy assessment. For example, certain reference data for forest canopy cover were derived using digital ortho-photographs, viewing forest cover synoptically from above the canopy. On the other hand, field estimates for shrub and herbaceous canopy cover were made using visual estimation from close-range, oblique positions that limited objectivity and consistency. We did not experience these problems when determining forest, shrub, and herbaceous *height*, which was usually directly measured and had a high degree of user-confidence.

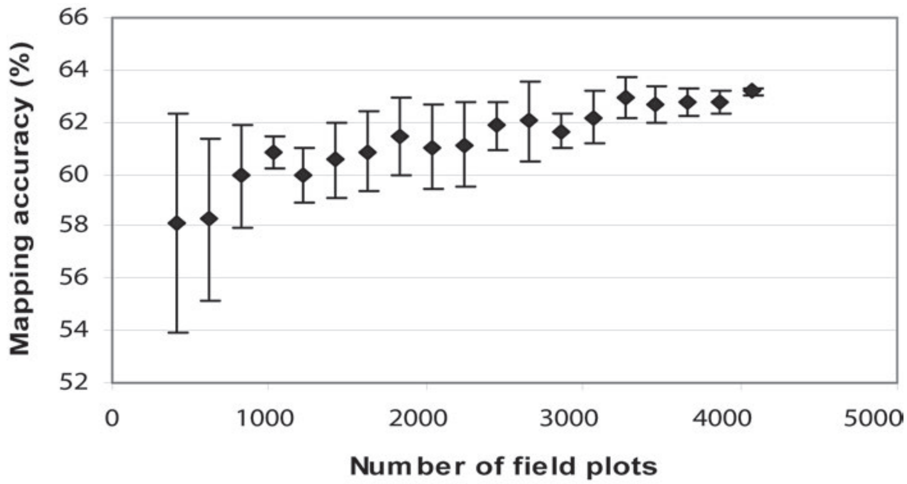

Figure 4—Cross-validation accuracy estimates obtained for the mapping of forest cover types as a function of the number of forest field plots. More plots contributed to better accuracy and consistency (smaller standard deviation) to a certain point, after which the relationship became flat.

Third, as discussed above, rare map units and ecologically and biophysically similar map units affected mapping accuracies. For example, if the Juniper cover type was merged with the combined Pinyon – Juniper cover type, forest cover type accuracy increased by more than 10 percent. The rationale for keeping such similar cover types separate is that, even though they occupy similar ecological niches and have similar site characteristics, separating them increases the utility of the LANDFIRE wildland fuel and fire regime products.

Utility of Biophysical Gradient Data for Vegetation Mapping

Although the use of DEM data for improving mapping results has been widely documented, the effects of a whole host of biophysical gradient layers and PVT-probability data layers is largely untested at the scale and scope of this study. These data layers provide information that supplements satellite imagery. Plant distribution patterns and conditions are strongly linked to a multitude of environmental factors (for example, temperature, soil, weather patterns, day length, soil properties, and rainfall), and the accurate characterization of these variables should, at least in theory, improve mapping results. In addition, spatial information that indicates where particular vegetation types can and cannot exist across a wide region (that is, PVT-probability data layers) should be similarly useful. Figure 5 compares cross-validation results using mapping models with and without the additional biophysical gradients listed in table 1 and using PVT-probabilities as predictor variables. Figure 6 displays mean and standard deviation values of a subset of the biophysical variables intersected with vegetation cover types from field plot data collected in the central Utah prototype area. These figures show that the incorporation of certain biophysical gradients and PVT-probabilities in mapping models contributes to increased mapping accuracy and consistency. These results are consistent with the findings of Keane and others (2002) and Rollins and others (2004).

Vegetation Patterns in Areas of Major Disturbances

Wildfires, insect and disease outbreaks, and forest clear cuts are some of the major disturbances to ecosystems captured by the satellite sensor in terms of their spectral properties. How well did our mapping capture and reflect these changes in vegetation conditions? We evaluated our mapping methods' effectiveness in this regard by looking at known areas of wildland fire, bark beetle infestation, and clear-cuts in the prototype mapping zones.

We evaluated two wildland fires areas that burned in Bryce (summer 2001) and Zion (fall 2001) national parks to determine what differences might exist between pre-fire and post-fire vegetation maps when mapped with the same pre-fire models. Pre- and post-fire map comparisons showed distinct differences between both

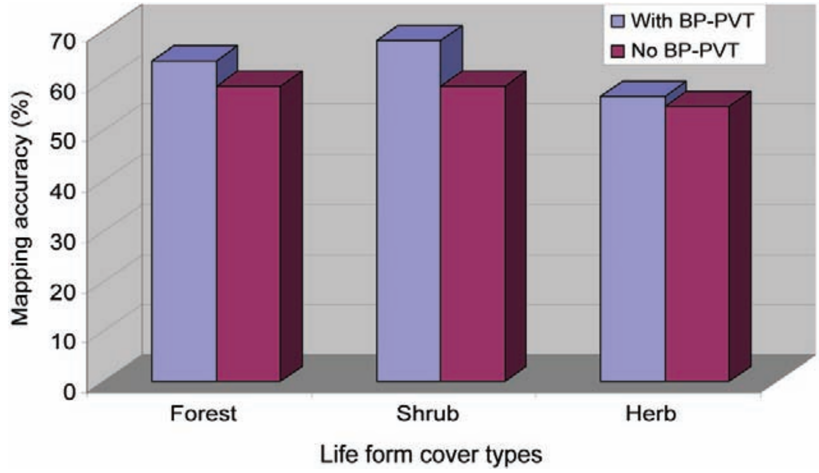

Figure 5—Cross-validation accuracy estimates obtained in the Zone 16 prototype area, by life form, with and without the 15 biophysical gradients and PVT-probabilities in the mapping models. An average of 8 percent increase in cross-validation accuracy was obtained by incorporating the selected biophysical gradients and PVT-probabilities that together describe the habitats of the cover types to be mapped.

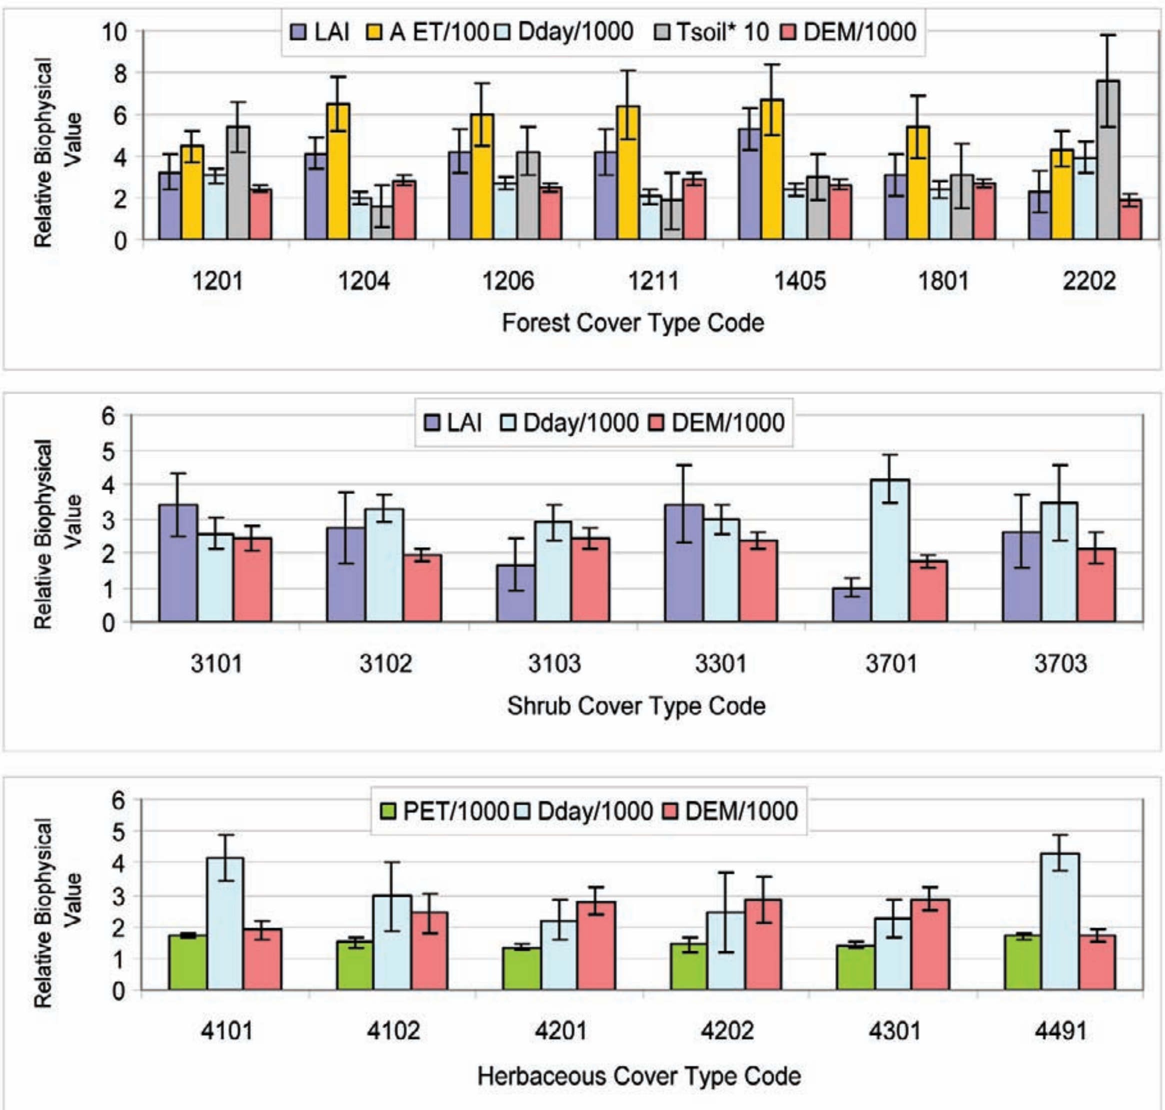

Figure 6—Mean and standard deviation values of selected biophysical variables found effective in mapping cover type against various forest (top), shrub (middle), and herbaceous (bottom) cover types of field-reference data. Most of the biophysical variables were divided or multiplied by a constant for display purposes. Refer to table 1 for definitions and descriptions of the biophysical variables. Refer to Long and others, Ch. 6 appendix 6-A for vegetation cover type coding protocol.

vegetation cover types and structural stages. The Bryce fire, a prescribed fire, showed general shifts from forest to shrub map units and, regarding structure, showed a shift toward increased low-height shrubs. The Zion fire, a wildfire, revealed a shift from predominately deciduous forest types to low shrubs.

Using bark beetle survey data obtained from the Dixie National Forest, we conducted simple zonal statistical analyses. Results indicated that the mapped species composition corresponded fairly well to that of those species identified in the survey data for the years 1998-2000. (Note that the level of actual disturbance varied within the survey data and was not differentiated in this study.) Structure information was not available in the survey data, but mapped structure data indicated that most bark beetle infestations occurred in areas identified as high forest cover (greater than 40 percent canopy cover) and height (greater than 10 m), indicating old-growth forest.

Similarly, we compared clear-cut areas, identified using modeling and masking methods, with mapped vegetation cover type and structure variables. Shrubs and a high percentage of grasses were dominant in clear-cut areas. Structural stages indicated a trend from forests with high canopy cover and canopy height to a high percentage of low cover (less than 40 percent), low height (less than 1 m) shrubs. Herbaceous cover was identified as being high cover (greater than 40 percent) with mixed heights.

Field Data Quality and Quantity Requirements

The acquisition of field-referenced data posed a significant challenge to the LANDFIRE Prototype effort, both logistically and technically. Caratti (Ch. 4) describes the logistical efforts and complications associated with conducting a national field data campaign. Specifically, technical challenges encountered during the mapping process, such as uneven amounts and disparate quality of field data used to meet various vegetation mapping objectives, were tied to the fact that the LFRDB was based on data from varying sources and collected with different objectives. As discussed above, such issues necessitated the careful implementation of a quality-control and quality-assurance (QA/QC) process prior to the training of the mapping algorithms for existing vegetation types and structure. "Lessons learned" from the QA/QC process follow:

- Accuracy and consistency are a function of the amount of available field-referenced data. Greater amounts of field-referenced data contribute to enhanced confidence in mapping accuracy (fig. 4), whereas limited field-referenced data are correlated to reduced confidence in mapping accuracies of affected cover types.
- The use of data from different sources requires that special attention be given to those cover type map units that are not supported with sufficient numbers of field plots. Both prototype mapping zones had map units with only a few field reference data points for training. As discussed above, the question of how to define and treat rare map units arose during the prototype, and we defined rare map units as those having less than 30 field reference plots scattered spatially within a mapping zone. Options for the treatment of these rare map units included keeping the map units in maps, omitting them, or omitting them and then "burning" the few field plots to the map in a post-process and merging them with floristically similar cover types. For the prototype, we chose to retain the rare map units in the models and resulting map products to inform the development of the LANDFIRE vegetation map unit classification system. For national implementation, rare map units that cannot be supported with a sufficient number of field plots will not attain target-level accuracies. We recommend omitting such map units from the mapping of existing vegetation cover types.
- Spatial distribution and a valid probability-based sampling design increase the consistency and accuracy of the map products. Compared with field-referenced data from various agency sources, the use of FIA forest inventory plots for mapping forest cover types and structure produced more consistent and accurate mapping results because the sampling design for FIA data produced training data that were spatially well-distributed across the landscape. Further, FIA data required very little additional processing time and were easy to use; in contrast, non-FIA field data required extensive processing time, related to QA/QC and re-selecting/re-sampling, to derive suitable data sets (in terms of spatial distribution and data quality) from available data points. For example, in Zone 19, a Bureau of Land Management study produced more than 4,800 field plots, mostly describing sagebrush, Douglas-fir, and lodgepole pine vegetation communities, in a relatively small area of approximately 1,152 km^2, near Salmon, ID. Spatially, this data set equated to approximately one plot for every 24 ha, versus a mapping zone average of one plot for every 835 ha. The inclusion of this data set in the

training process overwhelmed the mapping models and overrode areas with sparse plot coverage of different cover types. We therefore determined that the application of locally limited or concentrated data collected using various sampling designs to an entire mapping zone could have adverse effects on the accuracy of final products. For this reason, forest mapping in LANDFIRE National should employ FIA data exclusively. Rangeland mapping in LANDFIRE National, however, will require extensive QA/QC processing steps to transform available field-referenced data to a more suitable data set.

- As noted above, the following critical steps should be taken prior to the development of the mapping models: 1) examine field-referenced data, 2) conduct QA/QC procedures to detect spatial errors as well as information content-related errors, 3) correct these errors if necessary, and 4) derive a final, refined, error-free data set for training and accuracy assessment. This is a time-consuming yet necessary process that will contribute to increased consistency and confidence of map products.

Effects of the Vegetation Map Unit Classification System

Determining accuracy objectives and the appropriate extent of mapping areas are among the factors that need to be considered when defining a workable national vegetation map unit classification system. If floristically or ecologically overlapping cover types (such as Juniper and Pinyon -- Juniper or Upland Microphyllous and Upland Sclerophyllous) are to be mapped for LANDFIRE National, then guidelines must be developed for defining how the mapping accuracy of such overlapping map units is to be assessed.

Next, although our use of the NVCS was a reasonable starting point for vegetation map unit classification and the approach worked fine for each individual mapping zone, vegetation cover types were not always comparable between the two prototype mapping areas, however, as is evidenced by the legends in figures 2 and 3. As a result, accuracy estimates for the two prototype mapping zones could not be compared in a straightforward fashion, particularly for shrub cover types.

As discussed above, another challenge encountered during the application of the two vegetation map unit classification approaches (as discussed above in the *Vegetation Map Unit Classification* section) was answering the question of how to treat rare map units. There were no guidelines for consistently defining and treating rare map units. Moreover, there was no answer as to whether dropping rare map units, instead of using the alternative options discussed above, might affect the utility of LANDFIRE vegetation maps in other future natural resource management projects.

Recommendations for National Implementation

Because of the size and complexity of this research effort, many questions concerning LANDFIRE's national implementation are as of yet unanswered. The field data compilation effort will be an expensive and time consuming task, and a pressing need exists regarding the study of links between mapping performance, resource expenditure, and methods of field data collection. Ecological relationships between mapped potential vegetation and existing vegetation need to be investigated. Further research must be conducted to quantify the relative contributions of the different approaches and data sets used in the prototype. Performance consistency must be tested between adjacent western mapping zones, as well as in one or more prototype areas located in the eastern United States. Repeatability of the methods used in the prototype, both temporally and spatially, must also be evaluated. Furthermore, it is not clear whether the LANDFIRE Prototype methodology will suffice for other vegetation metrics, such as quantifying woody or non-woody biomass; a study in this area could yield information leading to enhanced applications of LANDFIRE vegetation maps. Nevertheless, the LANDFIRE Prototype Project provides sufficient information on which to base several recommendations regarding the national implementation of LANDFIRE.

Ways to Ensure Consistent National Vegetation Mapping

As noted above, several tasks related to existing vegetation mapping for the prototype effort may be standardized and potentially automated to facilitate LANDFIRE's national implementation. These tasks include: 1) the creation of a national vegetation map unit classification system that is mappable using spectral and biophysical/ecological data and is supported with adequate field-referenced data; 2) the consistent acquisition and processing of a multi-seasonal Landsat database; 3) the application of QA/QC procedures to the LFRDB to ensure a robust field-referenced database that can be used for a wide variety of applications; 4) the consistent modeling of biophysical data layers and probabilities of existing vegetation species or types associated with potential vegetation types; and 5) the continued application of CART as the primary mapping algorithms to ensure objectivity and flexibility when using high volumes of field data and predictor variables. We discuss these points in detail below.

Need for a Mappable Vegetation Map Unit Classification System

The vegetation map unit classification system used for the national implementation of LANDFIRE must meet a number of key criteria including the following: 1) the system must be nationally consistent, ecologically logical and hierarchical, acceptable to a wide array of users and groups, and must meet existing Federal Geographic Data Committee (FGDC) standards; 2) vegetation map units must be mappable using operational methodology to achieve reasonable accuracies; and 3) the map unit classification system must include vegetation map units that have high relevance with respect to the core LANDFIRE products. The Ecological Systems classification (Comer and others 2003) developed by NatureServe meets these objectives. This system represents the hierarchical merging of NVCS alliances into a nationally available suite of vegetation map units. Unlike alliances, which have proved exceedingly difficult to map accurately, most Ecological Systems classes are mappable, assuming an adequate number of field plots exist for training purposes. In addition, the Ecological Systems classification was developed by plant ecologists, lending credibility to the approach and resulting in a greater level of acceptance throughout the user community. We anticipate that a few additional "target alliance" map units will be added to the LANDFIRE National map unit classification legend on a case-by-case basis. These will be added only when it is determined that a particular map unit not specifically identified by the Ecological Systems classification has special relevance to LANDFIRE.

Need for National Field-referenced Data Collection and Processing

Many LANDFIRE tasks rely on a comprehensive, consistent, and extensive field-referenced database. The database serves as a reference for the development, testing, and accuracy assessment of all LANDFIRE vegetation, biophysical settings, and wildland fuel data layers and of all vegetation and fire regime simulation models. Field data from existing projects should be incorporated into this database whenever available and should include but not be limited to data sets such as FIREMON fire monitoring databases, USFS Landscape Ecosystem Inventory Systems databases, and the National Park Service fire monitoring databases. In addition, the USFS FIA Program's forest inventory plot database proved a useful source for the majority of forest data. Where data are lacking, supplemental field data collection is required to fill informational needs on rangeland map units. This assortment of field-referenced data should be collectively scrutinized for quality assurance, regularly updated, and maintained as a comprehensive LANDFIRE field-referenced database.

Need for Nationally Consistent Imagery Database

The availability of a quality Landsat imagery catalog is a key prerequisite for national implementation of the approaches developed for the LANDFIRE Prototype Project. Among all predictor variables, it is satellite imagery that usually captures the most current vegetation conditions, and, when used repeatedly over time, identifies changes in vegetation conditions and distributions. Thus, we recommend that LANDFIRE National continue to play an active role in the MRLC Consortium. This membership ensures the continued development of suitable multi-seasonal Landsat image catalogs, optimal levels of image processing (geometric, radiometric, and atmospheric rectification and calibration) for the rest of the country, and mapping zone-based image compilation for national vegetation mapping. In addition, LANDFIRE National should support studies that examine and compare the characteristics of other mid-resolution sensors with those of Landsat. Even though the LANDFIRE Project does not currently require any additional Landsat imagery, the potential benefits of using different satellite data for future updating should be considered.

Need for Nationally Consistent Set of Biophysical Gradient Layers

Biophysical gradients have effects similar to that of Landsat imagery on the spatial and information integrity of existing vegetation maps. Many of the biophysical layers are physiologically and ecologically related to the establishment, distribution, and conditions of plant species, and the incorporation of these gradient layers into the mapping process contributes to increased accuracies. For the national implementation of LANDFIRE, we recommend that a set of biophysical gradient layers similar to those listed in table 1 be used to map vegetation in all mapping zones. In addition, we recommend that further research be conducted to quantify the contribution of the individual biophysical variables to mapping accuracy. Furthermore, research should be conducted to minimize residual coarse-resolution imprints in 30-m biophysical data resulting from the coarser resolution weather and soil databases used to produce these data. The development of standard minimum mapping units in modeling simulations has shown promise in standardizing the process and eliminating coarse imprints.

The Need to Continue with Research and Improvements

Although results of the LANDFIRE Prototype Project indicate that the general approach should effectively meet target accuracy and consistency requirements for national implementation, there are areas where continued research and improvements are needed. One ongoing research effort involves the development of a new and more consistent approach to mapping shrub and herbaceous canopy cover. Current research is testing ways to effectively correlate calibrated Landsat-based NDVI to shrub and herbaceous canopy cover (Liu and others 2004). Other research areas include more efficient use of the individual biophysical gradient layers, more effective mapping of riparian vegetation, and a national accuracy assessment strategy.

Conclusion

The mapping of existing vegetation with complete national coverage at a 30-m spatial resolution is a core requirement of the LANDFIRE Project. National data at this 30-m resolution do not currently exist. As a result, the prototype research was needed to answer questions related to the mapping and characterizing of cover types and structure variables. LANDFIRE's existing vegetation products are expected to provide data not only for use in wildland fire management, but also for use in many other natural resource and environmental applications. Findings from the LANDFIRE Prototype effort are summarized as follows:

If supported with an adequate amount of field-referenced data, target accuracies of 60 percent or better are achievable for a mid-level vegetation map unit classification at the regional scale. The addition or subtraction of floristically or ecologically similar cover types has significant effects on resulting accuracies. Of the three major life forms, herbaceous cover types are the most difficult to map because these species adapt to many general biophysical characteristics and have few unique spectral signatures. Relationships between the floristic complexity of the vegetation map unit classification and mapping accuracies indicate that the national vegetation map unit classification will need to be designed carefully to include adequate flexibility.

For LANDIFRE, vegetation structure is defined by canopy cover and canopy height of forest, shrub, and herbaceous life forms. These structure attributes can be mapped consistently as categorical variables. Mapping these attributes as continuous variables, particularly for shrub and herbaceous height and cover, is inconsistent and, thus, is not recommended for national implementation of the LANDFIRE prototype methods.

Field data collection and processing are the most critical factors in ensuring that LANDFIRE maps of existing vegetation are objective and accurate. The detection and correction of errors existing in field-referenced data are time-consuming but absolutely necessary tasks, particularly for field data from sources other than FIA (as these other data sets tend to be locally limited and have various sampling designs). The objective of repeated field data processing and quality control is to derive a refined, high-quality field data set.

The incorporation of LANDFIRE biophysical gradient layers and cover-type probabilities associated with potential vegetation types into the mapping models contributes to a significant increase in mapping accuracy. In addition, the use of the biophysical and ecological stratifications that describe the environmental effects on species establishment and growth also contributes to enhanced mapping consistency.

The Authors

Zhiliang Zhu is a Research Physical Scientist with the DOI USGS Center for Earth Resources Observation and Science (EROS). Zhu's research work focuses on mapping and characterizing large-area land and vegetation cover, studying land cover and land use change, and developing remote sensing methods for the characterization of fuel and burn severity. His role in the LANDFIRE Prototype Project has been to design and test a methodology for the mapping of existing vegetation cover types and vegetation structure and to direct research and problem-solving for all aspects of the methodology. He received his B.S. degree in Forestry in 1982 from the Nanjing Forestry University in China, his M.S. degree in Remote Sensing in 1985, and his Ph.D. degree in Natural Resources Management in 1989, both from the University of Michigan.

James Vogelmann is a Principal Scientist with the Science Applications International Corporation (SAIC), contracting with the DOI USGS Center for Earth Resources Observation and Science (EROS). Vogelmann's research work focuses on large-region land cover characterization and change assessment using remote sensing and ancillary sources of spatial data. His roles in the LANDFIRE Prototype Project have been to assess different methods for mapping vegetation types, to serve on the LANDFIRE Vegetation Working Group, and to help direct project research activities. He received his B.A. degree in Botany from the University of Vermont in 1978 and his Ph.D. degree in Plant Sciences from Indiana University in 1983.

Donald Ohlen is a Environmental Scientist for the Science Applications International Corporation (SAIC) at the DOI USGS Center for Earth Resources Observation and Science (EROS), 47914 252nd Street, Sioux Falls, SD 57198; phone: (60. Ohlen's research work and interest focus on land cover mapping for fire science applications, including the characterization of satellite data for fuel mapping and post-fire burn mapping. He earned his B.S. (1976) and M.S. (2000) degrees in Geography from South Dakota State University.

Jay Kost is a Research Physical Scientist with the Science Applications International Corporation (SAIC), contracting with the DOI USGS Center for Earth Resources Observation and Science (EROS). Kost's work focuses primarily on mapping existing vegetation and vegetation structure (percent canopy and height) for the LANDFIRE Project using decision and regression tree models. Optimization of these models and high map accuracy results are paramount in his work and improvements in methodology and results are continually pursued. He received his B.S. in Electronic Engineering Technology in 1987 from Minnesota State-Mankato and his M.S. degree in Space Studies from the University of North Dakota, Grand Forks. In addition, Kost has completed four years of post-graduate study in the Atmospheric, Environmental, and Water Resources Ph.D. program at South Dakota State University, Brookings.

Xuexia (Sherry) Chen is an Environmental Scientist with the Science Applications International Corporation (SAIC), contracting with the DOI USGS Center for Earth Resources Observation and Science (EROS). Chen's research work focuses on vegetation mapping of canopy cover and canopy structure. Her role in the LANDFIRE Prototype Project has been to develop a hierarchical methodology for the mapping of existing vegetation cover types and vegetation structure and to explore new technologies for accuracy and efficiency improvements in LANDFIRE products. She received her B.S. degree in Geography in 1997 and her M.S. degree in Environmental Sciences in 2000, both from Peking University, China. Chen received her Ph.D. degree in Atmospheric, Environmental, and Water Resources in 2004 from the South Dakota School of Mines and Technology.

Brian Tolk is a Research Scientist with the Science Applications International Corporation (SAIC), contracting with the DOI USGS Center for Earth Resources Observation and Science (EROS). Tolk's research work focuses on the mapping and characterization of large-area land and vegetation cover and on the use of close-range remote sensing methods to aid and improve LANDFIRE mapping techniques. His role in LANDFIRE has been to map land cover and structure variables for the prototype zones, implement a data management scheme, and produce promotional products for the project. He received his B.A. degree in Geography from Augustana College, Sioux Falls in 1990 and his M.A. degree in Geography from the University of Nebraska, Lincoln in 1996.

Acknowledgments

We acknowledge the funding provided by the USDOI Office of Wildland Fire Coordination and the USFS Fire and Aviation Management. In addition, the cooperation of the USFS FIA office in Ogden, Utah, is gratefully acknowledged. We also wish to acknowledge the help and support provided by the staff at the USDA Forest Service Fire Sciences Laboratory in Missoula, Montana and by the staff at Utah State University in Logan, Utah. The research was performed in part by the Science Application International Corporation under U.S. Geological Survey Contract 1434-CR-97-40274 and 03CRCN0001.

Scoping Comments for the Encino Vista Landscape Restoration Project

Dear Mr. Nieto,

I am respectfully submitting these comments to the U.S. Forest Service concerning the scope of the agency's analysis under the National Environmental Policy Act (NEPA) of the Encino Vista Landscape Restoration Project across approximately 128,400 acres within the Coyote Ranger Districts on the Santa Fe National Forest.

I. General comments:

The Encino Vista Landscape Restoration Project is located on the Coyote Ranger District of the Santa Fe National Forest south of the communities of Cañones, Youngsville, Coyote, and Gallina, New Mexico. The project boundaries encompass over 128,400 acres of which 119,767 acres are national forest lands. The project area overlaps thirteen HUC 12 sub-watersheds. The majority of the project is within these sub-watersheds: Coyote Creek, Cañones Creek, Headwaters Rio Puerco, Poleo Creek, Outlet Rio Puerco, Upper Rio Galina and Rio Capulin.

The project area is situated between the elevation of 6,450 and 10,600 feet. The area includes piñon/juniper woodlands, ponderosa pine, mixed conifer, aspen and spruce-fir forest types.

It includes essential habitat for many wildlife species, including several endangered or at-risk species including Mexican spotted owl, Northern goshawk, New Mexican meadow jumping mouse, Southwestern willow flycatcher, Jemez Mountain salamander, and Rio Grande cutthroat trout.

The project area is an ecologically diverse treasure and valued by many local residents for recreation.

The Proposed Action envisions thinning treatments on a total of up to 88,400 acres of the project area. It envisions prescribed burning on a total of up to 110,213 acres, and maintenance burning would occur in areas treated with prescribed fire at 5-20 year intervals. This is the largest project ever proposed in the Santa Fe National Forest. Only 22,225 acres of forest would be managed for old growth characteristics.

An Environmental Impact Statement *must* be prepared. The Encino Vista Landscape Restoration project, including the proposed Forest Plan amendment, "may' have a significant impact on the environment, and thus the Forest Service must prepare a robust EIS, ensuring that it complies with NEPA's required "hard look." The EIS must analyze the baseline conditions of the project area, and the direct, indirect and cumulative impacts of the proposed timber management activities, road construction and maintenance, and all other activities. The public must be fully included in the project planning process.

Sufficient notice of the project and the comment period was not given. Very few people in the Santa Fe area, where most of the forest protection advocates focused on the Santa Fe National Forest reside, were aware of the project and the ongoing comment period until the comment period was half way complete. There was no notice placed in any newspaper, and the notice was only put out on a very limited mailing list. I strongly suggest the USFS start over on the scoping comment period and put out proper notice so all citizens and conservation groups who are interested will have time to write comprehensive scoping comments.

The best available scientific information (BASI) must be utilized in project planning, and the U.S. Forest Service is require to explain how it met this mandate. There are numerous studies that support a much more conservationist approach to managing the Encino Vista project area that have not even been considered. The USFS must consider a broad range of best available science.

While the SFNF's lower elevations were historically dominated by low-severity fire, there was an under-appreciated and substantial moderate severity and high severity fire component. This forest evolved in a mixed intensity fire regime, and all intensities of fire are important for maintaining ecological processes and integrity. Moderate and high intensity fire should be considered as natural to our forest ecosystem and no attempt should be made to exclude them except for the safety of important values such as human lives (egress from communities and forest recreational areas) and structures. Research shows that medium and long-term the effectiveness of watersheds is not substantially impaired by fire, even high intensity fire.

The model framework the USFS is using is found in GTR-310, a framework developed primarily in and for an entirely different eco-region, focused primarily in reference study sites around Flagstaff. It is appropriate for use for the SFNF. A more appropriate and region-specific framework must be developed. Please provide examples of where the desired condition has been achieved. It is important that areas in which the desired condition have been achieved be evaluated.

Planning treatments based on general landscape categories such as Ecological Response Units is not nearly targeted and strategic enough, and is a broad stroke way of planning that is likely to result in much ecological damage. These days, in cancer treatment, therapies are no longer broad poisoning of much of the system, but targeted and strategic, and often have a much more positive outcome with much less adverse effects. This should be emulated. The forest is not "ill" in a way that it cannot largely recover from through its own regenerative processes.

Forest that were treated with mechanical thinning in fuel treatment projects that have occurred recently and in the more distant past in the Santa Fe National Forest, and subsequently treated with prescribed fire periodically are not healthy forests and do not in any way resemble historical forests. Forest fuel treatments must be re-evaluated and done in a much more limited, light-handed and strategic way, if a comprehensive cost/benefit analysis indicates that it is beneficial that they be done at all.

There must be a strong focus on connectivity, and on preserving the forest as free of adversely impactful interventions as possible. Much more acreage of forest should be managed for old growth characteristics.

No amendment should be made of the existing Forest Plan for this project relating to Mexican Spotted Owl. The Encino Vista Landscape Restoration Project directly contradicts the current injunction on logging activities in Mexican Spotted Owl habitat. It is highly disappointing that the USFS is proposing to contradict an existing court ordered injunction. This should not occur.

The USFS must consider an alternative that truly conserves and protects the SFNF while focusing on fire moderation from the home and other values outward. The Proposed Action does not go nearly far enough in conserving forest ecology and resources. Also, it is essential to incorporate into the project the major elements from the Santa Fe Conservation Alternative, submitted by WildEarth Guardians, Defenders of Wildlife and Sierra Club for the Santa Fe Mountains Landscape Resiliency Project. It is equally applicable to the Encino Vista Landscape Restoration Project, and included below.

Please use the principles of the Santa Fe Conservation Alternative to develop a much more nuanced restoration project, focused primarily on real restoration such as decommissioning unneeded roads, planting in riparian ways and erosion control. A robust monitoring program is of the essence.

II. Additional Concerns:

1) Monitoring — There must be a robust monitoring program developed and put into in place. It should thoroughly consider effects of fuel treatments on overall forest ecology, connectivity, riparian ways, wildlife (especially endangered and at-risk species), tree health, affects on recreation and the health impacts of prescribed burn smoke on humans and wildlife. Mexican spotted owl populations must be monitored. It is necessary for a requirement to be put into place that the project be halted if the monitoring plan is not thoroughly and comprehensively carried out.

2) Assumptions — Many assumptions are based on unproven science or studies that have substantial flaws and invalid conclusions. Assumptions should be thoroughly evaluated using a broad range of research including studies that support a more conservationist view of forest management. The explanation in the Scoping Document of why there is an increased and substantial fire risk is very limited to one scientific perspective (connectivity of fuels), when as delineated in the Common Ground report, there are three important scientific perspectives regarding the condition of our forests. Climate needs to be considered much more in the analysis of this project, both as a causative factor for fire and that there is a need to preserve trees to sequester carbon.

3) Conservation — There should be a general strong bias in project planning towards conserving our forest in as natural a condition as possible, and to allow forest ecology itself to bring our forest into greater balance through natural processes. There are too many substantial adverse impacts related to intensive tree thinning and prescribed burning. Treatments should be very limited, site-specific and strategic, as recommended by the Santa Fe Conservation Alternative.

4) Genuine restoration — Focus should be on genuine restoration activities instead of cutting and burning. Decommissioning of all unneeded roads must be included in project planning. Focus should be on true restoration such as planting in riparian areas as needed and hand-building structures in arroyos to slow flood waters.

5) Reduce prescribed burns for public health — The Proposed Action contains up to 110,213 acres of prescribed burning. That much burning will have very large negative impacts on public health. There is a great deal of upset and controversy among the public about the adverse health effects many are experiencing from the large number of prescribed burns and wildfires expanded with fire accelerants in recent years. The number of days per year that the USFS performs prescribed burns must be capped, so that there is a very limited number of days that create smoke impacts on the public. The effects of volatilized fire accelerants must be analyzed. A system

must be set up to take in and document public health impact reports.

6) Roads — There are 6,900 miles of roads in the SFNF, many of which are leaking sediment into streams and fragmenting wildlife habitat. According to the 2008 Travel Management Record of Decision for the Santa Fe National Forest, 2,878 miles of open system roads were to be closed for public use. A minimum network of roads should be identified for the Encino Vista Landscape Restoration Project area, and all unneeded roads should be closed and/or decommissioned.

7) Invasive species — The Proposed Action does not include sufficient actions for limiting the spread of invasive species via management of livestock grazing, roads, equipment used for thinning and OHVs. A thorough plan must be developed.

8) Thinning — The framework provided by GTR-310 clearly supports over-thinning in the SFNF. Projects done in the SFNF post GTR-310 are not much healthier in appearance than pre-GTR-310. The cost/benefit analysis of thinning, especially the severe thinning recommended by GTR-310, a document not focused on our forest type, has not been done. Any thinning done should be very light-handed, targeted and limited to protect specific discreet values or for extremely dense areas previously damaged by logging.

9) Prescribed burns — There may be some justification for limited prescribed burns where the duff and understory are very thick, but the widespread prescribed burning that is repeated every several years has clearly not supported forest health. The forest understory is never allowed to return, or as soon as it has started to return it is burned off again. The use of prescribed burns needs to be re-evaluated using the full range of the best available science.

10) Connectivity — Connectivity is inadequately addressed in the Proposed Action, having an emphasis on vegetation management in Ecological Response Units. Connectivity should be a major focus and strong and effective wildlife corridors developed.

11) IRAs — No mechanical thinning should occur in Inventoried Roadless Areas, and very little prescribed burning — only when there is a limited, strategic and site-specific reason. IRAs should be left as intact as possible.

12) WUI communities — Thinning should not be done further than 150 feet from structures in WUI areas for the prevention of fire in WUI communities as it has been proven to not be an effective strategy for this purpose by former USFS researcher Jack Cohen and others. Forests adjacent to communities should be left intact and natural as possible to be used for recreation. Support and education should be given to WUI property owners to effectively fire proof their homes and the surrounding 150 feet. The development of alternative egresses for communities that have only one egress should be supported.

III. The Santa Fe Conservation Alternative

The Proposed Action does not adequately meet the conservation requirement of the 2012 forest planning rule. "Conservation. The protection, preservation, management, or restoration of natural environments, ecological communities and species." Alternative 2 includes forest fuel treatments and road development that clearly, in the SFNF, greatly harm the forest ecosystem in numerous ways.

WildEarth Guardians, along with Sierra Club and Defenders of Wildlife have developed an alternative for analysis in both an EA and/or an EIS for the Santa Fe Mountains Landscape Resiliency Project called the Santa Fe Conservation Alternative, to address forest management in a way that conserves forest resources. It is equally applicable to the Encino Vista Landscape Restoration Project and would meet the conservation requirement of the 2012 forest planning rule very well. These principles should be applied to the Encino Vista Landscape Restoration Project

It is based on education, engineering and enforcement. Instead of widespread fuel treatments out in the forest away from the WUI, it recommends the more effective and conservationist steps of educating the public about maintaining a safety zone around WUI structures and campfire safety, engineering to protect communities and values from post-fire flooding in key areas, maintaining power lines, etc. and increased law enforcement to reduce unsafe fire behavior in the forest.

I am submitting it as the preferred general approach for the Encino Vista Landscape Restoration Project.

The basic principles of the Santa Fe Conservation Alternative are:

Thinning
—Limited hand thinning (up to 9") only in dry pine and mixed conifer outside of IRAs.
—Stumps cut down to the ground
—No thinning adjacent to the WUI for the purpose of protection of structures or communities except within 150 feet of structures, and for fire fighter safety zones.
—Maximum trees removed in most thinned areas to 80 BA
—Leave more tree groupings (50% minimum) and maintain a shrub understory. Utilize a wildlife habitat-based determination of tree and vegetation retention
—Identify riparian area concerns and create plan to protect

Slash management
—Pile burning of activity fuels
—Reevaluate slash management timing and methods to avoid potential bark beetle outbreaks, and sterilization of soil under slash piles. No slash over 3" left on the ground during the dry season

Prescribed burning
—Utilize managed wildland fire and pile burning wherever possible. Utilize minimal broadcast prescribed burns only in areas that are not assessable for pile burns.

IRAs
—No thinning in IRAs
—Identify Roadless Area concerns and develop a policy to restore

Monitoring (key means of reaching desired outcomes of healthy forest habitat and protection of public health)
—Test plots for monitoring purposes
—Soil sampling - plot number and spacing to be determined
—Baseline species evaluation (i.e. population capacity and presence/absence)
—Improved air quality standards and monitoring to protect sensitive (human) population

Reclamation and restoration
—Reclamation of any USFS roads deemed unessential in Travel Management Plan
—Hand building of structures (example Zuni bowls) in arroyos to slow flood waters
—Planting native, stream side vegetation where appropriate to slow floodwaters
—Reintroduction of beaver where appropriate

WUI and community forests
—Develop a program to support fire-proofing of structures and surrounding 100 feet, at least

through increased outreach and education. This should be a homeowner responsibility
—If possible, support development of an alternative egress for communities with a single egress
—Leave most areas that the public uses for recreation, including forests adjacent to communities, natural and intact.
--Take into greater account the need to preserve areas that are special to communities, such as Cougar Canyon
—Increased law enforcement to protect against unsafe fire behavior by forest visitors

Scenic quality
—Maintain the scenic quality of all treated areas. Develop a standard for acceptable scenic quality

Sincerely,

Sarah Hyden

Re: Scoping Comments on the Encino Vista Landscape Restoration Project Purpose and Need for Action and Proposed Action

Dear Mr. Nieto,

WildEarth Guardians respectfully submits these comments to the U.S. Forest Service concerning the scope of the agency's analysis under the National Environmental Policy Act (NEPA) of the Encino Vista Landscape Restoration Project across approximately 128,400 acres within the Coyote Ranger Districts on the Santa Fe National Forest (Santa Fe NF). The landscape-scale project includes a number of activities requiring rigorous environmental analysis including forest plan amendments, significant vegetative treatments in TES species habitats, road construction and road management actions. These activities will occur in multiple sub-watersheds, specifically the Coyote Creek, Cañones Creek, Headwaters Rio Puerco, Poleo Creek, Outlet Rio Puerco, Upper Rio Galina and Rio Capuling. *See* Encino Vista Landscape Restoration Project Purpose and Need for Action and Proposed Action (hereinafter "Scoping Notice"), p. 2. Please add my names and organization to the contact list to receive any future public notices regarding this project.

Most, if not all, of the sub-watersheds in the project are impaired or functioning at risk and many of the roads in the project area are in poor condition. *See* Scoping Notice, p. 5. Improving these conditions at a measurable level is an outcome we urge the Forest Service to demonstrate in the subsequent analysis. Given the scope and scale of the proposed action, including two Forest Plan amendments, and thus the potential for significant impacts, we strongly urge the Forest Service to prepare an environmental impact statement (EIS).

I. The Forest Service must ensure that this is truly a "Restoration" project.

> The purpose of the Encino Vista Landscape Restoration project is to restore overall forest health, lower fire risk, improve watershed health, and enhance wildlife habitat across the landscape. There is a need to increase forest ecosystem sustainability and resiliency to insects, disease, and climate change by shifting forest composition and structure toward desired conditions within the historic (or natural) range of variability for each forest type. There is also a need to reduce the risk of uncharacteristic wildfires, to improve species habitat, and overall watershed conditions.

This project focuses on forest restoration and resiliency treatments to:

- Reduced stand densities
- Reintroduce fire on the landscape
- Revitalize meadows and aspen stands
- Promote a diverse forest structure for a variety of wildlife species
- Improve watershed conditions across the landscape, which would safeguard the water supply for villages, towns and ranches within the project area as well as downstream communities, by increasing the quality and quantity of water that flows through the network of streams improving watershed function within the Encino Vista Project area
- Significantly reduce the risk of catastrophic wildfire and its aftermath (flooding, debris flow)

Scoping Notice, pp. 8-9.

Yet, despite being touted as a landscape restoration project, the proposed action provides little in actual restoration activities such as identifying the Minimum Road System and associated actions such as decommissioning system roads, removing non-system roads and fixing poorly placed and/or sized culverts, in-stream and riparian restoration, and reducing the impacts of livestock grazing and motorized use. Without such restoration work, the Encino Vista project is merely a logging and burning project, not restoration. These restoration actions are essential to meeting the stated purpose and need, and achieve the desired results, above.

According to the Scoping Notice,

> The project area overlaps twelve HUC 12 sub-watersheds, but the majority (74%) of the project is within these sub-watersheds: Cañones Creek, Coyote Creek, Headwaters Rio Puerco, and Poleo Creek. These four sub-watershed are a crucial source of recharge of ground water used as drinking water for the communities of Coyote, Youngsville, Cañones and Abiquiu. Portions of four other sub-watersheds make up nearly 23% of the project area, they are: Outlet Poleo Creek, Upper Rio Gallina, Rio Capulin, and Abiquiu Reservoir. The Cañones Creek is an impaired functioning watershed. The other previously mentioned watersheds are functioning at risk.

Scoping Notice, p. 5. Yet, there is no substantive information as to how these watersheds will be improved to ensure the necessary groundwater recharge. Extensive timber management is not the answer, especially without other substantive restoration activities such as road decommissioning, riparian restoration, and addressing the impacts of livestock grazing.

Indeed, according to the Scoping Notice, livestock grazing plays a significant role in why the area is purportedly outside of historic ecological conditions. "Fire suppression is the primary reason which has allowed for change in fuels (suppression combined with grazing and logging are the driving factors for change in fuel abundance, type, and arrangement)." Scoping Notice, p. 5. In the Juniper Grass ERU, "Typically, native understory grasses are perennial species, while forbs consist of both annuals and perennials. Shrubs are characteristically absent or scattered. Due to the effects of long-term fire suppression and grazing in this type, in many locations the current condition is severely departed from historic conditions." *Id.*, pp. 5-6. It is unclear how livestock grazing has impacted the other vegetation communities such as Aspen, mixed conifer, Ponderosa pine, dry mixed conifer, Pinion-Juniper woodlands, and pinion-juniper sagebrush. This must be analyzed as part of the baseline conditions and cumulative effects analysis.

Further, replacing Forest Plan standards with desired conditions and guidelines weakens the Forest Plan. The Forest Service's desired conditions are not based on the best available science and are static conditions used as an excuse for the Forest Service to continuously log in areas where natural fire should be returned. Forests are not static, they are constantly changing, and natural fire is an essential component of this change.

II. Mexican Spotted Owl

We are dismayed at the Forest Service's failure to ensure the protection and restoration of MSO and their habitat. The Encino Vista project directly contradicts the current injunction on logging activities in Mexican Spotted Owl habitat, and the proposed Forest Plan amendments do not comply with the 1996 Standards and Guidelines that still apply on the Santa Fe NF and impose significant restrictions/constraints on management activities in protected habitat (i.e., PACs and steep slopes). One of the assumptions of the current programmatic Biological Opinion for the Santa Fe NF is that the Forest Service will implement the the Forest Plan, including the 1996 Standards and Guidelines. So, since the proposed Forest Plan amendments deviate from the 1996 Standards and Guidelines, that is an action "outside" of the programmatic Biological Opinion that requires a separate "stand alone" Biological Opinion. Further, the Encino Vista project and associated MSO Forest Plan Amendment fails to incorporate significant and essential components of the 2012 Recovery Plan.

The 2012 Recovery Plan states that scientific

> studies suggest that at least some kinds of mechanical forest treatments may negatively affect spotted owls. No clear guidance emerges from these studies relative to types, extents, or spatial arrangement of treatment that might minimize effects to owls. Such information is needed if management is to proceed in owl habitat. Lacking such information, managers should proceed cautiously in terms of treatment intensity and extent. That is, initial treatments should be limited in spatial extent and treatment intensity, and should be aimed at balancing reduced fire risk with maintaining the mature forest structure that seems to be favored by spotted owls. Treatments in owl habitat should be linked to rigorous monitoring of owl response, to allow us to evaluate the effects of different types and extents of treatments in an adaptive management context... The Recovery Team recommends mechanical treatment in PACs only if such monitoring occurs.

2012 Recovery Plan, p. 73.

Pursuant to the 2012 Recovery Plan, "Forest restoration and fuels-reduction treatments must be evaluated over time using appropriate modeling, rigorous monitoring, management experiments, and/or research to assess their effectiveness in maintaining or creating owl habitat and/or their effectiveness in reducing the threat of high severity or stand-replacing wildland fire." *Id.*, p. 250. Accordingly, the NEPA analysis for this project must include the results of past monitoring of the impacts of timber management activities, roads and motorized use, noise and recreational activities, and livestock grazing on MSO. And, this project must incorporate the rigorous monitoring and other recovery recommendations of the 2012 Recovery Plan. We expect to see the results of at least two years of rigorous pre-project monitoring in the NEPA analysis.

The Forest Service must comply with the ESA, its Forest Plan (including the 1996 Standards and Guidelines), and the 2012 Recovery Plan to provide for the recovery of MSO. This includes limiting activities that impact critical habitat, Protected Activity Centers (PACs), and recovery habitat. The FS must consult with the U.S. FWS on the impacts of the project and Forest Plan Amendment on MSO, and these consultation documents must be provided to the public during the NEPA process on the agency's website for this project.

The Forest Service should follow the management recommendations in the 2012 Recovery Plan (see Appendix C of the 2012 Recovery Plan), for PACs, recovery habitat, and other habitats, and must also analyze the impacts of climate change on MSO, as discussed in the 2012 Recovery Plan.

III. As part of the analysis of the Encino Vista Project under NEPA, the Forest Service must not only consider the Santa Fe National Forest's Travel Analysis Report and identify unneeded roads to prioritize for decommissioning or other uses, but it must also identify the Minimum Road System.

The Forest Service faces many challenges with its vastly oversized, under-maintained, and underfunded road system. The Santa Fe National Forest is no exception. According to the 2008 TAR, "we estimate that the Santa Fe National Forest needs over $4 million per year for adequate maintenance for all of our roads, using recommended maintenance frequencies and costs." 2008 Travel Analysis Process Report, p. 18. The TAR identifies as a partial resolution will be to reduce the miles of the designated road system." *Id.* It does not appear that the TAR has been updated since 2008, so this $4 million could have significantly increased since then, and there is no information on the Forest Service's progress in decommissioning unneeded roads.

The impacts from roads to water, fish, wildlife, and ecosystems are well documented in scientific literature. The following is just a small list of examples:

- Increased sedimentation in stream beds has been linked to decreased fry emergence, decreased juvenile densities, loss of winter carrying capacity, and increased predation of fishes, and reductions in macro-invertebrate populations that are a food source to many fish species (Rhodes et al. 1994, Joslin and Youmans 1999, Gucinski et al. 2000, Endicott 2008).
- Roads can act as barriers to [fish] migration (Gucinski et al. 2000). Culverts in particular often interfere with sediment transport and channel processes such that the road/stream crossing becomes a barrier for fish and aquatic species movement up and down stream.
- Where both stream and road densities are high, the incidence of connections between roads and streams can also be expected to be high, resulting in more common and pronounced effects of roads on streams (Gucinski et al. 2000).
- Roads and trails impact wildlife through a number of mechanisms including: direct mortality (poaching, hunting/trapping) changes in movement and habitat use patterns (disturbance/avoidance), as well as indirect impacts including alteration of the adjacent habitat and interference with predatory/prey relationships (Wisdom et al. 2000, Trombulak and Frissell 2000).
- Forman and Hersperger (1996) found that in order to maintain a naturally functioning landscape with sustained populations of large mammals (such as elk), road density must be below 0.6 km/km2 (1.0 mi/mi2).
- The MSO 2012 Recovery Plan identifies the impacts that roads, noise and motorized recreation have on MSO, including breeding.

Indeed, the scoping notice admits that "[m]any of the roads in the project area are in poor condition. These roads do not provide safe and efficient access. Their degraded state may be causing soil erosion." Scoping Notice, p. 5. Yet, despite this project being touted as a "restoration" project, there is no mention of a resilient road system, road decommissioning, or otherwise improving vegetation, habitat, and riparian conditions by removing roads and limiting motorized use. Instead, the Forest Service proposed to construct approximately 5 to 10 miles of temporary roads and conduct road infrastructure improvement and maintenance on existing Forest Service roads within the project area. Scoping Notice, p. 10. In order to meet the restorative purpose and need for the project and eliminate or reduce the impacts of the roads within the project area to water quality, fish and wildlife habitat, the Forest Service needs to take steps related to its road system.

Local communities and visiting recreationists are also impacted by the oversized, under-maintained and under-funded road system. Since roads are not regularly maintained or upgraded, they are highly susceptible to storms. Small culverts become plugged with debris, forcing water over the road and often resulting in the road getting washed out. Gullies can form along roadbeds making it difficult to drive a car on the road. This "storm damage" can eliminate access and often takes years to fix, if it even gets fixed at all. In order to ensure access to beloved trails, campsites, fishing and swimming holes, etc., the Forest Service should target limited road maintenance funding to high priority recreation/community access roads.

The Forest Service recognized the challenges related to the oversized and deteriorating road system nearly two decades ago. In 2001, the Forest Service promulgated the Roads Rule (referred to as "subpart A"). 66 Fed. Reg. 3206 (Jan. 12, 2001); 36 C.F.R. part 212, subpart A. The Roads Rule created two important obligations for the agency. One obligation is to complete a Travel Analysis. 36 C.F.R. § 212.5(b)(2). Another obligation is to identify the minimum road system needed for safe and efficient travel and for the protection, management, and use of National Forest system lands. *Id.* § 212.5(b)(1).

In 2008 the Santa Fe National Forest took the first step and completed its travel analysis report (2008 TAR). The next step under Subpart A is to consider the valid portions of the travel analysis report and begin to identify and implement the minimum road system (MRS) in the analysis of site-specific projects of the appropriate geographic size under NEPA.[1] Here, extensive time that has passed since the 2008 TAR, and it doesn't appear that the Forest Service has made any effort to identify the MRS within the project area. Given that the Encino Vista Project is considering changes to a number of roads, and given its geographic scale, this is precisely the type of project where the Forest Service must consider its Travel Analysis Report and identify unneeded roads to prioritize for decommissioning or to be considered for other for the Santa Fe National Forest, and identify the MRS.[2] This is essential to meeting the restoration purpose and need.

The minimum road system is the road system the Forest Service determines is needed to:

- "meet resource and other management objectives adopted in the relevant land and resource management plan";
- "meet applicable statutory and regulatory requirements";
- "reflect long-term funding expectations"; and
- "ensure that the identified system minimizes adverse environmental impacts associated with road construction, reconstruction, decommissioning, and maintenance."

---

[1] See Memorandum from Leslie Weldon to Regional Foresters et al. on Travel Management, Implementation of 36 CFR, Part 212, Subpart A (Mar. 29, 2012) (hereafter 2012 Weldon Memo), page 2 (directing forests to "analyze the proposed action and alternatives in terms of whether, per 36 CFR 212.5(b)(1), the resulting [road] system is needed").
[2] *Id.* (directing forests to use the travel analysis report to identify the minimum road system for proposed actions at the scale of a 6th code subwatershed or larger).

36 C.F.R. §212.5(b)(1). The Forest Service should identify the minimum road system by analyzing whether a proposed project is consistent with the relevant portions of the travel analysis report and consider the minimum road system factors under 36 CFR 212.5(b)(1) for each road the agency decides to keep as part of the specific project.[3]

Subpart A directs the agency to "identify the roads on lands under Forest Service jurisdiction that are no longer needed," and therefore should be closed or decommissioned.[4] The rule refers to all roads, not just National Forest System roads. The rule defines a road as "[a] motor vehicle travelways over 50 inches wide, unless designated and managed as a trail."[5] The forest must assess these proposed actions in relation to the risks and benefits analysis in the Travel Analysis Report, as well as the factors for a minimum road system, with the goal of minimizing adverse environmental impacts.

We are concerned that the scoping notice for this project didn't even reference the Travel Analysis Report and has not identified any roads to be closed, much less decommissioned, or culverts to be replaced. We believe these actions are essential to achieve the restoration purpose and need of the project and move the forest towards a more economical and storm resilient road system. We expect to see the incorporation of the Travel Analysis Report into the draft Environmental Impact Statement, along with reasoning if decisions are made that are different from the recommendations in the report. Sometimes we have seen this as a table and sometimes as an appendix to the analysis. The overall purpose being to minimize environmental impacts, ensure reliable access and be in-line with road maintenance budgets.

IV. The Forest Service must prepare a robust Environmental Impact Statement (EIS) under NEPA.

The Encino Vista project, including the proposed Forest Plan amendment, "may" have a significant impact on the environment, and thus the Forest Service must prepare a robust EIS, ensuring that it complies with NEPA's required "hard look." The agency may not ignore topics if the information is uncertain or unknown. Where information is lacking or uncertain, the Forest Service must make clear that the information is lacking, the relevance of the information to the evaluation of foreseeable significant adverse effects, summarize the existing science, and provide its own evaluation based on theoretical approaches. 40 C.F.R. § 1502.22.

The EIS must analyze the baseline conditions of the project area, and the direct, indirect and cumulative impacts of the proposed timber management activities, road construction and maintenance, and all other activities. There are a number of large landscape projects throughout the Santa Fe NF, and the agency has yet to address the cumulative impacts of so much timber management and associated road building, especially on old growth, MSO and other species' and their habitats. Other issues that must be analyzed include the impacts of livestock grazing, particularly in light of climate change, on forest ecosystems, vegetation, riparian areas, and overall forest health. Livestock grazing and the poor condition of the road system must be assessed as part of the baseline conditions.

---

[3] *Id.* ("The resulting decision [in a site-specific project] identifies the [minimum road system] and unneeded roads for each subwatershed or larger scale").
[4] 36 C.F.R. § 212.5(b)(2). See also Center for Sierra Nevada, 832 F. Supp. 2d at 1155 ("The court agrees that during the Subpart A analysis the Forest Service will need to evaluate all roads, including any roads previously designated as open under subpart B, for decommissioning.").
[5] 36 C.F.R. § 212.1.

a. The Forest Service should clearly articulate the statement of purpose to include its duty to identify the minimum road system, and provide support for the claimed need.

The Forest Service must shape the project's purpose and need statement according to applicable statutory and regulatory requirements. When the agency takes an action "pursuant to a specific statute, the statutory objectives of the project serve as a guide by which to determine the reasonableness of objectives outlined in an EIS." *Westlands Water Dist. v. U.S. Dept. of Interior*, 376 F.3d 853, 866 (9th Cir. 2004). The Forest Service has a substantive duty to address its over-sized road system. *See*, 36 C.F.R. 212.5. This underlying substantive duty must inform the scope of the project and be included in the agency's NEPA analysis. It's been nearly 2 decades since the agency finalized the Subpart A rules, and 11 years since the Santa Fe NF conducted its TAR, and the Forest Service can no longer delay in addressing this duty.

b. The Forest Service should accurately define the official road network as the baseline for the NEPA analysis.

The baseline and no-action alternative can differ.[6] Current management direction does not compel the Forest Service to recognize decommissioned roads and unauthorized roads as part of the road system. Disclosure of the number and location of decommissioned routes and unauthorized routes, as well as the impacts of those routes, is a necessary component of the no-action alternative. But it is separate and distinct from the identification of the baseline, which should be the official open route system.

In addition, it is helpful for public understanding to have clearly articulated which roads proposed for closure and decommissioning are already not drivable by the public due to lack of maintenance, road wash-outs and storm damage. It's incumbent upon the Forest Service to accurately describe the road network now, what is planned for the future and why those steps will be taken. There is significant room for improvement on how the agency describes the current challenges and how changes may or may not impact communities.

c. The Forest Service must consider a broad array of impacts related to forest roads in its NEPA analysis.

Impacts from Forest Roads

The best available science shows that roads cause significant adverse impacts to National Forest resources. Erosion, compaction, and other alterations in forest geomorphology and hydrology associated with roads seriously impair water quality and aquatic species viability. Roads disturb and fragment wildlife habitat, altering species distribution, interfering with critical life functions such as feeding, breeding, and nesting, and resulting in loss of biodiversity. Roads facilitate increased human intrusion into sensitive areas, resulting in poaching of rare plants and animals, human-ignited wildfires, introduction of exotic species, and damage to archaeological resources. We will look to see if the Santa Fe National Forest outlines a range of activities focused on reducing road impacts, as part of its' draft Environmental Impact Statement. These activities should include road maintenance, installation of BMPs, culvert replacements, hydrologically-disconnecting roads from streams, fish passage improvements, appropriate road closures (sometimes seasonal) and road decommissioning which can all be beneficial to wildlife, water quality, aquatic species and forest users if

[6] See, e.g., FSH 1909.15, 14.2; Council on Environmental Quality's (CEQ) Forty Most Asked Questions (1981), #3 (explaining "[t]here are two distinct interpretations of 'no action'"; one is "'no change' from current management direction or level of management intensity," and the other is if "the proposed activity would not take place").

properly considered and implemented. As this project moves forward, we ask that the Agency ensure that activities on the ground result in changes to the current net negative impacts from these roads.

Climate Change and Forest Resources

Climate change intensifies the impacts associated with timber management, livestock grazing and roads. Draft guidance from the Council of Environmental Quality (CEQ) indicates the Forest Service must include existing and reasonably foreseeable climate change impacts as part of the affected environment, assessed as part of the agency's hard look at impacts, and integrated into each of the alternatives, including the no action alternative. The Forest Service has a substantive duty under its own Forest Service Manual to establish resilient ecosystems in the face of climate change.[7] The Forest Service should analyze in detail the impact of climate change on the Forest, streams, groundwater, roads, and fish and wildlife habitat. Removing culverts, improving stream/road crossings, upgrading culverts, and decommissioning roads are all very important activities that can increase resiliency to climate change impacts. We encourage the Forest Service to consider climate change impacts – especially related to increasing storm intensity - to ensure that culverts are large enough and/or stream crossings are appropriately designed.

IV. The Forest should not construct temporary roads. If avoidance is impossible, the roads should be immediately reclaimed after use.

We encourage the Forest to take a hard look at the proposed temporary roads in order to be certain that they are needed. Current USFS policy is that road beds be restored to natural condition after such project, yet the scoping notice does not contain any such requirement. And, even when temporary roads are restored to natural condition, there is still an impact when temporary roads are developed. In addition to their hydrologic impact, roads fragment habitat, disturb wildlife, invite more noxious weeds and increase fire danger. Additionally, if they are not properly rehabilitated post-project, they can invite illegal incursions and more damage to natural resources. At minimum, we ask that the Santa Fe National Forest restore these segments as soon as the project activities within that specific area are completed. In addition, we ask that the segments are monitored and enforcement actions taken to ensure proper closure.

Conclusion

As conservationists and visitors to the Santa Fe National Forest, we are certain that with thoughtful planning and clear communication, the Santa Fe National Forest staff can create a true restoration project that includes less logging and road building, and more actual restoration actions such as identifying and implementing a minimum road system, road decommissioning, riparian restoration, returning natural fire to the ecosystem, decreasing livestock grazing, and improving watershed health and groundwater recharge. This endeavor is one of the most important efforts the Forest Service can undertake to restore aquatic systems and wildlife habitat, facilitate adaptation to climate change, ensure reliable recreational and community access, and lower operating expenses.

From: Chuck Hathcock
To: Imler-Jacquez, Sandra R -FS
Subject: Comments on the Encino Vista project #54965
Date: Monday, December 2, 2019 8:42:51 AM

Hi Sandra,

Please accept my comments below for the Encino Vista Landscape Restoration Project # 54965. Thanks!

Hello,
My name is Chuck Hathcock and I am a wildlife biologist in the Jemez and I also own property and live along the Rio Puerco just downstream of this project's boundary between Youngsville and Coyote. Overall I support this project and agree that this restoration needs to be completed before a stand-replacing wildfire hits this area. I have some comments for you to consider.

--You addressed owl habitat thoroughly, thank you.
--The use of goats is mentioned once as a means to control Gambel oak on page 10. Goats can be very destructive, you should detail the proposed use of goats and how you'll mitigate the impacts to other plant species on the lansdcape from the goats.
--You do not mention the Jemez Mountains salamander. While the project boundary looks to be just outside of designated critical habitat on the southern edge, this area is still within the salamander's historic range. You should have some considerations for salamander habitat along the boundary with the VCNP and just west of there.
--You do not mention any compliance requirements for the Migratory Bird Treaty Act. You should have some mention of this federal law and have best management practices that can help mitigate impacts to migratory birds. The primary impact would be from active nest destruction, so having some guidelines to prioritize tree and shrub removals outside of the peak bird nesting season would be appropriate.
--You do not mention removing non-native species. Areas along the Rio Puerco are choked closed with Russian olive and to a lesser extent salt cedar. You mention this and other watercourses in the background and mention that they are at risk, but I don't see any treatments listed for riparian health improvement. Consider adding treatment options that include non-native tree removals.
--Lastly, why is the northern goshawk the only RFSS species mentioned? Others could be impacted by this work as well such as the boreal owl, pale Townsend's bid-eared bat, spotted bat, water and masked shrews, and several plant species.

Thanks for your consideration.

Re: **Comments on the Santa Fe National Forest Draft Land Management Plan and Draft Environmental Impact Statement (DEIS)**

Please accept these comments for the public record regarding the Santa Fe National Forest Draft Land Management Plan and DEIS. I am a conservation scientist with over 30 years-experience in forest ecosystems, including documenting the importance of fire-mediated biodiversity in dry pine and mixed conifer forests of the West (DellaSala and Hanson 2015[1]). My relevant expertise also includes developing robust conservation strategies for land managers to accommodate wildfires for ecosystem benefits while reducing fire risks to communities. I am submitting the enclosed publications as pdfs in support of my comments, including how extensive logging has increased fire severity in forests (Bradley et al. 2016), limitations of forest thinning in reducing fire intensity (DellaSala et al. 2018), livestock grazing and climate change cumulative impacts on national forests (Beschta et al. 2012), fire ignitions associated with roads (Ibisch et al. 2016), climate change effects on fire regimes (Abatzoglou and Williams 2017), and ecological importance of high severity burn patches in dry pine/mixed conifer forests including New Mexico (DellaSala and Hanson 2019), among other relevant peer reviewed publications. My comments are meant to improve the Forest Service's approach to forest-fire resilience in the Santa Fe National Forest (SFNF) and surroundings with the intent of showing how the agency can and must do better with respect to using the best available science along with involving scientists with a biodiversity perspective on wildfire and not just a fuel centric perspective dominated by fuel management.

The SFNF encompasses 1.6 million acres (nearly the size of Yellowstone National Park) of diverse conifer forests, woodlands, riparian forests, native grasslands and shrublands that make up the scenic beauty and quality of life for surrounding communities, including unmatched recreation, clean water, hunting and fishing, and iconic wildlife species. The SFNF includes nationally significant roadless areas; designated and proposed Wilderness and Wild and Scenic rivers; tribal-cultural sites; and essential habitat for large carnivores, ungulates, and at-risk wildlife such as Mexican Spotted Owl, Southwestern Willow Flycatcher, Jemez Mountain

[1] Note – a copy of the book – a very large pdf – can be purchased here https://www.sciencedirect.com/book/9780128027493/the-ecological-importance-of-mixed-severity-fires. For the purpose of these comments, I included the relative chapter, however, these included editing notes as the publisher did not provide chapter pdfs.

salamander, Rio Grande cutthroat trout, and New Mexico meadow jumping mouse. These and many other species in the project area require intact areas periodically maintained by wildfires of low and mixed severity effects on vegetation that also include occasional large and small patches of high severity fire effects. The SFNF's low elevation forests are predominately influenced by frequent fires of low severity with fire-flare ups that often kill overstory trees (site and landscape heterogeneity). During drought cycles and under extreme fire weather these flare ups can include small and large high severity patches that are important ecologically (DellaSala and Hanson 2019). Upper elevation spruce-fir forests are on centuries long *fire rotation intervals* (landscape scale) where high severity fire effects are characteristic (Margolis et al. 2002) and climatic factors are the top-down driver of fire behavior, not fuels (see Bessie and Johnson 1995). This variability is not appropriately recognized, planned for, or even properly analyzed in the DEIS, which mostly emphasizes mechanical treatments designed to move substantial amounts of closed canopy forests into low fuel condition conducive of low-severity fire effects lacking diversity/heterogeneity at site or landscape levels.

Much of the Santa Fe National Forest biodiversity is distributed along elevation gradients with changes in life zones prominent from valley bottoms and foothills to montane and alpine. Thus, a primary objective of the DEIS should be to maintain landscape connectivity that accommodates biological diversity across life zones and for focal species, species of conservation concern, and at-risk species and ecosystems. The DEIS is deficient in analyzing how connectivity is being impacted specifically by habitat fragmentation in the project area and surroundings (cumulative effects) caused by roads, extensive thinning and forest canopy reductions, ski area development, mining, livestock grazing and infrastructure, off highway vehicles (OHVs), and other developments. Connectivity cannot simply be maintained at the coarse-filter level via vegetation management and very general site-specific measures incorrectly presented as a fine filter approach. Connectivity maintenance requires proper analysis (species-specific trigger points and population viability analysis, see Noon et al. 2003, Schultz et al. 2013) to meet the best available scientific information (BASI) requirement of the 2012 forest planning rule. None of the alternatives in the DEIS meet the BASI requirement for connectivity (Box 1 and Box 2).

Box 1. Ecological integrity. The quality or condition of an ecosystem when its dominant ecological characteristics (e.g., composition, structure, function, connectivity, and species composition and diversity) occur within the natural range of variation and can withstand and recover from most perturbations imposed by natural environmental dynamics or human influence (36 CFR 219.19).

Box 2. Connectivity. Ecological conditions that exist at several spatial and temporal scales that provide landscape linkages that permit the exchange of flow, sediments, and nutrients; the daily and seasonal movements of animals within home ranges; the dispersal and genetic interchange between populations; and the long distance range shifts of species, such as in response to climate change.

Planning deficiencies regarding integrity and connectivity are summarized as follows:

- Connectivity is inadequately addressed by an emphasis on vegetation management in Ecological Response Units (mostly coarse filter), general site-specific measures (inadequate fine filter), and some road closures/decommissioning. Notably, in a comprehensive analysis of biodiversity strategies in a changing climate, connectivity (site-specific structural features, landscape intactness, corridors) was identified as the single most important strategy for enabling plants and wildlife to adapt to climate change and is critical to achieving climate resilient ecosystems (Haber and Nelson 2015). These authors recommend far more measures for maintaining connectivity than what was provided in the DEIS.
- There are substantial roads (6,900 miles) throughout the SFNF, many of which are leaking sediments into streams and pose a barrier and mortality risk to wildlife (vehicle collisions). Roads, cattle, and logging/thinning all affect the biological and physical environment of focal species, at-risk species, and species of conservation concern and this requires fine-scale analysis ("trigger points," and population viability analysis (PVA); as in Noon et al. 2003, Schulz et al. 2013) along with stepped up conservation (see conservation requirement of the planning rule below) that must be analyzed at the appropriate scale using BASI to take a hard look at connectivity and not just providing unsupported claims that vegetation management actions satisfy this requirement.
- The DEIS must analyze connectivity to maintain viable populations of focal species, at-risk species, and species of conservation concern (i.e., via PVA and trigger points) especially in a changing climate and in the context of both direct and indirect cumulative effects (e.g., analyze habitat fragmentation as the antithesis of connectivity).
- A connectivity analysis needs to incorporate cumulative impacts (e.g., livestock, thinning, roads), importance of intact areas (especially connecting life zones along gradients for species movements), and barriers to terrestrial and aquatic focal species, at-risk species, and species of conservation concern along with specific measures for reconnecting habitat. Examples of connectivity analyses include identification of species-specific road density thresholds (generally >1 mi/square mile is problematic for aquatic species), identification and protection of ungulate migration corridors (e.g., deer and elk winter and summer range movements) and large carnivore travel routes (especially along riparian areas) (i.e., the Forest Service must follow approaches in Haber and Nelson 2015).

Maintaining the mixture of fire severity effects on the SFNF is key to meeting the diversity requirements of the 2012 forest planning rule (see section on diversity of plant and animal communities), including mixed-severity fires that produce high-severity patches having unique ecological functions (DellaSala and Hanson 2019). The DEIS is deficient in this regard as it over emphasizes low-severity fire at the expense of mixed-severity fire effects (including high severity patches) essential to ecological processes, ecological conditions, and ecological integrity (Box 1, 3, 4, 5).

Box 3. The selected set of ecological conditions and key ecosystem characteristics related to the composition, structure, ecological processes, and connectivity of plan area ecosystems (terrestrial, riparian, and aquatic), provide the basis for monitoring ecosystem integrity (36 CFR 219.8(a)(1)) and the diversity of plant and animal communities (36 CFR 219.9).

Box 4. System drivers, including dominant ecological processes, disturbance regimes, and stressors, such as natural succession, wildland fire, invasive species, and climate change; and the ability of the terrestrial and aquatic ecosystems on the plan area to adapt to change (§ 219.8)

Box 5. Ecological conditions. The biological and physical environment that can affect the diversity of plant and animal communities, the persistence of native species, and the productive capacity of ecological systems. Ecological conditions include habitat and other influences on species and the environment. Examples of ecological conditions include the abundance and distribution of aquatic and terrestrial habitats, connectivity, roads and other structural developments, human uses, and invasive species.

The DEIS conflicts with the above planning rule requirements in the following ways:

- Alternative 3 (natural process alternative) is erroneously dismissed for Alternative 2 (preferred alternative) that relies on far more mechanical treatments than natural processes. More natural process features from Alternative 3 need to be incorporated into the final plan. Ostensibly, the main reason for the Forest Service rejecting Alternative 3 stems from inaccuracy problems inherent to LANDFIRE, fire scar analysis sampling biases, and inappropriate reference conditions tied to Forest Service research publication GTR-310 that have led to an over-reliance on mechanical treatments to achieve novel ecosystems devoid of most small trees with remaining trees prone to blowdown.
- The DEIS assumes high-severity fire patches are an anomaly of contemporary fire systems and therefore does not properly analyze positive contributions of high-severity patches in contributing to diverse ecosystems (DellaSala and Hanson 2019), particularly high elevation areas that experience characteristic high-severity fires (the predominant fire regime) on long fire rotation intervals.
- High-severity patches are ecological diverse habitats (DellaSala and Hanson 2019) and are important as foraging habitat for raptors such as Northern Goshawks and Mexican Spotted Owls (see Lee 2018), woodpeckers and songbirds (Hutto et al. 2015), small mammals and ungulates (Bond 2015), and may play a role in snowshoe hare/lynx dynamics. This needs to be acknowledged and the at-risk species tables in the DEIS

adjusted to include positive effects of high-severity fires on wildlife instead of all negative effects as incorrectly noted in the DEIS.

- The DEIS does not include sufficient actions for limiting the spread of invasive species via vector management of livestock (maximum permitted stocking rate of 11,400 AUMs is not sufficiently mitigated), roads, and OHVs. Improved foraging habitat for cattle through thinning and infrastructure changes under the preferred alternative is inadequate for addressing the chronic invasive species problems across the SFNF that will accumulate (cumulative effects) over space and time through active management (thinning entries), continued grazing especially in a changing climate (see Beschta et al. 2012) and road developments (see Ibisch et al. 2016 for a review of road impacts, including spread of invasive species).
- The DEIS is completely inadequate in addressing the critical habitat needs and population dynamics of threatened Mexican Spotted Owls (MSO), which require site specific and region-wide population monitoring and not just knowledge of habitat availability. Notably, a federal judge on September 11 enjoined all "timber management actions" in eleven national forests in New Mexico and Arizona for failing to survey and protect the MSO. The SFNF through Endangered Species Act section 7 consultation must engage in specific and region-wide population monitoring to ensure the MSO population is recovering and its habitat protected from thinning and other project actions (e.g., effects of livestock grazing on prey species).

Overall, the DEIS and supporting documents do not meet the BASI requirement of the 2012 forest planning rule with respect to *accurate, reliable, and relevant issues being considered* (Box 6). There are incorrect reference conditions tied to the Forest Service research publication GTR-310 extrapolated from a completely different region, accuracy problems inherent with the LANDFIRE program at the SFNF scale, uncertainties with fire return interval estimates using fire scar sampling, and arbitrary determinations regarding closed canopy forest conditions that has led to an over emphasis on mechanical treatments to achieve desired open forest canopy conditions at the expense of plant and wildlife diversity.

Box 6. § 219.3 Role of science in planning. The responsible official shall use the best available scientific information to inform the planning process required by this subpart. In doing so, the responsible official shall determine what information is the most accurate, reliable, and relevant to the issues being considered. The responsible official shall document how the best available scientific information was used to inform the assessment, the plan decision, and the monitoring program as required in §§ 219.6(a)(3) and 219.14(a)(4). Such documentation must: identify what information was determined to be the best available scientific information, explain the basis for that determination, and explain how the information was applied to the issues considered. (emphasis added)

The DEIS does not sufficiently meet the *conservation* requirement of the 2012 forest planning rule (Box 7).

Box 7. Conservation. The protection, preservation, management, or restoration of natural environments, ecological communities, and species. Conserve. For purposes of subpart A, § 219.9, to protect, preserve, manage, or restore natural environments and ecological communities to potentially avoid federally listing of proposed and candidate species.

Noted deficiencies in the *conservation* requirement include:

- Lack of preservation and protection of natural environments (especially roadless areas, closed canopy mature forests, riparian areas, critical MSO habitat), ecological communities, focal species, at-risk species, and species of conservation concern. Alternative 2, for instance, emphasizes extensive mechanical treatments that may cause irreparable harm to MSO, focal species, at-risk species, and species of conservation concern through major reductions in canopy closure and understory vegetation. Extensive thinning of forest canopies may constitute an adverse effects determination in section 7 consultation for the MSO (and prey species) that uses closed canopy forests for nesting and may use severely burned areas for foraging (see Lee 2018).

Importantly, the DEIS presents a questionable analysis of fire emissions derived from assumptions in the LANDFIRE program and does not include an appropriate analysis of the emissions from logging (in-boundary and transportation/manufacturing of wood products), livestock grazing and infrastructure, and road building/maintenance. An emissions analysis related to all project activities is necessary to properly assess air quality impacts to surrounding communities and CO_2 contributions to climate change with an alternative chosen that minimizes emissions related specifically to forest plan activities (direct, indirect, cumulative emissions impacts).

In sum, I am requesting that the Forest Service modify or include a new alternative that meets the following requirements:

- Identification and protection of specific connectivity areas (e.g., roadless areas, intact riparian and watersheds) for achieving viable populations of focal species, species of conservation concern, and at-risk species in a changing climate (see Noon et al. 2003, Schulz et al. 2013, Haber and Nelson 2015, especially Table 1). Such areas should be protected from mechanical treatments especially habitat of at-risk species (e.g., MSO).
- Consistent with the guidelines for connectivity in Haber and Nelson (2015:Tables 1 and 2), it is essential for the forest plan to identify key characteristics of connectivity (also

Haber and Nelson 2015:Table 3), including composition, structure, process/function at scale: site, landscape, corridors, riparian areas, and wildlife travel routes.

- An analysis and mitigation of how conditions on the SFNF and surrounding areas (logging, roads, development, grazing especially in riparian areas) affect connectivity (cumulative effects analysis).
- Substantial reduction in livestock AUMs and increase in riparian, native meadows, and aspen grove protections, restoration and invasive species containment. This should include opportunities for local conservation groups to purchase grazing leases from willing sellers with the allotments and AUMs permanently retired by the Forest Service. Livestock should be removed from riparian areas and curtailed in areas with native plant communities.
- Accuracy determination and field verification (and error correction) of LANDFIRE and forest canopy determinations, particularly in relation to site-specific reference conditions and ecologically appropriate definitions of closed canopy forests; the >30% closed canopy definition in the DEIS is arbitrary and has resulted in excessive canopy reduction measures to achieve "open" conditions.
- Use of multiple lines of evidence (e.g., see Odion et al. 2014a, Moritz et al. 2018) in estimating historic fire regimes and recognition/ analysis of the importance of mixed-severity fire effects on plant and wildlife diversity, including small and large patches of high-severity fire effects characteristic of drought cycles, fire flare ups, and upper elevation forests.
- A substantial reduction in mechanical treatments that are otherwise resulting in novel forest conditions that lack integrity and climate resilience because of the over-emphasis on open forest conditions that retain few trees. Forests opened by excessive thinning lack understory shrubs, forbs and small trees that contribute to climate resilience (see Baker and Williams 2015, Baker 2018); small trees may also have mature/old growth characteristics because of slow growth rates and more of them need to be maintained as an important understory cohort for future old-growth development (e.g., by creating small gaps and leaving many more tree cohorts).
- A focus on community wildfire risk reduction through partnerships with private landowners that emphasize defensible space measures for homes instead of extensive thinning in the backcountry.
- A substantial reduction in livestock grazing including large no-grazing zones that more aptly address cumulative effects of livestock, infrastructure, and climate change (see Beschta et al. 2012).
- A reduction in project related carbon dioxide emissions by a project level comparison of emissions alternatives.

My detailed comments and supporting publications follow this signature page.

Sincerely,

Dominick A. DellaSala

Independent Conservation Scientist

UNCERTAINTIES OF FIRE SCAR METHODOLOGY, REFERENCE CONDITIONS, AND FAILURE TO MEET BASI REQUIREMENTS OF THE PLANNING RULE

The 2012 planning rule requires forest plans to meet the best available scientific information (BASI) standard during planning assessments. Ryan et al. (2018) provide specifics on how best to meet this standard illustrated in their Figure 2:

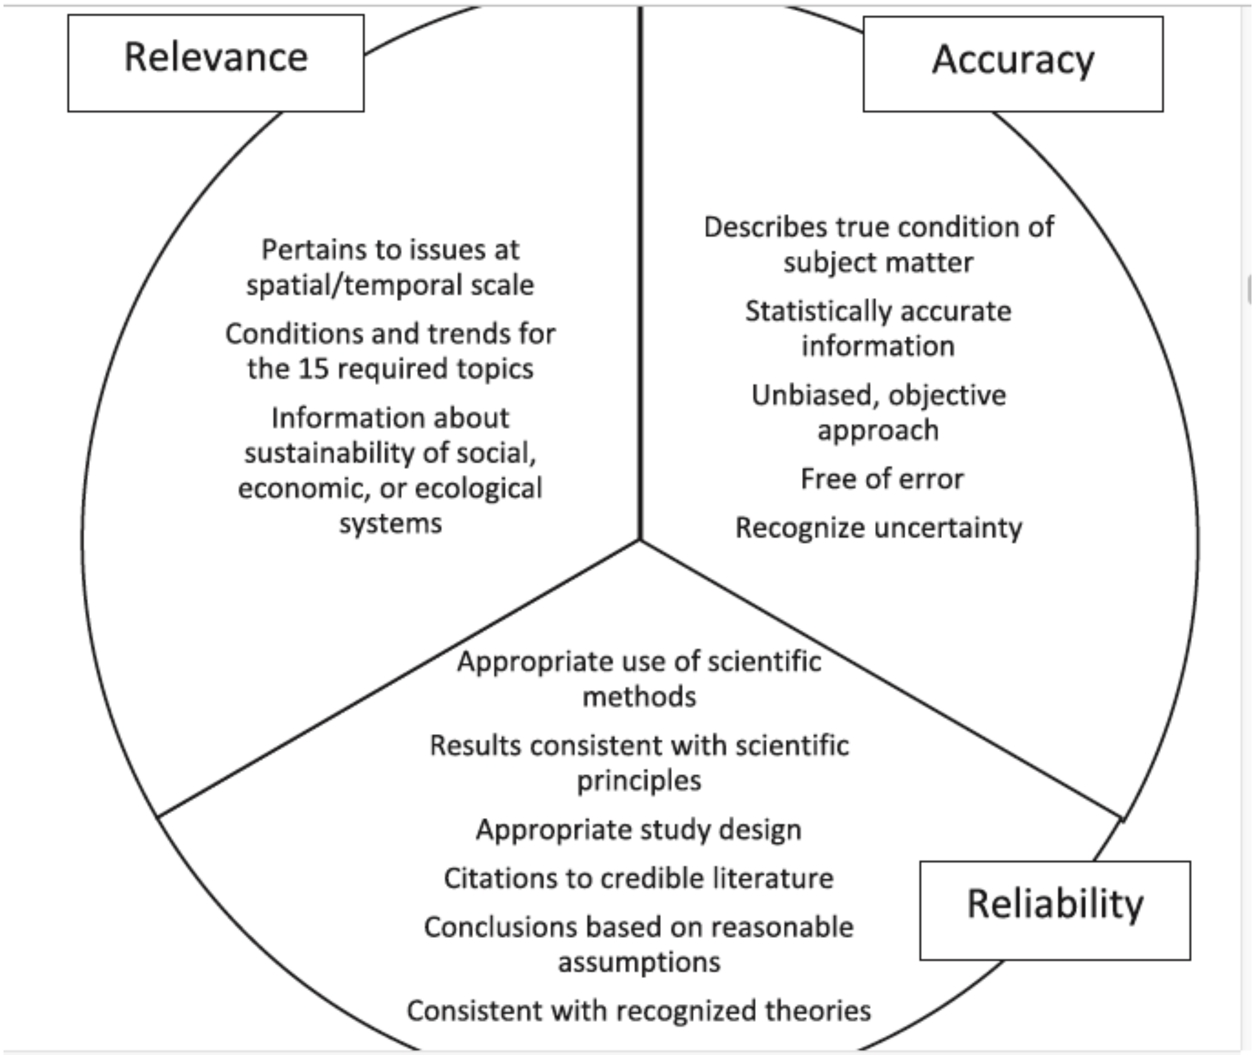

Figure 2 (from Ryan et al. 2018). Criteria for determining best available scientific information (BASI). Source: Forest Service Handbook 1909.12.07.12

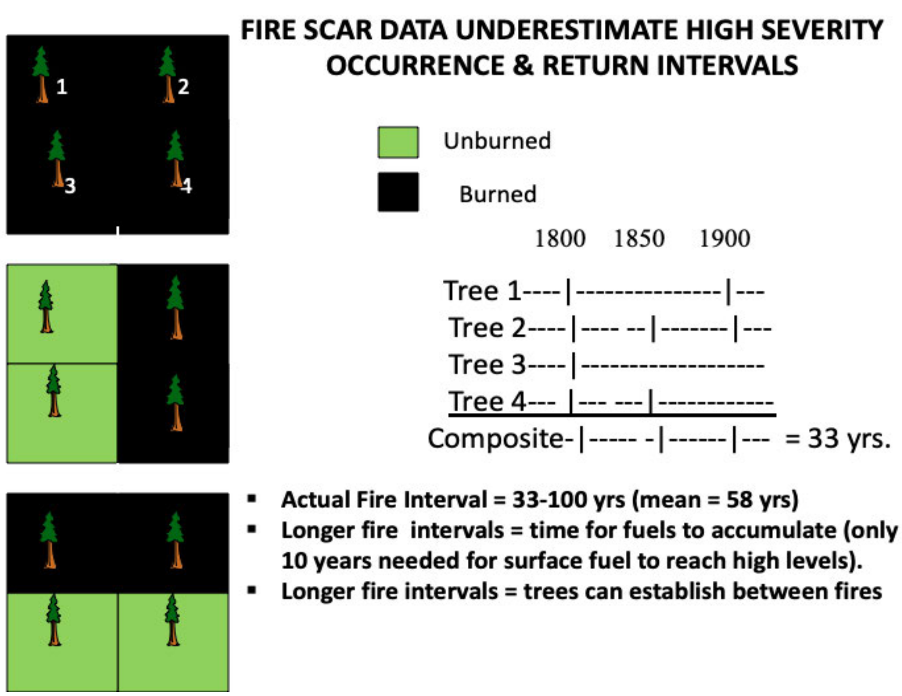
According to Ryan et al. (2018) "the definition of BASI is contained in the "zero code" chapter of the handbook and specifies three primary criteria: accuracy, reliability, and relevance (FSH 1909.12.07.12), in addition to referencing the Data Quality Act (PL 106–554) for guidance on evaluating available information (Figure 2). Available is defined as information that currently exists in a form useful for the planning process without further data collection, modification, or validation (FSH 1909.07.01).

Based on the BASI standard above (especially Ryan et al. 2018: Figure 2), there are two main problems with the DEIS fire assumptions: (1) over reliance on fire scar estimates used to determine fire return intervals that are then extrapolated over large areas instead of the more appropriate use of multiple lines of evidence used to calculate *fire rotation intervals* (landscape scale; see Odion et al. 2014a, Moritz et al. 2018); and (2) accuracy and reliability problems with use of LANDFIRE to estimate reference and contemporary conditions in forest plan analyses (discussed below).

Fire return intervals are biased - While local sampling is important for estimating fire return intervals at the stand level, there are significant uncertainties with extrapolating fire scar point sampling data over large landscapes often used by researchers to re-construct historic fire regimes for comparisons to contemporary conditions (Baker 2017). They include sample-site selection bias, lack of tree scars in fire-killed trees (thereby underestimating high severity occurrence), and inappropriate extrapolation of site-specific data to draw landscape-level inferences (Baker 2017). The hypothetical figure below illustrates the inherent sampling bias of grouping individual fire scar data to construct composite fire interval (mean CFI).



In sum, variability in CFI estimates is masked whenever the mean return interval is used (instead of the range or scope-of-inference is inappropriately extrapolated from sites to large areas and whenever measures of central tendency (rather than the range) are used in fire return intervals.

This results in a cascade of errors beginning with a bias toward very short fire return intervals (i.e., because the mean and not the range was used), conclusions that historic conditions were predominately open forests (especially when open is arbitrarily defined using LANDFIRE, see below), conclusions that contemporary forest conditions are way out of bounds, and, the inappropriate need for aggressive mechanical treatments. To fix this problem, the best estimator of fire intervals at landscape scales is to use the fire rotation interval (Baker 2017).

Baker (2017) notes that fire rotations at the landscape scale can be derived from:

1. Areas burned in recent fires from agency fire records or records from remotely sensed data.
2. Historical areas burned reconstructed from scarred trees or plot locations.
3. Historical areas burned reconstructed using a ratio method and scarred-tree or plot records, or comparable data in a table or graph.

The Forest Service must provide information on the fire rotations using methodologies in Baker (2017) supplemented wherever possible with the paleo-ecology literature that can be used to reduce sampling bias associated with shorter sampling timelines and lack of high severity detectability from fire scar extrapolations. For instance, Baker (2017) goes through each source of bias in tree-ring reconstructions and shows that using corrected estimators actually yields longer fire rotation periods for dry pine/mixed conifer areas. Note that Figure 3 and Figure 4 in Baker (2017) show the diversity of fire rotations (longer intervals) in the Santa Fe area and the S2 Table has individual estimates for New Mexico. The sampling bias in fire-scar data must be disclosed as the DEIS is based mainly on fire-scar interpolation from plots to landscapes thereby compounding errors.

To correct for sampling bias, the Forest Service must account for variability in fire-free intervals using more robust methodologies, disclose whether there are historic accounts of fires in the DEIS area beyond just fire-scars, and include paleo-ecology studies from comparable sites to illustrate variability in fire regimes over longer time intervals. Significant discrepancies and debate among researchers about fire scar sampling must be disclosed (e.g., see Odion et al. 2016 response to Stephens et al. 2016 and Moritz et al. 2018).

As an example, a key fire-history study for the Santa Fe watershed is Margolis and Balmat (2009). These researchers indicate that the historical low-severity fire rotation in this watershed for dry pine forests was estimated at 39.80 years. They define frequent fire as < 25 years. Using their definition means that the Santa Fe watershed would not qualify as a frequent-fire regime, as this is a sufficient mean number of years between surface fires to allow understory fuels including shrubs and small trees to accumulate levels that would certainly enable the occurrence of some mixed and high-severity fires and some dense forests overtime. Moreover, this longer period corresponds with the paleo-record from charcoal sediments showing that when wet periods are followed by successive droughts, large fires, including patches of high severity, do indeed occur (Meyer 2010).

It is important to accommodate this variability in fire return interval estimates as heterogeneity in the ensuing burn severity patches at the landscape scale results in high levels of biodiversity (i.e., pyrodiversity of fire severity patches begets biodiversity, DellaSala and Hanson 2015). Notably, even slight differences in fire-return intervals are consequential. Baker (2017) reports that understory fuels in dry forests recover after fires in 7-25 years. If mean fire-return intervals were <25 years, understory fuels would be limited. However, if the interval was >25 years, as reported by Margolis and Balmart (2009), then shrubs and small trees would recover across the landscape and excessive thinning to shift forest to more open-canopy forests with minimal small tree and shrub cover would be inappropriate at large spatial scales.

The role of shrubs and understory vegetation is also a key ecosystem component in dry forests allowing for nutrient cycling and below-ground processes, water absorption and retention, provision of wildlife habitat, pollination and other ecosystem services. Spatial heterogeneity in fire-return intervals at landscape scales is a key indicator of resilience as it allows for both fire refugia (longer return intervals) and fire-maintenance (short return intervals). It is essential to manage for this variability at the site and landscape scale to accommodate wildlife that require a range of severity effects on vegetation: low, moderate and high severity. In other words, when it comes to fire, nature is complex (e.g., mixed severity) while management tends for uniformity (mainly low severity) typically at the expense of fire-mediated biodiversity.

The following Baker (2017) observations about fire interval estimators need to be addressed in the DEIS:

> "Dry-forest landscapes until recently were thought to have historically been primarily old growth forests, with a history of frequent low-severity fire, across their extent (e.g. [72]), but this has been refuted by GLO reconstructions and early aerial photographs (Table 6), paleoecological evidence [24], and early forest-reserve reports and other evidence [63 , 73]. Even in Arizona, which had abundant old forests with frequent fire (Fig 3), denser forests and high severity fire were extensive at certain times and in certain places, as on Black Mesa and parts of the Mogollon Plateau [60 , 73]. It is sensible to restore low-severity fire to its former dominance in the parts of dry-forest landscapes with a history of primarily low-severity fire, historically averaging about 34% of western dry-forest landscapes (Table 6). Estimated mean PMFI/FRs [population mean fire interval/fire rotation] here provide a guide for restoration and management of low-severity fire in extant old-forest parts of landscapes. For most dry-forests today, which are not old, using frequent fire (PMFI/FR <25 years) in restoration is not supported, and fuels do not need to be substantially reduced, because historical PMFI/FRs naturally allowed historical shrubs and small trees to fully recover after fires. Restoration of low-severity fire is still

> needed. The most appropriate approach, given likely long but uncertain mean rates of historical low-severity fire, is for most dry forests today to receive at most one prescribed fire, followed by managed fire for resource benefit, with the goal of mimicking mean historical PMFI/FRs and variability in fire (fire-size distributions, unburned area) as forests reach old age."

Thus, based on Baker (2017) and the problems noted in estimating fire return intervals, the DEIS needs to greatly scale back thinning except where thinning of small trees is needed to re-introduce fire nearest homes.

Problems with GTR-310 reference conditions - The DEIS tiers to GTR-310 (Restoring Composition and Structure in Southwest Frequent Fire Forests). However, GTR-310 does not even align with the geographic scope of the SFNF, as the SFNF is within the Colorado Rockies Forest Ecoregion yet GTR-310 is predominately within the Arizona Mountain Forest Ecoregion, which has a different climate, soil types, historical conditions, and fire regime. Extrapolating from one region to another is inappropriate (Moritz et al. 2018) and thus GTR-310 cannot be relied on for project-specific descriptions or actions.

The DEIS relies upon General Technical Report 310 as a primary source for desired conditions in the SFNF. This is inappropriate because none of the reference studies were from the Sangre de Cristo Mountains, and the two locations in the Jemez Mountains represent just 12 acres of sampled forest. The DEIS should instead rely on site-specific reference conditions and exercise caution when extrapolating fire regimes and forest structures from one geographic location to another given differences in vegetation, fire rotation intervals, elevation gradients, regional climate, and the influence of a rapidly changing climate on contemporary and future fire conditions (see Moritz et al. 2018). Thus, applying the "Flagstaff fire model" derived from GTR-310 is completely inappropriate for the SFNF.

ACCURACY PROBLEMS WITH LANDFIRE NEED FULL DISCLOSURE AND CORRECTION

Fire regime condition class (FRCC) and LANDFIRE vegetation models and maps are used by the Forest Service in planning assessments. These approaches are useful at large spatial scales (national) but they have well known accuracy problems at the project level that need full disclosure, cross validation with field data, and error correction.

For instance, Swetnam and Brown (2010) examined accuracy of LANDFIRE and FRCC assessments in Utah for similar vegetation types as in the DEIS planning area (Box 7).

Box 7. "LANDFIRE map data were found to be ~58% accurate for BpS and ~60% accurate for existing vegetation types. Results suggest that limited sampling of age-to-size relationships by different species may be needed to help refine reference condition definitions used in FRCC assessments, and that more empirical data are needed to better parameterize FRCC vegetation models in especially low-frequency fire types."

Zhu et al. (2006) tested the vegetation mapping protocol of LANDFIRE and likewise *concluded mapping accuracies of 60% or better at 30-m spatial resolution*. Notably, such low accuracy determinations do not comport with Ryan et al. (2018) summary of BASI criteria (their Figure 2 above) and the intent of the Data Quality Act.

Helmbrecht and Blankenship (2016) tested the ability of LANDFIRE to accurately reflect the true or accepted geographic location of features finding problems with errors in feature locations, source data, precision of field measurements, and data entry. Problems in map unit assignments may arise through "*errors or limitations in remote sensing data, field plots, statistical modeling, processing logic, or a combination of these and other factors*" (emphasis added). This is especially the case for forest vegetation and fuels data depending on the age of the source data. For instance, LANDFIRE data are updated every two years but by the time the data are delivered to the user, the data are 3 or more years out of date.

To correct for these problems, Helmbrecht and Blankenship (2016) recommend (and the DEIS should as well) include the following:

1. update for landscape changes that have occurred since the LANDFIRE version,
2. calibrate to local data and knowledge,
3. improve the thematic agreement (accuracy),
4. change the spatial or thematic resolution (e.g. lump or split map units),
5. modify the map unit classification,
6. create additional data versions that reflect temporal variability (e.g. peat soils being available for burning in drought situations, or exotic annual grasses being present in wet years but not dry years),
7. facilitate comparative analysis by creating data versions (e.g. analyzing pre- and post-treatment effects or comparing treatment alternatives),
8. analyze future conditions (e.g. modifying data to represent future conditions under a climate change scenario).

In Northern Idaho, Hyde et al. (2015) evaluated two LANDFIRE fuel loading raster options: (1) Fuels Characteristic Classification Systems (LANDFIRE-FCCS); and (2) Fuel Loading Model (LANDFIRE-FLM) vs. measured fuel loadings for a 20,000-ha mixed conifer study area. They found that the LANDFIRE-FCCS layer showed 200% higher duff loadings relative to measured loadings that led to 23% higher total mean consumption and emissions when modeled in FOFEM. The LANDFIRE-FLM layer showed lower loadings for total surface fuels relative to measured data, especially in the case of coarse woody debris that led to 51% lower mean total consumption and emissions when modeled in FOFEM. Additionally, LANDFIRE-FLM consumption was *59% lower relative to that on the measured plots, with 58% lower modeled emissions*. The authors concluded that these differences in fuel loadings led to significant differences in consumption and emissions depending upon the data and model chosen. The DEIS therefore needs to disclose how errors in fuel loading consumption were addressed in emissions determinations regarding wildfires and how these errors were corrected.

In the Sierra Nevada region, Odion and Hanson (2006) found FRCC *was not able to accurately predict occurrence of high-severity fire* (Box 8).

Box 8. "We found that the proxy for fire suppression effects, Condition Class, was not effective in identifying locations of high-severity fire. Condition Classes 2, 3, and 3+ in the McNally fire all had similar fire severity proportions. When the same Condition Class criteria were applied to the other two fires, we found that fire severity generally decreased rather than increasing from Condition Class 2 to 3+. In short, Condition Class identified nearly all forests as being at high risk of burning with a dramatic increase in fire severity compared to past fires. Instead, we found that the forests under investigation were at low risk for burning at high-severity, especially when both spatial and temporal patterns of fire are considered. The lack of an observed relationship between Condition Class and fire severity suggests that exogeneous forces such as weather, climate, topography, and neighboring vegetation (for example, pyrogenic shrubs) largely determine fire-severity patterns in forests."

Vogelmann et al. (2014) recognized four major potential sources of error associated with field plot data used in LANDFIRE:

1. Errors occur frequently in the identification of species and measurement of vegetation structure in the field (for example, in the data for one prototype field plot, a misplaced decimal point indicated a shrub height of 60 feet).
2. The vegetation on some field plots has undoubtedly changed between the time the field data were collected and when the imagery was acquired.
3. Geo-location errors in plot and imagery data result in inaccurate characterization of some imagery pixels.
4. The assignment of plots to specific vegetation classes will have errors associated with the wide array of opinions among professional field ecologists regarding the field classification of any given field plot.

To correct for these problems, Vogelmann et al. (2014) suggest (and the DEIS should follow) that the Forest Service conduct a suite of accuracy assessment methods for LANDFIRE, ranging from mostly qualitative assessments (such as the critical inspection of products, consultation with regional experts, and comparisons with existing data sets) to more quantitative analyses (such as cross-validation assessments, traditional accuracy assessments at the superzone level, and select evaluations at local levels). These combined approaches will provide the Forest Service with the accuracy information necessary to facilitate the appropriate use of the data in the DEIS.

Cruz and Alexander (2010) note additional problems with related fire modeling summarized in their abstract. The Forest Service needs to disclose errors associated with use of these models in the DEIS:

Abstract. To control and use wildland fires safely and effectively depends on creditable assessments of fire potential, including the propensity for crowning in conifer forests. Simulation studies that use certain fire modelling systems (i.e. NEXUS, FlamMap, FARSITE, FFE-FVS (Fire and Fuels Extension to the Forest Vegetation Simulator), Fuel Management Analyst (FMAPlus[!]), BehavePlus) based on separate implementations or direct integration of Rothermel's surface and crown rate of fire spread models with Van Wagner's crown fire transition and propagation models are shown to have a significant underprediction bias when used in assessing potential crown fire behavior in conifer forests of western North America. The principal sources of this underprediction bias are shown to include: (i) incompatible model linkages; (ii) use of surface and crown fire rate of spread models that have an inherent underprediction bias; and (iii) reduction in crown fire rate of spread based on the use of unsubstantiated crown fraction burned functions. The use of uncalibrated custom fuel models to represent surface fuelbeds is a fourth potential source of bias. These sources are described and documented in detail based on comparisons with experimental fire and wildfire observations and on separate analyses of model components. The manner in which the two primary canopy fuel inputs influencing crown fire initiation (i.e. foliar moisture content and canopy base height) is handled in these simulation studies and the meaning of Scott and Reinhardt's two crown fire hazard indices are also critically examined.

DellaSala et al. (2015) further summarize the problems with fuel models and simulations not comporting with field data and resulting in over-emphasis of efficacy of fuel reduction treatments and these uncertainties need to be addressed in the DEIS as follows:

"Fuel reduction also has been overpromised to be effective, using questionable logic and unvalidated models. First, fire intensity in most forest types is much more strongly affected by wind than by fuel. High fire-line intensity, the primary fire characteristic that promotes crown fires, is the product of the energy released by burning fuel and the rate of spread of fire (Alexander, 1982). Energy release by fuel varies over perhaps a 10-fold range, however, whereas rate of spread can vary over more than a 100-fold range; thus a high rate of spread caused by strong winds can easily overcome the limited reductions in fuel that are feasible (Baker, 2009). This was confirmed by a recent analysis of the 2013 Rim Fire in California, which concludes: "Our results suggest that even in forests with a restored fire regime, wildfires can produce large-scale, high-severity fire effects under the type of weather conditions that often prevail when wildfire escapes initial suppression efforts. . . . During the period when the Rim fire had heightened plume activity... no low severity was observed [in thinned areas], regardless of fuel load, forest type, or topographic position" (Lydersen et al., 2014, p. 333). Second, common fire models used to show that forests would be fire-safe after fuel reductions have an underprediction bias and are not validated. These flawed models include NEXUS, FlamMap, FARSITE, FFE-

FVS, FMAPlus, and BehavePlus (Cruz and Alexander, 2010; Alexander and Cruz, 2013; Cruz et al., 2014). The underprediction bias means that these models often predict that fuel reductions would reduce or eliminate the potential for crown fires in forests, when in fact fuel reductions do not achieve this effect. Fixing these models would be difficult and has not yet occurred (Alexander and Cruz, 2013). Also, these models have not been sufficiently tested and validated using a suite of actual fires, in which case they would likely be shown to fail (Cruz and Alexander, 2010). Alternative validated models are available and could be further developed, but they are not being used (Cruz and Alexander, 2010). Further, studies of tree mortality in thinned areas following fire do not typically take into account the mortality caused by the logging itself before the fire, leading to further biased results."

As further noted by DellaSala et al. (2015) "these concerns should raise red flags about the effectiveness of fuel treatments, as well as issues regarding liability and responsibility. Imagine if a company sold airplanes with identified flawed designs and without adequate test flights, which then crashed. There are thus sound scientific reasons to closely scrutinize government wildland fuel-reduction programs. Meanwhile, we need to be honest and warn the public that living within or adjacent to natural forests prone to burn is inherently hazardous. Only treating fuels in the immediate vicinity of the homes themselves can reduce risk to homes, not backcountry fuel reduction projects that divert scarce resources away from true home protection (Cohen, 2000; Gibbons et al., 2012; Calkin et al., 2013; Syphard et al., 2014)."

Closed Canopy Conditions Arbitrarily Defined - the DEIS arbitrarily defines closed canopy conditions in the mixed conifer-frequent fire and ponderosa pine ERUs as when *woody cover exceeds 30%* (DEIS: Figure 14, Figure 16), using LANDFIRE to determine the reference/baseline condition and contemporary departure indices for alternative analyses. The preferred alternative is based on moving closed canopy forests into desired open canopy conditions over 50 years. Closed canopy forests in some cases currently exceed 70% overstory cover and thus extensive thinning in the preferred alternative constitutes a major change in overstory cover impactful to species requiring closed canopy conditions. Large interspaces will be created across the landscape with substantial reductions in canopy cover and percent of forests in closed conditions to meet this arbitrarily defined "open" reference condition, creating novel ecosystems that do not comport with the ecological integrity or diversity requirements of the planning rule.

Importantly, Scott (2008) documented seven potential shortcomings with the canopy and fuel related provisions of LANDFIR, including:

- canopy cover values are too high,

- data discontinuities exist within and between map zones,
- canopy bulk density values are too low for use in FARSITE,
- canopy base height is too high to generate crown fire,
- treelist data sources may not be best for canopy fuel calculations
- alternative canopy fuel calculation programs may produce different results
- Refreshing and calibrating LANDFIRE data is needed

Scott (2008) reported that the dead fuel moisture model is especially sensitive to errors in canopy cover and concludes:

"Moreover, canopy cover mapping errors may lead to significant indirect fire modeling effects. Because canopy cover is a keystone variable, these indirect effects are difficult to quantify. If canopy cover is overestimated, LANDFIRE may subsequently map the incorrect fuel model, incorrect CBD, incorrect CBH, etc., all of which can strongly affect fire modeling outputs in a geospatial fire analysis."

"Because it is used as an independent variable, the importance of an accurate canopy cover layer in the LANDFIRE process should not be underestimated."

THE DEIS NEEDS TO RECOGNIZE THE ECOLOGICAL IMPORTANCE OF MIXED-SEVERITY FIRES, INCLUDING LARGE AND SMALL HIGH SEVERITY PATCHES FOR POSITIVE CONTRIBUTIONS TO PLANT AND WILDLIFE DIVERSITY

While low elevation pine and mixed conifer forests are predominately maintained by frequent fires of low severity effects on vegetation, there are occasional canopy flare ups and high-severity patches related to local fire-weather conditions, slope, aspect, elevation, and vegetation condition. This variability in fire effects needs to be maintained under the diversity requirement of the planning rule. Instead, the DEIS includes no analysis of the positive effects of mixed-severity fire influences on plant and wildlife communities, especially in upper elevation forests where fires are on centuries long rotation intervals (landscape scale) and produce diverse ecosystem effects including the creation of complex early seral forests (Swanson et al. 2011).

Notably, high-severity fire patches generate "biological legacies" (large live and dead trees, logs, shrubs) essential to forest succession and the maintenance of complex early seral forest conditions (Swanson et al. 2011, DellaSala et al. 2014, DellaSala and Hanson 2015, DellaSala and Hanson 2019). Large and small high severity patches provide important foraging habitat for Mexican Spotted Owls (federally listed, Lee 2018), Northern Goshawks (at-risk species), ungulate foraging habitat (Bond 2015), snowshoe hare/lynx dynamics, woodpeckers (including at-risk species: Lewis's woodpecker) and songbirds (Hutto et al. 2015), bats (Chambers and Saunders 2013), and boreal owls (at-risk species) in upper elevation spruce-fir forests. The DEIS inappropriately and arbitrarily assumes high-severity patches constitute wildlife habitat degradation (e.g., DEIS Volume 1: Tables 51, 57; "catastrophic fire analysis" p. 244).

Using LANDFIRE, the DEIS inappropriately assumes that current fire return intervals are highly departed from reference conditions (86%) as is fire severity leading to what the DEIS claims is a departure from NRV (DEIS Volume 1:89). However, based on a study of high-severity patches in dry pine and mixed conifer forests across the West, including New Mexico, large (>400 ha) high-severity fire patches have not been increasing since the 1990s (DellaSala and Hanson 2019.

From DellaSala and Hanson (2019):

Over the entire time series, 1984-2015, there was a significant increasing trend in the combined total area of CESF [complex early seral forests] patches >400 ha in each year ($\tau = 0.407$, $p = 0.001$), but no trend in patch size ($\tau = 0.009$, $p = 0.802$). However, when the data were analyzed by time periods, there was only a significant difference in the annual area of CESF habitat created by high-severity fire relative to the earliest time period (1984-1991), but no significant differences were detected among time periods since the early 1990s (Table 1, Figure 2). With regard to size of individual large CESF patches, there were no significant differences detected among time periods (Table 2).

Table 1. Critical values ($q_{0.05, 4}$), absolute difference between mean of ranks ($|R_A\text{-}R_B|$), standard errors (SE), and test statistics (q) to assess statistical significance, at $\alpha = 0.05$, of any differences between the four time groups ("1" = 1984-1991, "2" = 1992-1999, "3" = 2000-2007, and "4" = 2008-2015) for total annual area of CESF patches >400 ha using the Nemenyi non-parametric test for multiple comparisons between groups with an equal sample size (n = 8 years for each time group). Statistical significance of levels of q are shown as "Y" (significant) or "N" (not significant).

Time group comparison	$q_{0.05,4}$	$\|R_A\text{-}R_B\|$	SE	q	Significant? ($q > _{0.05,4}$?)
1-2	3.63	45.0	26.53	1.70	N
1-3	3.63	108.0	26.53	4.07	Y
1-4	3.63	107.0	26.53	4.03	Y
2-3	3.63	63.0	26.53	2.37	N
2-4	3.63	62.0	26.53	2.34	N

3-4	3.63	1.00	26.53	0.04	N

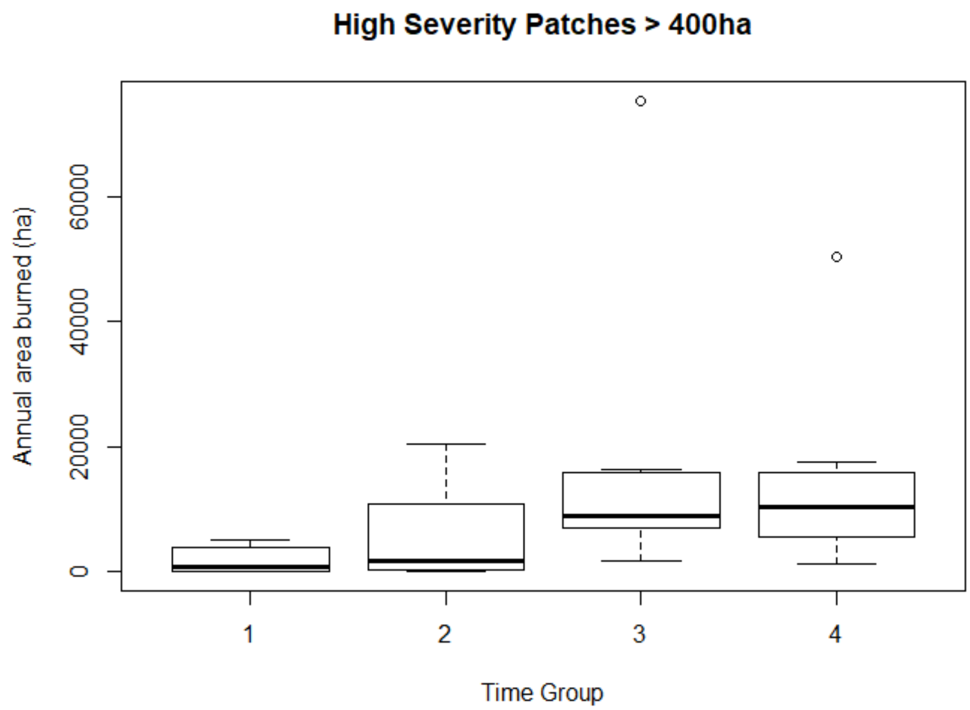


Figure 2 from DellaSala et al. Annual area of large patches (>400 ha) of high-severity fire in the four time periods ((“1” = 1984-1991, “2” = 1992-1999, “3” = 2000-2007, and “4” = 2008-2015).

Thus, the DEIS claims about uncharacteristically severe fires, for which mechanical treatments are based upon, cannot be substantiated by empirical data (including from New Mexico) and thus the DEIS does not meet the BASI requirements.

Importantly, Hutto et al. (2016) recommended that managers maintain ecological integrity of western dry pine and mixed-conifer forests through a more informed approach to the importance of mixed and high-severity fires. Here is their abstract:

Abstract. *We use the historical presence of high-severity fire patches in mixed-conifer forests of the western United States to make several points that we hope will encourage development of a more ecologically informed view of severe wildland fire effects. First, many plant and animal species use, and have sometimes evolved to depend on, severely burned forest conditions for their persistence. Second, evidence from fire history studies also suggests that a complex mosaic of severely burned conifer patches was common historically in the West. Third, to maintain ecological integrity in forests born of mixed-severity fire, land managers will have to accept some severe fire and maintain the integrity of its aftermath. Lastly, public education messages surrounding fire could be modified so that people better understand and support management designed to maintain ecologically appropriate sizes and distributions of severe fire and the complex early-seral forest conditions it creates.*

DellaSala et al. (2017) recommend that managers include mixed-severity effects in dry pine and mixed conifer forests to achieve ecological integrity and plant diversity. And while much of the

DEIS project area can be assumed to be in a xeric pine condition, mixed-severity fire effects, including large and small high-severity patches are indeed characteristic, need to be maintained, and are being grossly underestimated in ecological importance throughout the DEIS. Thus, the DEIS does not meet the BASI requirements of the planning rule as well as the diversity, ecological processes, ecological conditions, and integrity provisions as noted.

BIASED APPROACHES, AREAS OF AGREEMENT & DISAGREEMENT NEED TO BE ACKNOWLEDGED AND CORRECTED

Bias: The DEIS needs to clearly state scientific disputes (disagreements) and avoid biased perspectives on fire as generally noted by Iftekhar and Pannell (2015) and Moritz et al. 2018 (below). The following biased perspectives are inherent in the DEIS:

- Action bias – tendency to take actions even when it is better to delay action (in this case the impacts of aggressive thinning and roads may be more significant than effects of fire on ecosystems given uncertainties of treatment effectiveness as noted).
- Framing effect – tendency to respond differently to alternatively worded but objectively equivalent descriptions of the same item (use of catastrophic fire terminology in the DEIS that fails to account for ecosystem benefits of mixed-severity fires, including periodic flare-ups of high severity patches).
- Reference-point bias – tendency to overemphasize a pre-determined benchmark for a variable when estimating the level of that variably (i.e., over-reliance on fire scar sampling in the DEIS rather than presenting more robust and multiple lines of evidence).
- Satisficing rule – tendency to stop searching for a better decision (i.e., a NEPA based range of alternatives) once a decision that seems sufficiently good is identified.
- Loss aversion – tendency to value losses more highly than similar gains (i.e., managing wildfire of moderate-high intensity for ecosystem benefits instead of avoiding it by mechanical thinning and fire suppression as in the DEIS).
- Limited reliance on systematic learning – tendency to use information from past successful efforts rather than using information from both successful and failed efforts via extensive and well-funded ecosystem monitoring (adaptive management and learning is not possible without well-funded monitoring).

The best way to avoid these biases is to use multiple lines of evidence in re-constructing fire regimes, not rely mainly on fire scars, and conduct well-funded monitoring studies that fully assess project effects on species of conservation concern and ecological and cultural values. Multiple lines of evidence and monitoring are discussed in Odion et al. 2016 and Moritz et al. (2018) in the Common Ground Report (see below).

Areas of Agreement/Disagreement (Common Ground): I participated as one of the respondents in the so-called "Common Ground" report and am thoroughly familiar with the report's findings. The DEIS should pay particular attention to the following key findings in relation to areas of agreement, uncertainty, and disagreement and adjust project actions accordingly.

Areas of Agreement (high certainty):

- The role of changing climatic conditions is increasingly important in influencing fires.
- Multiple fire ecology and fire history research can be useful.
- Heterogeneity of fire effects, including patterns of patches created by fires of all severities, is important to forest resilience to future fires.
- Generalized models of historical fire regimes vary by ecoregion and forest type.
- Even within the same ecoregion and forest type, there is variation in historical fire regimes among differing environmental gradients.
- Historically, some degree of low-, moderate-, and high-severity fire has occurred in all forest types, but in substantially different proportions and patch size distributions at different locations.
- Classification of historical fire regimes according to forest types can be coarse; thus, failure to recognize variation of historical fire regimes *within* forest types can lead to overgeneralization and oversimplification of landscape conditions.
- Presence of roads, road density and railways, livestock grazing, invasive species, and mining can alter fire regimes. Even a single one of these influences can have profound effects on vegetation and fire behavior conditions. When present in combinations, cumulative effects will arise that may push ecosystems past tipping points (Paine et al. 1998, Lindenmayer et al. 2011).
- Knowledge of historical range of variability (HRV) is useful but does not dictate land management goals. HRV findings from one area may or may not have relevance elsewhere.
- Recent trends in many western forest regions of more large fires and more area burned are linked to recent climatic trends of hotter droughts and longer, more severe fire seasons.
- Respondents who emphasized the longer time scales of charcoal records noted that most areas of predominantly low-severity fires showed some incidence of moderate- or high-severity fire over longer time frames.
- It is desirable to use multiple methods to reconstruct historical fire regimes. More can be learned using multiple approaches and considering data from diverse temporal and spatial scales.

- Importance of local context in management of fire-prone landscapes underscores the need to move away from oversimplified narratives that encourage application of fire research beyond its original scope of inference. Note: the scope of inference is of particular concern here as over reliance on fire scar sampling for landscape scale interpolation has inherent biases and uncertainties.

Areas of Disagreement (high uncertainty):

- Fire regime inferences from historical and modern tree inventory data, simulation models, and other approaches have levels of uncertainty.
- Whether large, high-severity fires have increased to a significant and measurable degree in all forest types *in comparison to historical fire regimes* (i.e., prior to modern fire suppression) remains debatable.
- Fuel treatments are urgently needed across nearly all forests remains debatable.
- Fuel treatments should be focused around communities and plantations; but hazard fuel reduction elsewhere remains debatable.
- There is high uncertainty about where and when fuel treatments are beneficial.
- Commonly used vegetation classification schemes as a suitable basis for generalizing about fire regimes remains debatable. Known geographic variation in fire regimes within forest types argues for improved forest and fire regime classifications.
- Tree-ring evidence sometimes supports conclusions that contrast with those derived from landscape-scale inventory and monitoring data using different sampling frames creates uncertainty.
- General applicability of "thinning and prescribed burning remedies" to offset human influences is debatable.
- Human impacts on forest successional conditions in moist and cold forests remains debatable.
- Extent to which landscape tipping points have been reached as a result of high-severity fires is debatable.
- Effectiveness of fuel treatments under projected climate futures and associated more extreme fire weather is uncertain.
- Interpretation of any research evidence and the scope of related inferences is limited by scaling (uncertainty) and sampling concerns associated with the methods, and these limitations apply to all research methods.
- All methods for reconstructing historical fire regimes are necessarily indirect and have degrees of uncertainty. They may include, but are not limited to, interpreting evidence of past fires or the extent of fire-dependent ecosystems from historical documents, land surveys, aerial photographic reconstructions, fire-scar and growth-release data from tree rings, tree age and death dates from tree-ring data, climatic data linked with past fires,

charcoal and pollen deposits, current characteristics of stands (i.e., structure, species, and stand age distribution), fire perimeter mapping, historical timber survey data, and use of statistical distributions for modeling stand-replacing fire.

ROAD IMPACTS AND ROADLESS AREA IMPORTANCE NEED TO BE ANALYZED TO COMPLY WITH CONNECTIVITY REQUIREMENTS OF THE PLANNING RULE

Roads – Given the extensive and cumulative impacts of roads on ecosystem processes, wildlife, water quality, and fire ignitions (see below), *a minimum road density analysis* needs to be conducted to assure the public that there are no excessive roads and that more roads can and should be decommissioned and obliterated rather than improving and building more roads. The DEIS needs to provide a transportation plan analysis to fully assess road-related fire ignitions associated with improved access and to come up with an alternative that reduces them.

Simply improving culverts and surfacing primitive dirt roads with poor drainage also may not be enough to improve water quality. Notably, the DEIS provides no information on Clean Water Act 303d water-quality limited streams and how project-related impacts will be minimized to comply with state and federal water quality standards[2]. Water quality must be assessed in relation to road improvements, greater road access, thinning impacts, and road-stream intersections.

In sum, the DEIS needs to fully disclose road-related impacts as follows:

- Roads and thinning contributions to soil erosion and sediment inputs affecting water-quality even when roads are improved.
- Probability of human-caused wildfire ignitions associated with improved road access (see Balch et al. 2017 for human-caused ignitions, pdf enclosed).
- Fragmentation and degradation of wildlife habitat at road densities > 1 mi/sq mi, particularly impacts to large carnivores and aquatics.
- Spread of invasive species and their effects on fire regimes.
- Likelihood of mass-wasting events on steep erosive slopes along the road prism.

2Particularly in relation to EPA standards see https://nepis.epa.gov/Exe/ZyNET.exe/00001O9W.TXT?ZyActionD=ZyDocument&Client=EPA&Index=1986+Thru+1990&Docs=&Query=&Time=&EndTime=&SearchMethod=1&TocRestrict=n&Toc=&TocEntry=&QField=&QFieldYear=&QFieldMonth=&QFieldDay=&IntQFieldOp=0&ExtQFieldOp=0&XmlQuery=&File=D%3A%5Czyfiles%5CIndex%20Data%5C86thru90%5CTxt%5C00000001%5C00001O9W.txt&User=ANONYMOUS&Password=anonymous&SortMethod=h%7C-&MaximumDocuments=1&FuzzyDegree=0&ImageQuality=r75g8/r75g8/x150y150g16/i425&Display=hpfr&DefSeekPage=x&SearchBack=ZyActionL&Back=ZyActionS&BackDesc=Results%20page&MaximumPages=1&ZyEntry=1&SeekPage=x&ZyPURL

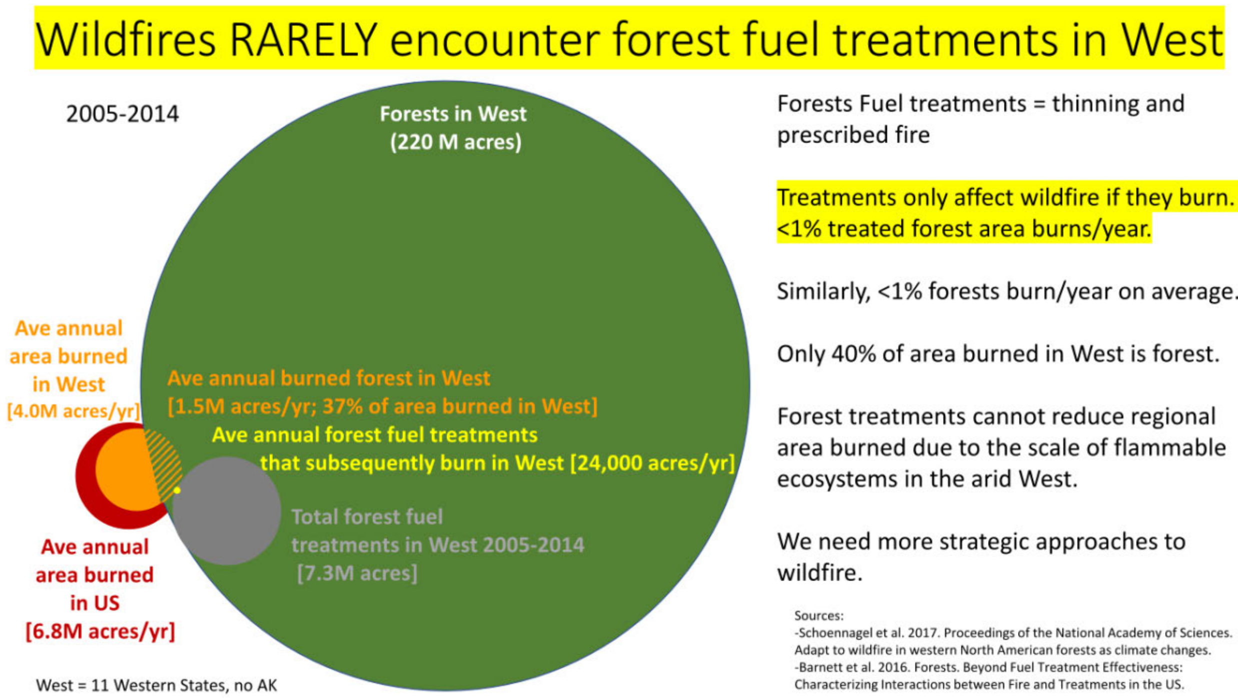
Ibisch et al. (2016) provide a global synthesis of road-related impacts including: wildlife mortality (vehicle collisions); poaching pressure; sediment increases (runoff); chemical contamination; carbon emissions; spread of invasive species; fire ignitions; and habitat fragmentation among others. These impacts can extend out to 1 km on either side of the road prism. Thus, road impacts need to be fully addressed and properly mitigated to assess planned extensive road upgrades and access.

Roadless Areas - The ecological importance of roadless areas is well-documented in the literature (Strittholt and DellaSala 2001, Loucks et al. 2003, Crist et al. 2005, Ibisch et al. 2016) and emphasized in landmark Forest Service policies such as the Roadless Conservation Rule[3] and Interior Columbia River Basin strategy[4]. At a minimum, the DEIS needs to disclose any treatments proposed in inventoried roadless areas and low density roaded areas (<1 mi/sq mi) and must avoid thinning in these areas because of their high conservation value, particularly as relatively unfragmented blocks of wildlife habitat. Roadless areas and low-density roaded areas are of considerable importance to ecosystem integrity (as defined by the 2012 planning rule) as they are often at the headwaters of watersheds essential in maintaining water quality and terrestrial and aquatic ecosystem integrity (DellaSala et al 2011). Roadless areas also tend to be of much lower priority for fuels reduction given their fire regimes are less altered by suppression and they lack the ignition problems associated with roaded areas (e.g., see Roadless Conservation Rule, Columbia River Basin strategy, DellaSala and Frost 2001).

LIMITATIONS OF THINNING ON FIRE BEHAVIOR IN A CHANGING CLIMATE NEED TO BE RECOGNIZED AND CORRECTED

The figure below illustrates uncertainties of relying on thinning to reduce fire intensity given that the period of when fuels are lowest is generally short lived and fires rarely encounter thinned sites when fuels are lowest (Schoennagel et al. 2017). The extremely low probability of fire and thinned site co-occurrence invalidates the DEIS assumptions about lowering fire intensity. Simply increasing the area thinned does not change these odds appreciably given one cannot accurately predict when and where a fire will occur and many areas are inaccessible (Schoennagel et al. 2017).

[3] https://www.fs.usda.gov/roadmain/roadless/2001roadlessrule
[4] https://www.fs.fed.us/r6/icbemp/html/ICBEMP_Frameworkmemorandum-and-strategy_2014.pdf



Moreover, the DEIS needs to disclose the difference between prescribed fire that is applied at the stand level (where impacts to soils can be dispersed and limited) vs. pile burning to consume slash that can cause localized soil damage (excessive soil heating) facilitating the spread of invasive plants and delaying forest succession (especially if livestock grazing also occurs, Besctha et. al 2012).

Excessive opening of the tree canopy can also lead to higher wind penetrance and rapid fire spread, particularly if thinning is conducted on steep slopes and in remote areas with limited access making fine fuel consumption via pile burning impractical. In a warming climate where more extreme fire weather is likely, thinning is even less likely to alter fire behavior (Abatzoglou and Williams 2017, Schoennagel et al. 2017).

CUMULATIVE IMPACTS OF LIVESTOCK GRAZING IN A CHANGING CLIMATE NEED TO BE FULLY ANALYZED AND GREATLY REDUCED

Livestock grazing and associated infrastructure in combination with climate change are causing extensive cumulative effects in the SFNF that are not properly analyzed or mitigated by the DEIS. The DEIS acknowledges that livestock have contributed to degradation of ecosystem resilience (DEIS Volume 1:5) but the alternatives contain numerous contradictions stating, for example, that the DEIS (Volume 1:13) "aims to provide *healthy* forested and non-forested lands that would supply forage for both livestock and wildlife" (Volume 1:13) and that it will "provide sustained multiple uses, products, and services in an *environmentally acceptable manner* (including timber, livestock forage, recreation opportunities, and leasable and locatable minerals) (emphasis added, DEIS Volume 1:16), all the while maintaining grazing at ecologically unacceptable levels (maximum of 11,400 AUMs).

The DEIS (Volume 1:37) recognizes that livestock grazing is "*not a natural process*" (emphasis added), yet, continues grazing under all planning alternatives even though it is inconsistent with ecological processes, ecological integrity, and ecological condition requirements of the planning rule (as noted in the boxes above). None of the alternatives meet these requirements given the high level of grazing maintained.

Importantly, the DEIS does not meet the BASI requirement of the planning rule by failing to analyze cumulative impacts of livestock from roads, infrastructure, and especially climate change. Besctha et al. (2012) noted livestock use affects a far greater proportion of BLM and Forest Service lands than do roads, timber harvest, and wildfires combined by altering vegetation, soils, hydrology and wildlife species composition and abundance "*in ways that exacerbate the effects of climate change on these resources*" (emphasis added). Livestock also contribute to greenhouse gas emissions globally (18% of the total anthropogenic emissions) and in the SFNF, thus, the DEIS needs to analyze livestock-related emissions.

Beschta et al. (2012) recommended large areas free of livestock use to "help initiate and speed the recovery of affected ecosystems as well as provide benchmarks or controls for assessing the effects of grazing versus no grazing at significant spatial scales in a changing climate."

The DEIS analyzed and dismissed Alternative 3 (lower livestock use) and dismissed a no grazing alternative as out of scope. However, Alternative 2 is deficient in meeting the ecological integrity, ecological condition, and ecological processes requirement of the planning rule. Therefore, the Forest Service needs to develop a new alternative or modify Alternative 2 to meet the specific recommendations of Beschta et al. (2012: Table 2) as follows.

Beschta et al. (2012:Table 2). Priority areas for permanently removing livestock and feral ungulates from Bureau of Land Management and US Forest Service lands to reduce or eliminate their detrimental ecological effects

- Watersheds and other large areas that contain a variety of ecotypes to ensure that major ecological and societal benefits of more resilient and healthy ecosystems on public lands will occur in the face of climate change
- Areas where ungulate effects extend beyond the immediate site (e.g., wetlands and riparian areas impact many wildlife species and ecosystem services with cascading implications beyond the area grazed)
- Localized areas that are easily damaged by ungulates, either inherently (e.g., biological crusts or erodible soils) or as the result of a temporary condition (e.g., recent fire or flood

disturbances, or degraded from previous management and thus fragile during a recovery period).

- Rare ecosystem types (e.g., perched wetlands) or locations with imperiled species or communities (e.g., aspen stands and understory plant communities, endemic species), including fish and wildlife species adversely affected by grazing and at-risk and/or listed under the ESA
- Non-use areas (i.e., ungrazed by livestock) or exclosures embedded within larger areas where livestock grazing continues.
- Such non-use areas should be located in representative ecotypes so that actual rates of recovery (in the absence of grazing impacts) can be assessed relative to resource trend and condition data in adjacent areas that continue to be grazed.
- Areas where the combined effects of livestock, wild ungulates, and feral ungulates are causing significant ecological impacts.

Notably, Ratner et al. (2018) document extensive impacts of livestock grazing on aspen groves in in Utah and their findings are generally applicable west-wide and therefore to the DEIS. These researchers found livestock significantly suppressed aspen sprout growth and trampled soils in study plots. They noted that livestock tended to concentrate in aspen groves due to forage availability and shading, even on allotments where livestock grazing is "controlled" and under "moderate" grazing. Ratner et al. (2018) recommended reducing livestock pressure via exclosures at least until aspen height exceeds browsing height and this will require periodic repetition (exclosures) to ensure proper aspen regeneration. At a minimum, exclosures should include entire aspen clonal areas and this needs to be incorporated into the DEIS.

Finally, the DEIS needs to allow for permanent allotment retirement and significantly reduced livestock grazing. This needs to include an analysis of the cumulative effects of *livestock grazing and climate change* and emissions related to livestock use, roads, and infrastructure. The DEIS (Volume 1:31) only allows for continuation of even vacant or understocked allotment and therefore should be modified or a new alternative developed to permanently retire vacant or understocked allotments and allow for voluntary buyout of grazing leases by conservation groups.

RIPARIAN AREAS NEED MORE EFFECTIVE PROTECTION, CONSERVATION, AND RESTORATION ESPECIALLY FROM LIVESTOCK AND THINNING TREATMENTS

The DEIS (Volume 1:153) correctly notes that although riparian areas occupy < 3% of the landscape, they support ~ 80% of the forest's plant and animal diversity, including several at-risk species (e.g., Mexican Spotted Owl, Lewis's Woodpecker, Arizona willow, Jemez Mountain salamander, masked and water shrew, New Mexican meadow jumping mouse, Northern leopard frog, Rio Grande chub, cutthroat trout, and sucker). Hubbard (1977; cited in Kauffman et al.

1984) report that 16-17% of the entire breeding avifauna of temperate North America reside in just 2 New Mexico river valleys and 77% of 166 nesting birds in the southwest depend on riparian habitat (Johnson et al. 1977 cited in Kauffman et al. 1984). Thus, riparian areas need stepped up conservation measures, especially protection from livestock grazing, given their exceptional importance in southwestern dry ecosystems.

Riparian areas also congregate livestock that have a strong preference for stream-side areas and wet montane meadows with high forage production. Livestock degrade this important wildlife habitat type in many ways, including soil compaction, spread of invasive species, stream-bank erosion, hydrological alterations, water quality and stream temperature degradation, and trampling effects (Kauffman et al. 1984, Besctha et al. 2012).

Kauffman et al. (1984) list several ways livestock grazing impacts can be reduced in riparian areas that should be readily adopted by the DEIS:

- Exclusion of livestock grazing;
- Alternative grazing schemes (e.g., late season – after bird nesting);
- Salting, alternative water sources, fencing, range riders to keep livestock out;
- Instream structures (e.g., trash catchers, gabions, small rock dams, individual boulder placement, rock jetties, and silt log drops) for increasing water table in areas of former wet meadows as well as improving fish habitat;
- Combining rest rotation with check dams (although the rest-rotation system may increase trailing and trampling damage, causing streambank erosion and instability);
- Selection of cattle with a preference for upland areas over riparian (cattle are known to have group-specific preferences)

Because of the disproportionate use of wildlife in riparian areas (especially at-risk species) and the extensive livestock damage in the area, the DEIS should incorporate the best elements from Alternative 3 with some notable additions as follows:

- Double the objectives in Alternative 2 (DEIS Volume 1:Table 3, p. 58) for restoring composition and structure in riparian vegetation.
- Within the riparian management zone, move toward desired conditions for vegetation types that are outside of or trending away from natural range of variability by restoring the composition and structure of 30 miles of stream every 10 years. Actions that could improve riparian areas would include removing invasive plant species, stabilising stream channels, planting native species, promoting natural revegetation of bare ground, and redirecting other uses (e.g., providing other watering sources or closing areas to camping – note this redirection needs to include redirecting cattle and not just "other uses").

- Complete aquatic restoration on priority projects on 60 miles of aquatic habitat (e.g., increasing pool quantity, providing stream cover, removing or installing fish barriers, restoring beaver populations, treating invasive aquatic species, etc.) every 10 years to benefit aquatic species.
- Every 10 years, restore native fish species to 40 miles of streams where nonnative fish are absent and where natural or human-made fish barriers exist.
- Further reductions in road densities throughout the forest and avoidance of permanent or temporary roads, particularly those that parallel or cross streams.
- Additionally, an emphasis on beaver reintroduction is complimentary with the above improvements.
- The DEIS should include large no-grazing riparian zones where cattle are fenced out and permanently removed to allow riparian recovery and reintroduction of beaver populations.

FOCAL SPECIES, AT-RISK SPECIES, SPECIES OF CONSERVATION CONCERN NEED TO BE MONITORED AND HABITAT PROTECTED FROM THINNING AND GRAZING

The DEIS (Volume 2:312) states that "the 2012 Rule does not require or prohibit monitoring of population trends of focal species. Instead, it allows the use of any *existing or emerging approaches for monitoring the status of focal species* that are supported by current science" (emphasis added). However, the DEIS is deficient in meeting the BASI requirement of the planning rule as it inadequately monitors population viability of species and does not provide enough habitat protection measures for focal species, species of conservation concern, and at-risk species. Specifically, the DEIS needs to meet the BASI requirement for these species with respect to connectivity (Haber and Nelson 2015), PVA (Noon et al. 2003), and species-specific "trigger points" (Schulz et al. 2012).

The DEIS largely bases management of these species on coarse-filter approaches. The DEIS site specific measures are very general and insufficient as a fine-filter approach.

Importantly, The Committee of Scientists (COS 1999[5]) stated, ''Habitat alone cannot be used to predict wildlife populations'' and ''diversity is sustained only when individual species persist; the goals of ensuring viability and providing for diversity are inseparable. For this reason, the fine-filter species assessment is critical." To meet the BASI requirements, therefore, the Forest Service must appropriately provide fine-filter approaches following recommendations of the COS (1999), Noon et al. (2003) and Schultz et al. (2012) as follows.

[5]COS (1999) https://www.fs.fed.us/emc/nfma/includes/cosreport/Committee%20of%20Scientists%20Report.htm

Noon et al. (2003) note: “to assess the viability of species, at least three assumptions must hold true: (1) attributes that define the coarse filter (i.e., dominant vegetation types) are sufficient and reliable surrogates for habitat and can effectively predict the occurrence of a given species; (2) managing coarse-filter attributes will address the factor(s) currently limiting abundance, density, and persistence of each species; and (3) the spatial resolution of the coarse filter matches the scale at which given species respond to environmental heterogeneity. Although these assumptions may be valid for some species in many circumstances, especially species that are small-bodied, abundant, and tightly linked to a particular vegetation community, the likelihood that the assumptions are met for all, or even most, species in an assemblage is low. For that reason, landscape planning employs “fine-filter” assessments, which are based on direct measures of the status and trends of individual species or on models of population viability to evaluate the needs of species at risk of decline. Noon et al. (2003) report numerous prediction errors associated with coarse-filter approaches that need supplementation with species-specific analyzes. For instance, forest planning needs to include PVA methods in its monitoring and adaptive management approach to better ensure coarse-filter requirements are representative of the community of interest.”

Similarly, Schultz et al. (2012) indicate monitoring plans must include species-specific trigger points that initiate a review of management actions and provisions to ensure species-specific (fine filter) monitoring will be well funded and implemented. The *trigger points must be enforceable and ensure* that specific project actions cease should they further impair the viability of select species (especially the case for at-risk and listed species).

Schultz et al. (2012) note the 2012 planning rule requires “at least, some amount of direct species measurement may be needed to assess the effectiveness of the ecological conditions provided under the coarse-filter approach in achieving the goal of conserving the biological diversity of the area (USFS 2012:124).”

Schultz et al. (2012) provide recommendations for incorporating more specific fine-filter monitoring lacking in the DEIS, as summarised:

- Focusing on distribution, rather than traditional measures of population size and growth rate, which greatly increases the efficiency of broad-scale monitoring programs.
- Advancements in wildlife monitoring, based on detection/non-detection data, including the use of sign surveys, genetic evaluation, and historical presence–absence survey data decrease the cost of monitoring changes in distribution, which can be inferred from the proportion of sample units at which the species is detected.
- Area occupied by a species can be used as an effective measure of a species’ spatial distribution.

- Temporal and spatial patterns in detection/non-detection monitoring data allow inference to changes in animal abundance, the single most influential parameter that provides insights into likelihood of species persistence.

The methods above recommended by Noon et al. (2003) and Schultz et al. (2012) along with connectivity measures recommended by Haber and Nelson (2015) should be applied to all 36 at-risk species, all 32 species of conservation concern, and all 7 focal species in the project area.

Mexican Spotted Owl (MSO) - The Santa Fe National Forest contains 198,888 acres of designated critical habitat for this owl. MSO requires dense conifer forests for nesting; however, will forage in recently severely burned areas (Lee 2018). The main factor involved in the decline of this species has been habitat destruction from logging; severe fire is not necessarily a habitat loss (Lee 2018), yet the DEIS assumes this to be the case. Large and small patches of severe burns juxtaposed with fire refugia for nesting may provide optimal habitat for MSO (Lee 2018). And while much is not known about how thinning affect MSO and its prey, declines in habitat and prey species have been noted for Northern Spotted Owl (see Odion et al. 2014b for review and analysis) and California Spotted Owl (Stephens et al. 2014). For all three subspecies of owls, removal of large trees (before/after fire) and reducing canopy cover (e.g., below 60% for NSO) constitutes habitat degradation that has been linked to nest occupancy failures (Lee 2018).

Thus, at a minimum, thinning units need to be dropped from MSO critical habitat and demographic monitoring implemented for this at-risk species.

FIRE EMISSIONS ARE OVER-ESTIMATED USING LANDFIRE AND EMISSIONS FROM PROJECT ACTIVITIES NEED TO BE ANALYSED FOR DIRECT, INDIRECT, AND CUMULATIVE EFFECTS

The DEIS pays an inordinate amount of attention to emissions from wildfires yet includes no analysis of emissions from livestock grazing, livestock infrastructure and transport, thinning and road development and maintenance. Therefore, the DEIS is deficient in assessing cumulative impacts of emissions and air quality to the surrounding community from project activities.

With respect to fire emissions, the DEIS needs to pay attention to the literature on wildfire emissions from related studies in dry pine and mixed conifer forests as follows.

For instance, Mitchell (2015: chapter 10 in DellaSala and Hanson 2015) has an excellent summary of ineffectiveness of thinning and reduction of carbon stores from thinning.

"While such treatments [referring to thinning and prescribed burning] can sometimes be effective in reducing fire severity, if and when fires occur in thinned areas (Rhodes and Baker, 2008), they can come at the expense of carbon storage. The majority of carbon stored in leaves, leaf litter, and duff is typically consumed by high-severity wildfire and often constitutes the majority of the carbon emissions during the a given fire, yet most of the carbon stored in forest biomass (stem wood, branches, and coarse, woody debris) remains unconsumed even by high-severity wildfires. Consequently, fuel removal via forest thinning almost always reduces carbon storage more than the additional carbon that a stand is able to store when made more resistant to wildfire. For this reason, removing large amounts of biomass to reduce the fraction by which other biomass components are consumed via combustion is inefficient (Mitchell et al., 2009). Fuel reduction treatments that involve the removal of overstory biomass (i.e., intermediate-sized and large trees) are, perhaps unsurprisingly, the most inefficient methods of reducing wildfire-related carbon losses because they remove large amounts of carbon for only a marginal reduction in expected fire severity (Figure 10.2)."

"The majority of carbon stored in montane forest ecosystems of western North America remains unconsumed, even in high-severity wildfires. Large carbon stores in the bole biomass of large forest trees are not consumed, and the substantial proportion of carbon stored in forest soils is only slightly consumed. Most of the carbon emissions in a wildfire are from combustion of litter, duff, and woody debris. In the 2002 Biscuit Fire, CFs for total forest biomass (i.e., trees, snags, shrubs, woody fuels, litter, duff, and soil), weighted according to their respective prefire biomass, were 0.13, 0.15, and 0.21 for low-, medium-, and high-severity fires, respectively. Such factors can be even lower among stands with a higher proportion of carbon storage in bole biomass that likewise remains unconsumed in high-severity wildfires, such as Sitka spruce (P. sitchensis)/Western Hemlock (T. heterophylla) forests in the coast range of the Pacific Northwest (Smithwick et al., 2002;Mitchell et al., 2009). The application of fuel treatments can be effective in reducing fire severity and carbon emissions, but such treatments come at the cost of a net reduction in carbon storage relative to fire alone (Mitchell et al., 2009)."

In a recent global study of pyrogenic carbon emissions, Jones et al. (2019) concluded that "large wildfires convert a significant fraction of the burned vegetation biomass into pyrogenic carbon that can be stored on site for centuries to millennia and this stored carbon is underestimated in emissions calculations. The amount of carbon emitted globally from wildfires is in fact buffered by pyrogenic carbon production resulting in burned landscapes becoming a significant carbon sink." The value of this sink is not even reported in the DEIS nor is it estimated in LANDFIRE and it needs to be in the forest plan. Here is the Jones et al. (2019) abstract, the pdf is attached.

Abstract

Landscape fires burn 3–5 million km2 of the Earth's surface annually. They emit 2.2 Pg of carbon per year to the atmosphere, but also convert a significant fraction of the burned vegetation biomass into pyrogenic carbon. Pyrogenic carbon can be stored in terrestrial and marine pools for centuries to millennia and therefore its production can be considered a mechanism for long-term carbon sequestration. Pyrogenic carbon stocks and dynamics are not considered in global carbon cycle models, which leads to systematic errors in carbon accounting. Here we present a comprehensive dataset of pyrogenic carbon production factors from field and experimental fires and merge this with the Global Fire Emissions Database to quantify the global pyrogenic carbon production flux. We found that 256 (uncertainty range: 196–340) Tg of biomass carbon was converted annually into pyrogenic carbon between 1997 and 2016. Our central estimate equates to 12% of the annual carbon emitted globally by landscape fires, which indicates that their emissions are buffered by pyrogenic carbon production. We further estimate that cumulative pyrogenic carbon production is 60 Pg since 1750, or 33–40% of the global biomass carbon lost through land use change in this period. Our results demonstrate that pyrogenic carbon production by landscape fires could be a significant, but overlooked, sink for atmospheric CO_2.

We repeat from above our concerns about problems with LANDFIRE fire emissions as follows.

In Northern Idaho, Hyde et al. (2015) evaluated two LANDFIRE fuel loading raster options: (1) Fuels Characteristic Classification Systems (LANDFIRE-FCCS); and (2) Fuel Loading Model (LANDFIRE-FLM) vs. measured fuel loadings for a 20,000 ha mixed conifer study area. They found that the LANDFIRE-FCCS layer showed 200% higher duff loadings relative to measured loadings that led to 23% higher total mean consumption and emissions when modeled in FOFEM. The LANDFIRE-FLM layer showed lower loadings for total surface fuels relative to measured data, especially in the case of coarse woody debris that led to 51% lower mean total consumption and emissions when modeled in FOFEM. Additionally, LANDFIRE-FLM consumption was *59% lower relative to that on the measured plots, with 58% lower modeled emissions*. The authors concluded that these differences in fuel loadings led to significant differences in consumption and emissions depending upon the data and model chosen. The DEIS therefore needs to disclose how errors in fuel loading consumption were addressed in emissions determinations regarding wildfires and how these errors were corrected.

CONCLUSIONS AND NEED FOR GREATLY IMPROVED PREFERRED ALTERNATIVE

Based on the above analysis, deficiencies in the DEIS, and need for an improved or new alternative to better meet the BASI and planning rule requirements, I am requesting that the SFNF revise the DEIS to include the following actions.

- **Prioritize community wildfire safety and fire-risk reduction, including home-hardening, defensible space, additional road closures/decommissioning to reduce ignitions, and identification/maintenance of community evacuation routes.** The most prudent means of community fire protection is to *work from the home-out* rather than the *wildlands-in* (emphasis added) according to retired Forest Service researcher Jack Cohen

(2000; also see Youtube interviews[6]) and related home fire-risk reduction work (Syphard et al. 2013, 2014). Community and fire-fighter safety actions should be directed at home protection and anthropogenic fire-ignitions along high-use roads (especially ingress/egress; see Balch et al. 2017). As noted above, research demonstrates that there is a very low (<1%) probability of thinned areas encountering a fire when fuels are lowest (Schoennagel et al. 2017). Therefore, it is imperative that the Forest Service strategically direct limited resources at protecting homes rather than extensive thinning in the backcountry that does nothing for home protection.

- **Reduce human-caused wildfire ignitions (see Balch et al. 2017) associated with road access**. The Forest Service needs to conduct project-specific transportation plans to determine the probability of human-caused fire ignitions in relation to road densities, road improvements, and increased human access along improved roads. These plans should address a broad scope of road-related impacts and choose an alternative based on minimal road access.
- **Protect high value conservation areas from logging/thinning/road improvements.** The DEIS needs to fully disclose impacts of road improvements and thinning on low-density (<1 mi/sq mile) and inventoried roadless areas (see below) and make clear how late-successional (closed canopy) forests within the project area will be maintained and restored to levels comparable to historic or documented reference conditions.
- **Disclose limitations and uncertainties of fire-scar sampling, importance of fire-free periods to shrub and tree recruitment and include more robust fire occurrence/ severity estimators that account for variability in fire-free and frequent-fire intervals.** The DEIS primarily relies on fire-scar sampling to determine the dominant fire regime present yet does not disclose uncertainties and limitations in sampling approaches (i.e., confidence levels). Notably, paleo-ecology studies conducted over longer timelines (millennia) than fire scar sampling show high variability in fire regimes related primarily to regional and local microclimatic factors (slope, aspect, elevation) over time (Meyer 2010). Large fires historically included high severity patches during alternating cycles of wet followed by droughts (Margolis et al. 2011). This is particularly important as extreme fire-weather (top-down driver) is known to over-ride bottom up influences (fuels) on fire behavior in the Rockies (Bessie and Johnson 1995, Schoennagel et al. 2004) and elsewhere (Abatzoglou and Williams 2017). The effect of global heating and increased likelihood of regional droughts may (Margolis et al. 2011) or may not (Parks et al. 2016, Margolis et al. 2017) increase fire severity. This uncertainty is most significant and must be analyzed to determine the need for and limitations of extensive fuels treatments based predominately on assumptions regarding frequent-fire regimes that may become increasingly unlikely in a rapidly changing climate. Additionally, variability in fire return

[6] National Fire Protection Association presentations by Jack Cohen - https://www.youtube.com/watch?v=vL_syp1ZScM; https://www.youtube.com/watch?v=RqKFDDBGd5o

(point/plot scale) and fire rotation (landscape scale) intervals accounts for longer fire-free periods that allow for shrub and small tree recruitment, including both dense and open forest conditions (see below). Thus, the DEIS needs to fully disclose its characterization of a low-severity fire regime, and "open" forest conditions (reference sites) with respect to heterogeneity and in relation to tree canopy mortality, shrub and small tree densities. Notably, even low severity systems have occasional fire-flare ups that kill dominant overstory trees and allow for sufficient shrub and small tree recruitment (see Baker 2017).

- **Substantially reduce livestock grazing in riparian areas and high value conservation areas.** Stepped up conservation and restoration need to be in the forest plan, including large no-grazing zones (exclosures), additional riparian and wet meadow/spring protections, road obliteration, invasive species removals, and beaver reintroductions.
- **More fully disclose and avoid impacts to at-risk species like the Mexican Spotted Owl (MSO).** There is no discussion of importance of mixed-severity wildfires in maintaining foraging habitat for spotted owls (Lee 2018, pdf enclosed). Instead, the DEIS incorrectly assumes, without site-specific data on owl occupancy or region-wide population trends, that wildfire (mostly high severity) degrades MSO habitat. However, Lee (2018) conducted a meta-analysis of fire effects on all three owl subspecies concluding that mixed-severity fire, including patches of large severity, was not the main cause of owl nest abandonment; pre- and post-fire logging was the predominant factor. Also, full disclosure of incidental take under the Endangered Species Act is required and the Forest Service needs to conduct population monitoring to assess MSO demographics and region-wide population trends.
- **Analyze and maintain connectivity especially for at risk, focal, and species of conservation concern.** The forest plan needs to properly analyze connectivity as noted herein including PVA, trigger points, and species/landscape specific measures that properly integrate coarse and fine-filter approaches under the BASI and connectivity requirements of the 2012 forest planning rule and the noted literature cited herein.
- **Reduce emissions from logging and roads.** A stated intent of the DEIS is to provide for resilience to climate change yet there is no requirement of an analysis of project-related emissions from tree clearing and road improvements. Notably, emissions from wildfires are typically much lower than landscape-level logging projects aimed at reducing wildfires (e.g., see Mitchell et al. 2009, Campbell et al. 2016, Law et al. 2018 as examples of appropriate methodologies). Project-specific alternatives must be developed to minimize emissions with alternatives selected that produce the lowest emissions. Alternatives should be compared in CO_2 equivalents, including the social cost of carbon[7].

[7]See https://19january2017snapshot.epa.gov/climatechange/social-cost-carbon_.html

- **Provide a cost-benefits analysis of managing wildfires for ecosystem benefits by working with fire under safe conditions.** The DEIS must disclose project-related costs of thinning, prescribed fire, and road improvements in comparison to managing fire for ecosystem benefits as a viable alternative (e.g., refer to the Cohesive Wildland Fire Management Strategy for wildfire ecosystem benefits[8] and 2012 forest planning rule regarding ecosystem integrity, vegetation diversity, and wildfire maintenance). Thus, it must be disclosed under what conditions will wildfires be managed for ecosystem benefits vs. suppressed so that when fires do eventually occur appropriate actions are taken based on pre-fire response planning and the Forest Service is accountable for implementing those actions accordingly.
- **Thinning to create open canopy forests at the expense of closed canopy forests needs to be greatly reduced and more strategically (surgically) applied.** The over-reliance on thinning stems from accuracy problems noted in the LANDFIRE program, biased fire scar fire estimates, inappropriate extrapolations from the Forest Service research publication GTR-310, and a failure to recognize site-specific and landscape heterogeneity. Thus, thinning treatments need to be greatly scaled back and strategic in application (mostly nearest homes).
- **In limited cases where thinning occurs, forest canopies need to be more fully maintained for closed canopy species associates by**: (1) stops and gaps (explain for the general reader) in thinning to for increased site heterogeneity; (2) retention of much more basal area (as compared to site-specific reference sites) especially around tree cohorts to make them wind firm; (3) retention of old/mature trees on site (based on increment core analysis and not just diameter at breast height); (4) in cases where tree thinning is necessary within the drip line of large mature trees, girdle those trees and leave standing on site as biological legacies; (5) retain more shrubs, forbs, and native grasses by reducing the interval between successive prescribed fires to allow for understory recruitment; and (6) fell and tip large trees in stream-side areas to create in-stream structures rather than thin and remove those trees from the site.
- **"Surgically" applied thinning treatments should be limited to the most drastically altered forests,** most notably, pine plantations in the Jemez and spruce/fir clearcuts on the eastern side of the SFNF.
- **Restoration and conservation measures should be greatly increased to address the following needs not sufficiently met in the DEIS**: (1) beaver reintroduction in riparian areas; (2) large livestock exclosures especially in riparian areas, wet meadows, and aspen groves; (3) road closures and road obliterations to provide connectivity; (4) defensible space within a narrow buffer (~60 feet) around homes; (5) ingress/egress routes for community protection; (6) increases in invasive species removal and containment; and

[8] See https://www.forestsandrangelands.gov/strategy/

(7) identification and protection of site and landscape specific habitat for focal species, species of conservation concern, and at risk species.

- **Compartmentalize the SFNF into fire management units** to determine when to suppress fire for community safety vs. working with fire for ecosystem benefits.[9]
- **Conduct a minimum road access analysis** and decommission/obliterate more roads to reduce impacts to water quality, wildlife habitat and human-caused fire ignitions.

In closing, while I respect the ability of the Forest Service to apply BASI to forest planning decisions on the Santa Fe National Forest, I remain greatly concerned that the noted inadequacies in the DEIS have not met the BASI standard. Instead the preferred alternative will (1) fragment and degrade important wildlife habitat; (2) jeopardize at-risk species (MSO), focal species, and species of conservation concern; (3) degrade water quality (mainly from roads, livestock, tree thinning), impact mature forests and riparian areas (along with wildlife and cultural values); and (4) uses methodologies (e.g., LANDFIRE, fire scar sampling, GTR-310) inappropriate to the SFNF. There is a heavy reliance on fire-scar sampling without disclosure of biases and uncertainties and thinning in stands that may possess old growth characteristics by moving them increasingly into open canopy conditions that lack overstory and understory structures. The efficacy of Alternative 2 mechanical treatments is highly uncertain because of the likelihood that the region's fire regimes will increasingly shift to larger burns due primarily to climate change (Abatzoglou and Williams 2017) and the extremely low odds that thinned sites will encounter a fire when fuels are lowest (Schoennagel et al. 2017).

Additionally, and contrary to what is often claimed by the Forest Service, insect and disease outbreaks are not associated with increased fire intensity. Insect-fire studies, including analysis of outbreaks and fire intensity in the Rockies and elsewhere (Romme et al. 2006, Kauffman et al. 2008, Bond et al. 2009, Black et al. 2011, Six et al. 2014, Hart et al. 2015, Meigs et al. 2016, Talucci and Krawchuck 2019) have repeatedly shown that there is no coupling of increased fire intensity with insect outbreaks. Instead, outbreaks may actually lower fire intensity once the needles of dead trees fall to the ground (within 1-3 years) as canopy fuels and therefore crown fires become highly unlikely. Dead trees also do not contribute to fire spread as they do not fall all at once nor result in accumulation of fine fuels (fine fuel accumulation is associated with logging). Dead trees are keystone legacies that provide essential habitat for cavity nesting birds, denning mammals, and numerous other wildlife. Their role in forest ecosystems needs to be better disclosed and maintained.

While wildfire clearly can be devastating to human communities, it is not an ecological catastrophe as often claimed. The Forest Service needs to develop better supported consensus

Increased forest fire activity across the western continental United States (US) in recent decades has likely been enabled by a number of factors, including the legacy of fire suppression and human settlement, natural climate variability, and human-caused climate change. We use modeled climate projections to estimate the contribution of anthropogenic climate change to observed increases in eight fuel aridity metrics and forest fire area across the western United States. Anthropogenic increases in temperature and vapor pressure deficit significantly enhanced fuel aridity across western US forests over the past several decades and, during 2000–2015, contributed to 75% more forested area experiencing high (>1 σ) fire-season fuel aridity and an average of nine additional days per year of high fire potential. Anthropogenic climate change accounted for ∼55% of observed increases in fuel aridity from 1979 to 2015 across western US forests, highlighting both anthropogenic climate change and natural climate variability as important contributors to increased wildfire potential in recent decades. We estimate that human-caused climate change contributed to an additional 4.2 million ha of forest fire area during 1984–2015, nearly doubling the forest fire area expected in its absence. Natural climate variability will continue to alternate between modulating and compounding anthropogenic increases in fuel aridity, but anthropogenic climate change has emerged as a driver of increased forest fire activity and should continue to do so while fuels are not limiting.

wildfire | climate change | attribution | forests

Widespread increases in fire activity, including area burned (1, 2), number of large fires (3), and fire-season length (4, 5), have been documented across the western United States (US) and in other temperate and high-latitude ecosystems over the past half century (6, 7). Increased fire activity across western US forests has coincided with climatic conditions more conducive to wildfire (2–4, 8). The strong interannual correlation between forest fire activity and fire-season fuel aridity, as well as observed increases in vapor pressure deficit (VPD) (9), fire danger indices (10), and climatic water deficit (CWD) (11) over the past several decades, present a compelling argument that climate change has contributed to the recent increases in fire activity. Previous studies have implicated anthropogenic climate change (ACC) as a contributor to observed and projected increases in fire activity globally and in the western United States (12–19), yet no studies have quantified the degree to which ACC has contributed to observed increases in fire activity in western US forests.

Changes in fire activity due to climate, and ACC therein, are modulated by the co-occurrence of changes in land management and human activity that influence fuels, ignition, and suppression. The legacy of twentieth century fire suppression across western continental US forests contributed to increased fuel loads and fire potential in many locations (20, 21), potentially increasing the sensitivity of area burned to climate variability and change in recent decades (22). Climate influences wildfire potential primarily by modulating fuel abundance in fuel-limited environments, and by modulating fuel aridity in flammability-limited environments (1, 23, 24). We constrain our attention to climate processes that promote fuel aridity that encompass fire behavior characteristics of landscape ignitability, flammability, and fire spread via fuel desiccation in primarily flammability-limited western US forests by considering eight fuel aridity metrics that have well-established direct interannual relationships with burned area in this region (1, 8, 24, 25). Four metrics were calculated from monthly data for 1948–2015: (*i*) reference potential evapotranspiration (ETo), (*ii*) VPD, (*iii*) CWD, and (*iv*) Palmer drought severity index (PDSI). The other four metrics are daily fire danger indices calculated for 1979–2015: (*v*) fire weather index (FWI) from the Canadian forest fire danger rating system, (*vi*) energy release component (ERC) from the US national fire danger rating system, (*vii*) McArthur forest fire danger index (FFDI), and (*viii*) Keetch–Byram drought index (KBDI). These metrics are further described in the *Materials and Methods* and *Supporting Information*. Fuel aridity has been a dominant driver of regional and subregional interannual variability in forest fire area across the western US in recent decades (2, 8, 22, 25). This study capitalizes on these relationships and specifically seeks to determine the portions of the observed increase in fuel aridity and area burned across western US forests attributable to anthropogenic climate change.

The interannual variability of all eight fuel aridity metrics averaged over the forested lands of the western US correlated significantly ($R^2 = 0.57$–0.76, $P < 0.0001$; Table S1) with the logarithm of annual western US forest area burned for 1984–2015, derived from the Monitoring Trends in Burn Severity product for 1984–2014 and the Moderate Resolution Imaging Spectroradiometer (MODIS) for 2015 (*Supporting Information*). The record of standardized fuel aridity averaged across the eight metrics (hereafter, all-metric mean) accounts for 76% of the variance in the burned-area record, with significant increases in both records for 1984–2015 (Fig. 1). Correlation between fuel aridity and forest fire area remains highly significant ($R^2 = 0.72$, all-metric mean) after removing the linear-least squares trends for each time series for 1984–2015, supporting the mechanistic relationship between fuel aridity and

Significance

Increased forest fire activity across the western United States in recent decades has contributed to widespread forest mortality, carbon emissions, periods of degraded air quality, and substantial fire suppression expenditures. Although numerous factors aided the recent rise in fire activity, observed warming and drying have significantly increased fire-season fuel aridity, fostering a more favorable fire environment across forested systems. We demonstrate that human-caused climate change caused over half of the documented increases in fuel aridity since the 1970s and doubled the cumulative forest fire area since 1984. This analysis suggests that anthropogenic climate change will continue to chronically enhance the potential for western US forest fire activity while fuels are not limiting.

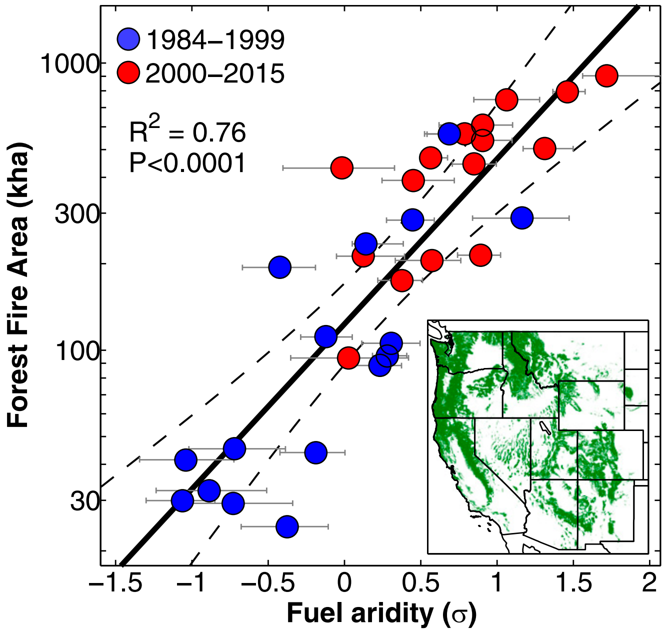

Fig. 1. Annual western continental US forest fire area versus fuel aridity: 1984–2015. Regression of burned area on the mean of eight fuel aridity metrics. Gray bars bound interquartile values among the metrics. Dashed lines bounding the regression line represent 95% confidence bounds, expanded to account for lag-1 temporal autocorrelation and to bound the confidence range for the lowest correlating aridity metric. The two 16-y periods are distinguished to highlight their 3.3-fold difference in total forest fire area. *Inset* shows the distribution of forested land across the western US in green.

forest fire area. It follows that co-occurring increases in fuel aridity and forest fire area over multiple decades would also be mechanistically related.

We quantify the influence of ACC using the Coupled Model Intercomparison Project, Phase 5 (CMIP5) multimodel mean changes in temperature and vapor pressure following Williams et al. (26) (Fig. S1; *Methods*). This approach defines the ACC signal for any given location as the multimodel mean (27 CMIP5 models) 50-y low-pass-filtered record of monthly temperature and vapor pressure anomalies relative to a 1901 baseline. Other anthropogenic effects on variables such as precipitation, wind, or solar radiation may have also contributed to changes in fuel aridity but anthropogenic contributions to these variables during our study period are less certain (22). We evaluate differences between fuel aridity metrics computed with the observational record and those computed with observations that exclude the ACC signal to determine the contribution of ACC to fuel aridity. To exclude the ACC signal, we subtract the ACC signal from daily and monthly temperature and vapor pressure, leaving all other variables unchanged and preserving the temporal variability of observations. The contribution of ACC to changes in fuel aridity is shown for the entire western United States; however, we constrain the focus of our attribution and analysis to forested environments of the western US (Fig. 1, *Inset*; *Methods*).

Anthropogenic increases in temperature and VPD contributed to a standardized (σ) increase in all-metric mean fuel aridity averaged for forested regions of +0.6 σ (range of +0.3 σ to +1.1 σ across all eight metrics) for 2000–2015 (Fig. 2). We found similar results with reanalysis products (all-metric mean fuel aridity increase of +0.6 σ for two reanalysis datasets considered; *Methods*), suggesting robustness of the results to structural uncertainty in observational products (Figs. S2–S4 and Table S2). The largest anthropogenic increases in standardized fuel aridity were present across the intermountain western United States, due in part to larger modeled warming rates relative to more maritime areas (27). Among aridity metrics, the largest increases tied to the ACC signal were for VPD and ETo because the interannual variability of these variables is primarily driven by temperature for much of the study area (28). By contrast, PDSI and ERC showed more subdued ACC driven increases in fuel aridity because these metrics are more heavily influenced by precipitation variability.

Fuel aridity averaged across western US forested areas showed a significant increase over the past three decades, with a linear trend of +1.2 σ (95% confidence: 0.42–2.0 σ) in the all-metric mean for 1979–2015 (Fig. 3*A*, *Top* and Table S1). The all-metric mean ACC contribution since 1901 was +0.10 σ by 1979 and +0.71 σ by 2015. The annual area of forested lands with high fuel aridity (>1 σ) increased significantly during 1948–2015, most notably since 1979 (Fig. 3*A*, *Bottom*). The observed mean annual areal extent of forested land with high aridity during 2000–2015 was 75% larger for the all-metric mean (+27% to +143% range across metrics) than was the case where the ACC signal was excluded.

Significant positive trends in fuel aridity for 1979–2015 across forested lands were observed for all metrics (Fig. 3*B* and Table S1). Positive trends in fuel aridity remain after excluding the ACC signal, but the remaining trend was only significant for ERC. Anthropogenic forcing accounted for 55% of the observed positive trend in the all-metric mean fuel aridity during 1979–2015, including at least two-thirds of the observed increase in ETo, VPD, and FWI, and less than a third of the observed increase in ERC and PDSI. No significant trends were observed for monthly fuel aridity metrics from 1948–1978.

The duration of the fire-weather season increased significantly across western US forests (+41%, 26 d for the all-metric mean) during 1979–2015, similar to prior results (10) (Fig. 4*A* and Table S2). Our analysis shows that ACC accounts for ~54% of the increase in fire-weather season length in the all-metric mean (15–79% for individual metrics). An increase of 17.0 d per year of high fire potential was observed for 1979–2015 in the all-metric mean (11.7–28.4 d increase for individual metrics), over twice the rate of increase calculated from metrics that excluded the ACC signal (Fig. 4*B* and Table S2). This translates to an average of an additional 9 d (7.8–12.0 d) per year of high fire potential during 2000–2015 due to ACC.

Given the strong relationship between fuel aridity and annual western US forest fire area, and the detectable impact of ACC on fuel aridity, we use the regression relationship in Fig. 1 to model

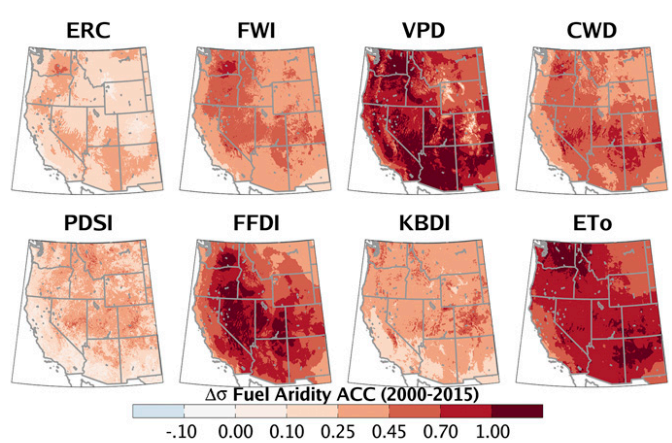

Fig. 2. Standardized change in each of the eight fuel aridity metrics due to ACC. The influence of ACC on fuel aridity during 2000–2015 is shown by the difference between standardized fuel aridity metrics calculated from observations and those calculated from observations excluding the ACC signal. The sign of PDSI is reversed for consistency with other aridity measures.

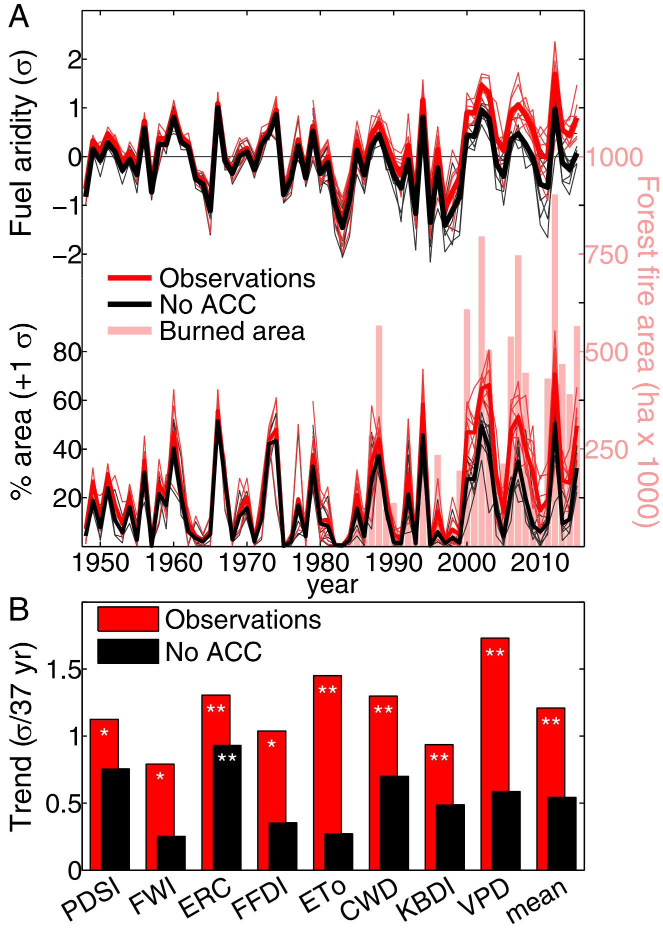

Fig. 3. Evolution and trends in western US forest fuel aridity metrics over the past several decades. (*A*) Time series of (*Upper*) standardized annual fuel aridity metrics and (*Lower*) percent of forest area with standardized fuel aridity exceeding one SD. Red lines show observations and black lines show records after exclusion of the ACC signal. Only the four monthly metrics extend back to 1948. Daily fire danger indices begin in 1979. Bold lines indicate averages across fuel aridity metrics. Bars in the background of *A* show annual forested area burned during 1984–2015 for visual comparison with fuel aridity. (*B*) Linear trends in the standardized fuel aridity metrics during 1979–2015 for (red) observations and (black) records excluding the ACC signal (differences attributed to ACC). Asterisks indicate positive trends at the (*) 95% and (**) 99% significance levels.

the contribution of ACC on western US forest fire area for the past three decades (Fig. 5 and Fig. S5). ACC-driven increases in fuel aridity are estimated to have added ~4.2 million ha (95% confidence: 2.7–6.5 million ha) of western US forest fire area during 1984–2015, similar to the combined areas of Massachusetts and Connecticut, accounting for nearly half of the total modeled burned area derived from the all-metric mean fuel aridity. Repeating this calculation for individual fuel aridity metrics yields ACC contributions of 1.9–4.9 million ha, but most individual fuel aridity metrics had weaker correlations with burned area and thus may be less appropriate proxies for attributing burned area. The effect of the ACC forcing on fuel aridity increased during this period, contributing ~5.0 (95% confidence: 4.2–5.9) times more burned area in 2000–2015 than in 1984–1999 (Fig. 5*B*). During 2000–2015, the ACC-forced burned area likely exceeded the burned area expected in the absence of ACC (Fig. 5*B*). A more conservative method that uses the relationship between detrended records of burned area and fuel aridity (2) still indicates a substantial impact of ACC on total burned area, with a 19% (95% confidence: 12–24%) reduction in the proportion of total burned area attributable to ACC (Fig. S5).

Our attribution explicitly assumes that anthropogenic increases in fuel aridity are additive to the wildfire extent that would have arisen from natural climate variability during 1984–2015. Because the influence of fuel aridity on burned area is exponential, the influence of a given ACC forcing is larger in an already arid fire season such as 2012 (Fig. 5*A* and Fig. S5*C*). Anthropogenic increases in fuel aridity are expected to continue to have their most prominent impacts when superimposed on naturally occurring extreme climate anomalies. Although numerous studies have projected changes in burned area over the twenty-first century due to ACC, we are unaware of other studies that have attempted to quantify the contribution of ACC to recent forested burned area over the western United States. The near doubling of forested burned area we attribute to ACC exceeds changes in burned area projected by some modeling efforts to occur by the mid-twenty-first century (29, 30), but is proportionally consistent with mid-twenty-first century increases in burned area projected by other modeling efforts (17, 31–33).

Beyond anthropogenic climatic changes, several additional factors have caused increases in fuel aridity and forest fire area since the 1970s. The lack of fuel aridity trends during 1948–1978 and persistence of positive trends during 1979–2015 even after removing the ACC signal implicates natural multidecadal climate variability as an important factor that buffered anthropogenic

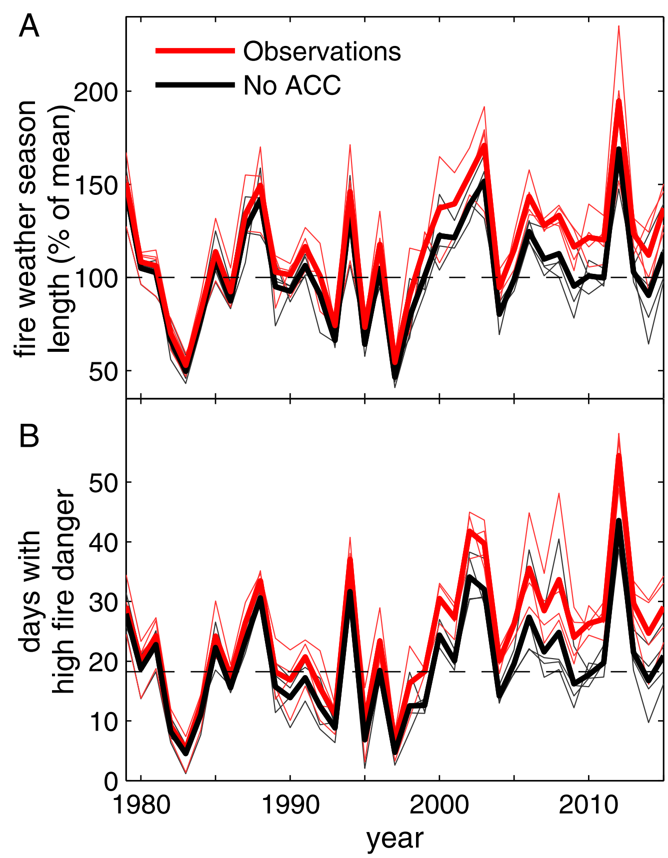

Fig. 4. Changes in fire-weather season length and number of high fire danger days. Time series of mean western US forest (*A*) fire-weather season length and (*B*) number of days per year when daily fire danger indices exceeded the 95th percentile. Baseline period: 1981–2010 using observational records that exclude the ACC signal. Red lines show the observed record, and black lines show the record that excludes the ACC signal. Bold lines show the average signal expressed across fuel aridity metrics.

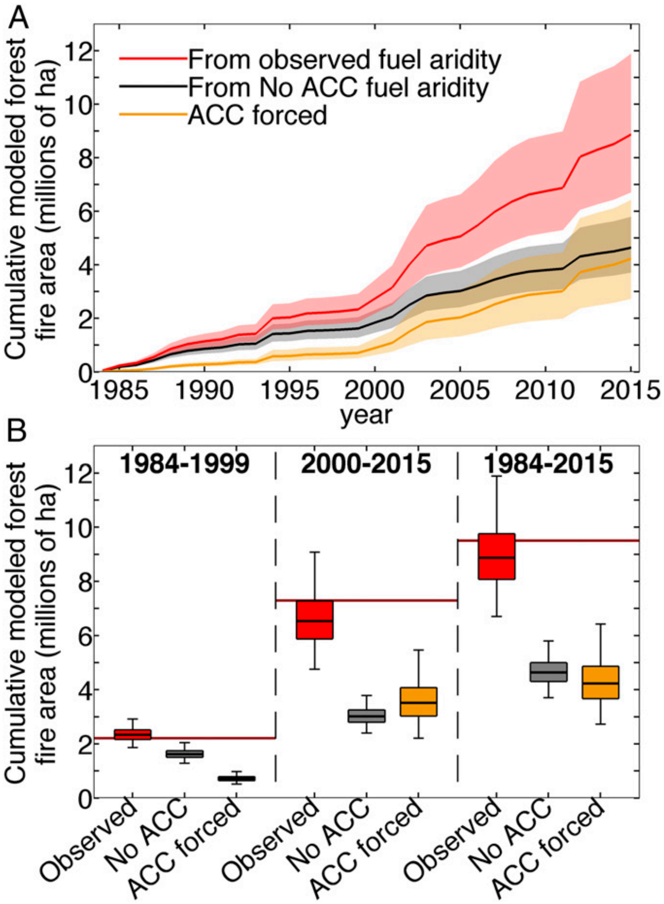

Fig. 5. Attribution of western US forest fire area to ACC. Cumulative forest fire area estimated from the (red) observed all-metric mean record of fuel aridity and (black) the fuel aridity record after exclusion of ACC (No ACC). The (orange) difference is the forest fire area forced by anthropogenic increases in fuel aridity. Bold lines in *A* and horizontal lines within box plots in *B* indicate mean estimated values (regression values in Fig. 1). Boxes in *B* bound 50% confidence intervals. Shaded areas in *A* and whiskers in *B* bound 95% confidence intervals. Dark red horizontal lines in *B* indicate observed forest fire area during each period.

effects during 1948–1978 and compounded anthropogenic effects during 1979–2015. During 1979–2015, for example, observed Mar–Sep vapor pressure decreased significantly across many US forest areas, in marked contrast to modeled anthropogenic increases (Fig. S6) (34). Significant declines in spring (Mar–May) precipitation in the southwestern United States and summer (Jun–Sep) precipitation throughout parts of the northwestern United States during 1979–2015 (Fig. S7 *A* and *B*) hastened increases in fire-season fuel aridity, consistent with observed increases in the number of consecutive dry days across the region (10). Natural climate variability, including a shift toward the cold phase of the interdecadal Pacific Oscillation (35), was likely the dominant driver of observed regional precipitation trends (36) (Fig. S7 *B* and *D*).

Our quantification of the ACC contribution to observed increases in forest fire activity in the western United States adds to the limited number of climate change attribution studies on wildfire to date (37). Previous attribution efforts have been restricted to a single GCM and biophysical variable (14, 16). We complement these studies by demonstrating the influence of ACC derived from an ensemble of GCMs on several biophysical metrics that exhibit strong links to forest fire area. However, our attribution effort only considers ACC to manifest as trends in mean climate conditions, which may be conservative because climate models also project anthropogenic increases in the temporal variability of climate and drought in the western United States (34, 38, 39). In focusing exclusively on the direct impacts of ACC on fuel aridity, we do not address several other pathways by which ACC may have affected wildfire activity. For example, the fuel aridity metrics that we used may not adequately capture the role of mountain snow hydrology on soil moisture. Nor do we account for the influence of climate change on lightning activity, which may increase with warming (40). We also do not account for how fire risk may be affected by changes in biomass/fuel due to increases in atmospheric CO_2 (41), drought-induced vegetation mortality (42), or insect outbreaks (43).

Additionally, we treat the impact of ACC on fire as independent from the effects of fire management (e.g., suppression and wildland fire use policies), ignitions, land cover (e.g., exurban development), and vegetation changes beyond the degree to which they modulate the relationship between fuel aridity and forest fire area. These factors have likely added to the area burned across the western US forests and potentially amplified the sensitivity of wildfire activity to climate variability and change in recent decades (2, 22, 24, 44). Such confounding influences, along with nonlinear relationships between burned area and its drivers (e.g., Fig. 1), contribute uncertainty to our empirical attribution of regional burned area to ACC. Our approach depends on the strong observed regional relationship between burned area and fuel aridity at the large regional scale of the western United States, so the quantitative results of this attribution effort are not necessarily applicable at finer spatial scales, for individual fires, or to changes in nonforested areas. Dynamical vegetation models with embedded fire models show emerging promise as tools to diagnose the impacts of a richer set of processes than those considered here (41, 45) and could be used in tandem with empirical approaches (46, 47) to better understand contributions of observed and projected ACC to changes in regional fire activity. However, dynamic models of vegetation, human activities, and fire are not without their own lengthy list of caveats (2). Given the strong empirical relationship between fuel aridity and wildfire activity identified here and in other studies (1, 2, 4, 8), and substantial increases in western US fuel aridity and fire-weather season length in recent decades, it appears clear from empirical data alone that increased fuel aridity, which is a robustly modeled result of ACC, is the proximal driver of the observed increases in western US forest fire area over the past few decades.

Conclusions

Since the 1970s, human-caused increases in temperature and vapor pressure deficit have enhanced fuel aridity across western continental US forests, accounting for approximately over half of the observed increases in fuel aridity during this period. These anthropogenic increases in fuel aridity approximately doubled the western US forest fire area beyond that expected from natural climate variability alone during 1984–2015. The growing ACC influence on fuel aridity is projected to increasingly promote wildfire potential across western US forests in the coming decades and pose threats to ecosystems, the carbon budget, human health, and fire suppression budgets (13, 48) that will collectively encourage the development of fire-resilient landscapes (49). Although fuel limitations are likely to eventually arise due to increased fire activity (17), this process has not yet substantially disrupted the relationship between western US forest fire area and aridity. We expect anthropogenic climate change and associated increases in fuel aridity to impose an increasingly dominant and detectable effect on western US forest fire area in the coming decades while fuels remain abundant.

Methods

We focus on climate variables that directly affect fuel moisture over forested areas of the western continental United States, where fire activity tends to be flammability-limited rather than fuel- or ignition-limited (1) (study region shown in Fig. 1, *Inset*). There are a variety of climate-based metrics that have been used as proxies for fuel aridity, yet there is no universally preferred metric across different vegetation types (24). We consider eight frequently used fuel aridity metrics that correlate well with fire activity variables, including annual burned area (Fig. 1 and Table S1), in western US forests.

Fuel aridity metrics are calculated from daily surface meteorological data (50) on a 1/24° grid for 1979–2015 for the western United States (west of 103°W). Although we calculated metrics across the entire western United States, we focus on forested lands defined by the climax succession vegetation stages of "forest" or "woodland" in the Environmental Site Potential product of LANDFIRE (landfire.gov). Forested 1/24° grid cells are defined by at least 50% forest coverage aggregated from LANDFIRE. We extended the aridity metrics calculated at the monthly timescale (ETo, VPD, CWD, and PDSI) back to 1948 using monthly anomalies relative to a common 1981–2010 period from the dataset developed by the Parameterized Regression on Independent Slopes Model group (51) for temperature, precipitation, and vapor pressure, and by bilinearly interpolating NCEP–NCAR reanalysis for wind speed and surface solar radiation. We aggregated data to annualized time series of mean May–Sep daily FWI, KBDI, ERC, and FFDI; Mar–Sep VPD and ETo; Jun–Aug PDSI; and Jan–Dec CWD. We also calculated the aridity metrics strictly from ERA-INTERIM and NCEP–NCAR reanalysis products for 1979–2015 covering the satellite era (*Supporting Information*).

Days per year of high fire potential are quantified by daily fire danger indices (ERC, FWI, FFDI, and KBDI) that exceed the 95th percentile threshold defined during 1981–2010 from observations after removing the ACC signal. Observational studies have shown that fire growth preferentially occurs during high fire danger periods (52, 53). We also calculate the fire weather season length for the four daily fire danger indices following previous studies (10).

The ACC signal is obtained from ensemble members taken from 27 CMIP5 global climate models (GCMs) regridded to a common 1° resolution for 1850–2005 using historical forcing experiments and for 2006–2099 using the Representative Concentration Pathway (RCP) 8.5 emissions scenario (Table S3 and *Supporting Information*). These GCMs were selected based on availability of monthly outputs for maximum and minimum daily temperature (T_{max} and T_{min}, respectively), specific humidity (*huss*), and surface pressure. Saturation vapor pressure (e_s), vapor pressure (e), and VPD were calculated using standard methods (*Supporting Information*). A variety of approaches exist to estimate the ACC signal (26). We define the anthropogenic signals in T_{max}, T_{min}, e, e_s, VPD, and relative humidity by a 50-y low-pass-filter time series (using a 10-point Butterworth filter) averaged across the 27 GCMs using the following methodology: For each GCM, variable, month, and grid cell, we converted each annual time series to anomalies relative to a 1901–2000 baseline. We averaged annual anomalies across all realizations (model runs) for each GCM and calculated a single 50-y low-pass-filter annual time series for each of the 12 mo for 1850–2099. We averaged each month's low-pass-filtered time series across the 27 GCMs and additively adjusted so that all smoothed records pass through zero in 1901. The resultant ACC signal represents the CMIP5 modeled anthropogenic impact since 1901 for each variable, grid cell, and month (*Supporting Information*).

We bilinearly interpolated the 1° CMIP5 multimodel mean 50-y low-pass time series to the 1/24° spatial resolution of the observations and subtracted the ACC signal from the observed daily and monthly time series. We consider the remaining records after subtraction of the ACC signal to indicate climate records that are free of anthropogenic trends (26).

Annual variations in fuel aridity metrics are presented as standardized anomalies (σ) to accommodate differences across geography and metrics. All fuel aridity metrics are standardized using the mean and SD from 1981 to 2010 for observations that excluded the ACC signal. Although the selection of a reference period can bias results (54), our findings were similar when using the full 1979–2015 time period or the observed data (without removal of ACC) for the reference period. The influence of anthropogenic forcing on fuel aridity metrics is quantified as the difference between metrics calculated with observations and those calculated with observations that excluded the ACC signal. Area-weighted standardized anomalies and the spatial extent of western US forested land that experienced high (>1 σ) aridity are computed for each aridity metric. Annualized burned area as well as aggregated fuel aridity metrics calculated with data from ref. 50 and the two reanalysis products are provided in Datasets S1–S3.

We use the regression relationship between the annual western US forest fire area and the all-metric mean fuel aridity index in Fig. 1 to estimate the forcing of anthropogenic increases in fuel aridity on forest fire area during 1984–2015. Uncertainties in the regression relationship due to imperfect correlation and temporal autocorrelation are propagated as estimated confidence bounds on the anthropogenic forcing of forest fire area. This approach was repeated using a more conservative definition of the regression relationship, where we removed the linear least squares trend for 1984–2015 from both the area burned and fuel aridity time series before regression to reduce the possibility of spurious correlation due to common but unrelated trends (Fig. S5). Statistical significance of all linear trends and correlations reported in this study are assessed using both Spearman's rank and Kendall's tau statistics. Trends are considered significant if both tests yield $P < 0.05$.

Abstract. Historical evidence suggests natural disturbances could allow more forest persistence, than expected from models, over 40 yr of transition to the net-zero emissions needed to limit warming to <2.0°C (e.g., Paris Agreement). Forests must ultimately equilibrate with committed warming from accumulated emissions. Historical dry-forest landscapes were heterogeneous from large, infrequent disturbances (LIDs) that reduced tree density and basal area, followed by slow, variable tree regeneration and recovery for 1–3 centuries. These together effectively provided bet-hedging through stand- and landscape-level heterogeneity that enhanced resistance and resilience to a diversity of unpredictable subsequent disturbances. Recent disturbances have not yet exceeded historical variability in rates and patterns, but could cause mortality of ~26–51% of dry-forest area in the transition. This also means 1/2 to 3/4 of dry-forest area could escape most mortality and the mortality area could also have substantial forest persistence. Projections are unavailable for droughts or beetle outbreaks, but they recently caused about 3–4 times as much tree mortality as did moderate- to high-severity fires. Mortality could reduce forest area if new trees do not regenerate, but 24 studies showed recent regeneration after high-severity fires was slow, but indistinct from historical variability. Survival of smaller trees provided regeneration after beetle outbreaks and droughts. Regeneration in general was projected by 2060 to decline by ~10% in one study and increase by 50% in another. If openings from disturbances increased, some grasslands and shrublands could be restored, increasing landscape heterogeneity and resistance to disturbance spread. Given these trends and our limited ability to prevent LIDs, I suggest (1) refocusing restoration to increase bet-hedging resilience to droughts and beetle outbreaks by retaining small trees and diverse tree species, (2) expanding development of fire-safe landscapes to protect people and infrastructure from unavoidable increased fire, (3) enabling more managed fire to restore and enhance stand- and landscape-scale bet-hedging, and (4) accepting that LIDs will revise resistance, resilience, and adaptation, which enhance forest persistence, particularly if post-disturbance survivors are not logged and trees are not planted. Natural disturbance and slow recovery, if bet-hedged to increase resistance and resilience, could enable substantial forest persistence.

Key words: adaptation; beetle outbreaks; bet-hedging; climate change; disturbances; droughts; dry forests; fire; natural recovery; resilience; succession.

Introduction

Since the 2015 Paris Agreement, the world plans to reduce emissions to limit warming to much less than 2.0°C, possibly 1.5°C, and it is worthwhile to focus on how major ecosystems may transition to this more limited level of warming that is now a global commitment. Extensive disappearing climates and ecosystem changes and the need for widespread assisted migration by the mid- to late 21st century under continuing moderate- to high emissions (e.g., Rehfeldt et al. 2014) are less likely. Understanding is now needed of impacts of more limited warming for specific ecosystems. Here, I review how bet-hedging and natural-disturbance processes (Baker and Williams 2015) could help transition current dry-forest landscapes in the western United States to limited committed warming. Bet-hedging uses small trees, large trees, and diverse trees to hedge against diverse disturbances. Committed warming occurs because once emissions are reduced so they are at net zero (emissions balanced by fixation), the long persistence of emitted CO_2 in the atmosphere and high oceanic heat capacity cause global temperatures to remain elevated for centuries near where they are at net zero (Collins et al. 2013, Mauritsen and Pincus 2017).

Dry forests are major montane ecosystems (Fig. 1), covering ~25.5 million ha of the western United States (Baker 2015). Dry forests include (1) dry pine forests most often dominated by ponderosa pine (*Pinus ponderosa*) or similar pines with relatively few associated trees, and (2) dry mixed-conifer forests with pines plus several other trees (e.g., *Abies concolor*, *Abies grandis*, *Populus tremuloides*, *Pseudotsuga menziesii*). Dry-forest landscapes historically also included grasslands and shrublands, as well as younger forests (Fig. 2), some of which were seral stages after high-severity fires in dry forests, although others were more persistent (Baker 2017*a*).

To keep committed warming below 2.0°C across dry forests of the western United States, emissions may need to be net zero by A.D. 2050 when 80% of projections show 2.0°C of warming would be reached with current emissions (Karmalkar and Bradley 2017). However, globally committed warming of well below 2.0°C that might allow 2.0°C of committed warming across dry forests of the western United States could also be achieved if net-zero emissions are reached by A.D. 2060 after rapid near-term reductions (Sanderson et al. 2016). The 2.6 representative concentration pathway (RCP), the lowest scenario of the Fifth Assessment Report (AR5) from the Intergovernmental Panel on Climate Change, was thought to feasibly constrain warming to <2.0°C (IPCC 2015), but this now appears unlikely (Sanderson et al. 2016). The next IPCC report (AR6), with newer scenarios congruent with 1.5–2.0°C of committed warming, is not due until 2022. However, Shared Socio-Economic Pathways (SSPs) that are being developed suggest a 1.9 RCP could feasibly constrain warming to 1.5°C (Rogelj et al. 2018). Updated global carbon-emissions accounting and pathways make 1.5°C feasible (Tokarska and Gillett 2018, Van Vuuren et al. 2018). Thus, net-zero emissions by 2060 are needed and feasible to avoid rising above 1.5–2.0°C (Tanaka and O'Neill 2018). Therefore, I consider A.D. 2060, ~40 yr, as the main period for transitioning dry forests, after which further, slower adjustment to committed warming continues.

No projections yet exist for extent of climate loss (current climate moves elsewhere or is changed) or its effects on tree populations in dry forests for pathways leading to net-zero emissions by 2060, but perspective is still possible now. Projections of climate loss in dry forests, primarily from bioclimate models, were mostly for A.D. 2060–2100 and/or RCPs of medium to high emissions (Table 1). Loss of climate would likely be lower than in RCP 2.6 (Table 1), but specific projections are lacking. Nonetheless, by 2015, total human-induced global warming was 0.93°C (Millar et al. 2017), about 1/2 to 2/3 of the way to 1.5–2.0°C, suggesting that effects that will occur are well underway. Here, I synthesize what might ensue in dry forests based on recent trends in natural disturbances, tree mortality, and tree regeneration, aided by projections and scenarios to 2060 for low or modest emissions, where available. Further refinement will be needed, but substantial evidence is available now that can provide useful perspective.

Also, bioclimate models do not reveal ecological effects, since they usually lack demography, dispersal, or natural disturbance, and mostly

Fig. 1. Dry forests covered about 25.5 million ha of the western United States, including about 12.6 million ha of dry pine forests and 12.9 million ha of dry mixed-conifer forests. Data are Landfire biophysical settings, which predict historical vegetation (http://www.landfire.gov).

only show how the climate of an ecosystem may change, not effects (Campbell and Shinneman 2017). Climate loss is expected to move upward from lower-elevation and northward from southerly trailing edges of dry-forest ranges, and tree mortality may follow, but unpredictably. Adult ponderosa may be most vulnerable in interior populations (var. *scopulorum*) and less in Pacific populations (var. *ponderosa*) of ponderosa pine, but vulnerability in dry forests may be heterogeneous in general (McCullough et al. 2017). These models are generally only for

Fig. 2. Historical dry-forest landscapes included forests as well as openings with grasslands and shrublands, as shown here in this Whitman Cross photograph from 1897 looking south at Mesa Verde (on the skyline), southwestern Colorado, across a ponderosa pine landscape with Gambel oak (*Quercus gambelii*) shrublands and montane grasslands. Reproduced from a scanned print of the original photograph (Cross 297) at the U.S. Geological Survey Denver Library, Photographic Collection, Denver, Colorado.

adult trees, but tree regeneration may ultimately control tree persistence and expansion (Bell et al. 2014, Dobrowski et al. 2015, Petrie et al. 2017). Natural disturbances (droughts, beetle outbreaks, wildfires, and diseases) will likely cause the tree mortality as climate is lost. Forest resilience could be exceeded and a tipping point (Reyer et al. 2015) crossed. However, inertia from long tree life spans, changing disturbances, and tree survival and regeneration might allow more forest persistence (Campbell and Shinneman 2017).

Here, I first review the historical roles of large, infrequent disturbances (LIDs), post-disturbance legacies, and slow natural recovery in dry forests. Then, I review recent natural disturbances, tree regeneration, and how persistence of tree populations in dry forests to warming could be aided by bet-hedging. Emergence of climates at higher elevations may offset losses in current ranges, if dispersal succeeds (Campbell and Shinneman 2017), but is not addressed here.

Historical Variability in Natural Disturbance and Recovery in Dry-Forest Landscapes

Large, infrequent disturbances historically accomplished most renewal in dry-forest landscapes

Historical dry-forest landscapes included open, low-density stands with large, old trees and a history of low-severity fires, but probabilistic landscape-scale studies found these open forests over only about 34%, on average, of dry-forest area (Baker 2017*a*). The other 66% historically had more diverse stand structures (examples in Table 2, reviews in Odion et al. 2014, Hanson et al. 2015). Historical forests were often younger, denser, and had been burned in fires varying in intensity and severity, as described explicitly in Hessburg et al. (2007:19): "Instead, area was dominated by forest structures that were intermediate between new and old forests, i.e., by pole to medium sized, rather than large trees.... This observation suggested that before any extensive management had occurred, the influence of fire in the dry forest was

† The change (%) is relative to the present.
‡ Emissions scenarios are A2 (High emissions), B1 (Low), and B2 (Low–Medium); RCP = representative concentration pathway, which is the change in radiative forcing (W/m^2) in 2100 relative to pre-industrial conditions, as defined for emissions scenarios by the Intergovernmental Panel on Climate Change (IPCC). RCP 2.6 is Low, 4.5 is Medium, 6.0 is Medium–High, and 8.5 is High emissions.
§ This is the “no dispersal” projection result.

of a frequency and severity that intermittently regenerated rather than maintained large areas of old, fire tolerant forest.” The intermittent regeneration likely followed LIDs which varied in intensity, but were at least partly intense enough to kill substantial woody plants. Large, infrequent disturbances included fires, insect outbreaks, diseases, droughts, and blowdowns (Foster et al. 1998).

Many historical LIDs in dry-forest landscapes occurred in periodic climatic episodes. Large fires were often during droughts, as in 1848 when 41 of 63 fire-history sites across southwestern dry forests recorded this fire year (Swetnam and Baisan 1996), and in 1910 when 1.2 million ha burned in the northern Rocky Mountains (Odion et al. 2014). About 10 bark beetles had large outbreaks in dry forests (Bentz et al. 2010) when tree defenses were weakened by drought or other events, weather favored beetle reproduction, and mass attack could overcome tree resistance (Bentz et al. 2010, Negrón and Fettig 2014). An example is the 200,000- to 300,000-ha 1895–1909 mountain pine beetle (MPB; *Dendroctonus ponderosae*) outbreak in the Black Hills, South Dakota (Graham et al. 2016). Historical droughts, such as the A.D. 1574–1594 drought in the Southwest, also likely led to extensive tree mortality in dry forests (Swetnam and Betancourt 1998, Williams et al. 2013).

Large disturbances were likely infrequent in historical fire regimes and in other disturbance regimes. Modern fire regimes globally nearly all have log-normal fire-size distributions in which large fires are exponentially less frequent than small fires (Hantson et al. 2016). Historical fire-

Table 2. Examples of probabilistic studies and ancillary supporting sources that showed evidence of historical mixed-severity fire regimes, with substantial area of high-severity fire, that fostered heterogeneous historical dry-forest landscapes in the western United States.

size and patch-size distributions in dry forests also had inverse-J shapes suggesting log-normal distributions (Williams and Baker 2012*a*, Baker 2017*a*). While rare, LIDs could be concentrated in episodes across large land areas, as were severe fires in the late 1800s in the southern Rocky Mountains (Veblen et al. 2000, Schoennagel et al. 2011, Baker 2017*b*), and large MPB outbreaks across the western United States and Canada (Jarvis and Kulakowski 2015).

The severely disturbed extent of LIDs had historical rotations (the expected time to affect the area of a landscape once) of one or more centuries. High-severity fires that killed >70% of basal area in dry forests historically had rotations of about 2–8 centuries (Baker 2015); moderate- to high-severity fires that killed 20% or more of basal area had rotations of 235–319 yr (Odion et al. 2014). Tree age distributions and early observations suggest large insect outbreaks and droughts were also infrequent events in dry forests (Blackman 1931, Swetnam and Betancourt 1998). The historical rotation for outbreaks of MPB, the main outbreak beetle in the western United States (Meddens et al. 2012), might be somewhat longer in ponderosa pine than lodgepole pine (*Pinus contorta*) forests, since ponderosa pine forests are more heterogeneous (Chapman et al. 2012). Jarvis and Kulakowski (2015) reconstructed MPB outbreaks in lodgepole pine at 10 sites in 200,000 ha of western Colorado and found four episodes from 1742 to 1910 that affected 0.5, 0.7, 0.5, and 0.4 of the 10 sites, a rotation of about 80 yr (168 yr/2.1). The rotation for drought-caused mortality in dry forests is unknown as there are no historical reconstructions. Pan-continental droughts that affected several U.S. regions occurred historically in ~12% of the last 1000 yr, but megadroughts of a decade or more, mainly in the Southwest and Central Plains, were rare in the last 500 yr (Cook et al. 2014). The 1574–1594 event, mentioned earlier, is the only historical one known to have caused extensive mortality in dry forests.

In the case of fires, the few percent that are large typically account for most of the total burned area (Strauss et al. 1989) and are often more intense (Swetnam and Baisan 1996). This importance of only a few percent of fires, the largest fires, to total burned area is evident in modern dry forests (Farris et al. 2010) and other forests (Baker 2009). Larger fires often have a mix of intensities and higher intensity, since fires become large because of rapid spread, driven by wind and drier fuels that allow more fuel consumption, increasing fire intensity (Alexander 1982). Large beetle outbreaks and lengthy droughts also appear to cause most tree mortality (Allen et al. 2010, Baker and Williams 2015, Graham et al. 2016), likely because resistance thresholds in trees are difficult to cross with smaller, less severe events (Romme et al. 1998).

Large, infrequent disturbances updated resistance, resilience, and legacies that facilitated recovery and bet-hedging

Large, infrequent disturbances with varying severities historically provided episodic adjustment across dry-forest landscapes, reducing area, density, and basal area of less disturbance-resistant trees, while increasing more disturbance-resistant trees, although current trees simply regenerate at times. Competition was lessened and the canopy was opened (Fig. 3a, b), often reducing vulnerability to subsequent disturbances for decades or longer (Parks et al. 2016).

Large, infrequent disturbances episodically tested and updated resistance, resilience, and bet-hedging across changing landscapes. Large, infrequent disturbances fostered diverse surviving tree species, sizes, and regeneration strategies that provided resistance and resilience to subsequent diverse disturbances (Table 3). This diverse stand and landscape structure and composition after LIDs could effectively provide stand- and landscape-level bet-hedging against an uncertain array of subsequent disturbances (Baker and Williams 2015). At the stand scale, bet-hedging was provided by combinations of large, old trees with thick bark that resisted mortality in fires and some beetle outbreaks (Graham et al. 2016, Welch et al. 2016), abundant small trees that resisted mortality in beetle outbreaks and droughts (Baker and Williams 2015), and diverse tree species so that some trees were not vulnerable to particular insects or diseases. At the landscape scale, areas of large trees, other fire-resistant trees, and low tree density provided landscape resistance to severe fires. Low-to-moderate fuel continuity allowed fires to spread, but with patchiness. Openings reduced ignitions, slowed disturbance spread, and reduced severity, while natural breaks could slow or terminate fires. Low–moderate contiguity of large trees and diverse patches may have reduced beetle spread and limited the size of patches of tree mortality (Graham et al. 2016). Young, recovering forests had high tree survival in beetle outbreaks (Graham et al. 2016) and droughts (Allen et al. 2010).

Natural recovery exemplifies resilience: "...the capacity of a system to absorb disturbance and reorganize while undergoing change so as to retain essentially the same function, structure, identity and feedbacks" (Walker et al. 2004:2). Large, infrequent disturbances in dry forests left behind complex effects from variable disturbance types and severities (Fig. 3), and these legacies (Foster et al.

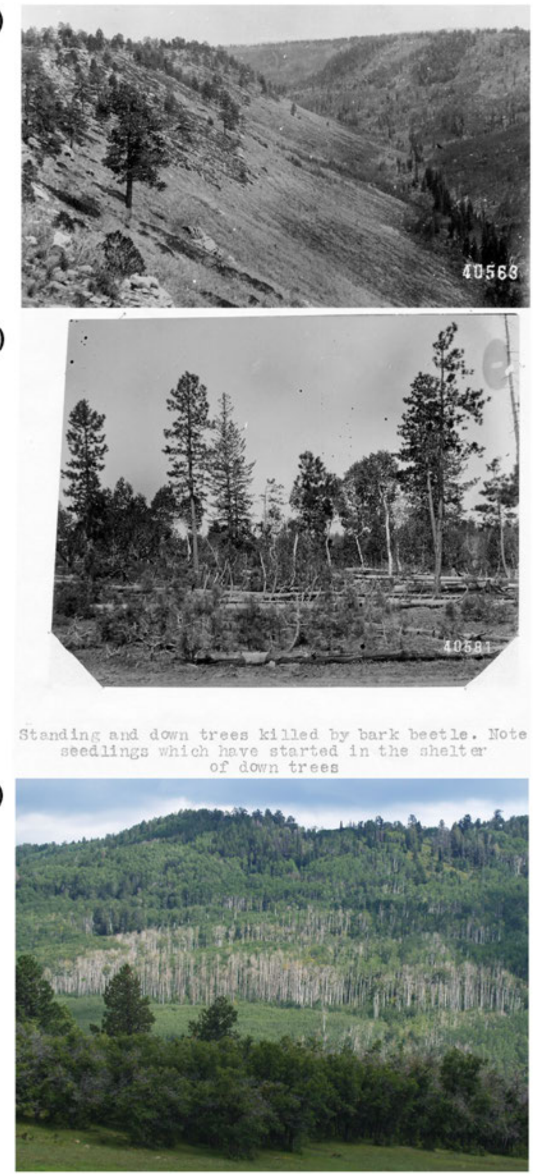

Fig. 3. Legacies after large, infrequent disturbances in dry forests: (a) a historical moderate- to high-severity fire in dry forests on the Uncompahgre Plateau, western Colorado, photograph in 1903 from Riley (1904); (b) a historical beetle outbreak in dry forests on the Uncompahgre Plateau, western Colorado, photograph in 1903 from Riley (1904); and (c) sudden aspen decline (SAD), a recent drought-linked disturbance, in southwestern Colorado, photograph by W. L. Baker, in 2006.

Table 3. Some historical structures (table entries), created by LIDs and environmental heterogeneity, that provided resistance and resilience at the stand and landscape scales to the three main types of LIDs in dry forests.

Property	Moderate- to high-severity fires	Beetle outbreaks	Droughts
Resistance–stand scale	Abundant large trees, some small trees	Abundant small trees, some large trees	Abundant small trees
	Fire-resistant trees	Diverse tree species	Diverse tree species
	Moderate fuel continuity (e.g., patches of rocks, low fuels)	Contiguous patches of small trees	Diverse topo-edaphic settings, some with more moisture
	Lower tree density/fuels, where this occurred, reducing fire severity	Lower tree density, where this occurred	Lower tree density, where this occurred
	Higher tree density/cover leading to shaded, moister fuels, where this occurred		
Resistance–landscape scale	Areas of large trees	Low–moderate contiguity of areas of large trees	Low–moderate contiguity of areas of large trees
	Areas of fire-resistant trees	Diverse patches dominated by different tree species	Diverse patches dominated by different tree species
	Areas of low tree density/fuels, where they occurred	Areas of low tree density, where they occurred	Areas of low tree density, where they occurred
	Limited areas of young, recovering forests	Large areas of young, recovering forests	Large areas of young, recovering forests
	Moderate fuel continuity	Discontinuous suitable host trees	
	Areas of higher tree density/ cover leading to shaded fuels		
	Openings that slowed fire spread (e.g., grasslands, wetlands)	Openings that broke up contiguous suitable host trees	
	Natural fire breaks (e.g., rock outcrops, streams, moist stands)	Natural openings with few or no host trees	
Resilience–stand scale	Resprouting trees and shrubs	Resprouting trees and shrubs	Resprouting trees and shrubs
	Surviving large seed trees, some patches of surviving small trees	Abundant small trees, some large surviving trees for seed	Abundant small trees, some large surviving trees for seed
		As much diversity in tree species as possible	As much diversity in tree species as possible
Resilience–landscape scale	Large seed trees, likely to survive, every 50–100 m, limited patches of small trees	Large areas with abundant small trees likely to survive, some patches of large trees	Large areas with abundant small trees likely to survive, some patches of large trees
	Diverse tree densities, basal areas, and tree species composition	Diverse tree densities, basal areas, and tree species composition	Diverse tree densities, basal areas, and tree species composition
	Most severely burned area within 100–200 m of an unburned edge	Patches with a diversity of dominant tree species	Patches with a diversity of dominant tree species

Note: LIDs, large, infrequent disturbances.

1998) or ecological memory (Johnstone et al. 2016) facilitated natural recovery. Resilience was enhanced by resprouting trees and shrubs, large old trees that provided post-disturbance seed, and variable tree densities and basal areas that provided diverse post-disturbance recovery (Table 3).

Highly variable historical tree regeneration, particularly in the Southwest

Successful ponderosa pine regeneration was limited by a required coincidence of favorable processes from seed formation to seedling survival (Pearson 1923, Feddema et al. 2013, Savage et al. 2013). However, land-survey records from 22,206 km of transects across 1.7 million ha of dry forests in the late 1800s showed that seedlings and/or saplings were present over 35–57% and dense over 20–30% of dry-forest area in Oregon, California, and part of northern Arizona (Baker and Williams 2015). Pulses of regeneration seen in some age structures were favored by canopy-reducing disturbances, particularly fire that created mineral seedbeds and reduced competition by grass, followed by fire-free periods or pluvials, that sustained regeneration (Dugan and Baker 2015). Moderate- to high-severity fires led to more regeneration than did low-severity fires (Wu 1999, Ehle and Baker 2003, Schoennagel et al. 2011, Baker and Williams 2015).

About 14% of dry-forest area, mostly in the Southwest, had sufficiently frequent low-severity fire (Baker 2017*a*) and drier climate to potentially limit regeneration to exceptional pluvials and fire-free periods (Covington and Moore 1994, Savage et al. 1996, 2013). Land-survey records document that seedlings and/or saplings were present over only 4–13% of two large landscapes in Arizona and one in Colorado (Baker and Williams 2015). However, forest age structure in two cases showed more continuous regeneration not limited to wet or fire-free periods, with broad peaks evident in one case (Mast et al. 1999). Broad episodes bring into question whether regeneration was rare and confined to unusual climatic episodes (Savage and Mast 2005).

Contrasting regeneration findings in the Southwest are also documented in early forest-reserve reports. Leiberg et al. (1904:28) said of the 329,000-ha San Francisco Peaks forest-reserve area on the western part of the Mogollon Plateau in northern Arizona:

> Reproduction of the yellow pine is, generally, extremely deficient as regards seedling and young sapling growth, except in an area lying east of Stoneman Lake and south of Morman Lake. Apparently there has been an almost complete cessation of reproduction over very large areas during the past twenty or twenty-five years, and there is no evidence that previous to that time it was at any period very exuberant.

What happened to favor regeneration near the lakes is unexplained, but a nearby landscape also had abundant regeneration. Stabler (1906:7) said of the eastern extension of the Mogollon Plateau onto Black Mesa and into the White Mountains:

> The reproduction of the yellow pine portion of the commercial forest type is wonderfully good. This in spite of the fact that the pine bunchgrass is as a rule very thick and vigorous and but little of it kept down by grazing. The fact that the grass is not grazed makes the numerous ground fires more serious than they otherwise would have been, but in spite of these fires. . .the reproduction is good and occurs in all ages.

A compelling explanation is lacking for contrasts in historical regeneration over large land areas.

Historically slow and incomplete natural recovery after LIDs in dry forests

Severely disturbed dry forests historically regenerated variably, but often slowly, and could remain unforested or sparsely forested for ≥100 yr (Table 4). Post-fire regeneration was at times very dense over extensive area in the Southwest (Fig. 4a, b). High-severity fires could be followed by extended tree regeneration lasting 20–60 yr, which could also be lagged by 15–20 yr and even have >50-yr lags with little or no tree regeneration (Table 4). Openings (grasslands, shrublands) created or maintained by high-severity fires could persist for 130–150 yr or more (Tables 4, 5) and be quite large. For example, in the Sierra, Show (1924:83) reported:

> Perhaps the most striking characteristic of the timber region of northern California. . .is the very large area occupied by brushfields. The brushfields, for the most part, are the results of fires which have destroyed the timber and allowed the brush to occupy the ground; in round numbers 1,500,000 acres [607,000 ha] are now in this condition. Of this million and a half acres probably 75% is restocking naturally, scattered individuals and groups of trees having survived the fires of the past, and can be depended on to take care of themselves. . ..

Forests often, but not always, recovered after intense fires, particularly if surviving seed trees were nearby; if so, trees regenerated and tree density and basal area increased, and forests often became denser (Fig. 4c). Probabilistic studies found dense middle-aged forests and created or maintained grasslands and shrublands in all dry-forest landscapes (Table 2). However, many pathways of forest recovery likely occurred (Kashian et al. 2007). In dry forests, open forest patches and some dense forest patches may have simply persisted and grown older, and some dense forest patches may have been thinned by competition or disturbances (Oliver 1995, Zhang et al. 2013) until a mature forest re-established (Moir and Dieterich 1988).

Including the lag before tree regeneration, recovery of a mature forest after high-severity fire historically required >100 yr (Table 6). Old growth could be reached within 150–200 yr (Mehl 1992, Hamilton 1993), but 150–300 yr for

Table 4. Historical lags in tree regeneration and the length of successful episodes of natural tree regeneration after high-severity fires in dry forests, based on tree-ring reconstructions and early observations.

Topic/Author(s)	Location	Observation
Huckaby et al. (2001)	Front Range, Colorado	Tree regeneration delayed on average by 18 yr after high-severity fires, ranging from 0 to 33 yr for 16 fires from A.D. 1531–1880
Boerker (1915:15)	Western Sierra, California	"Unlike the chaparral regions of southern California, this brush is only a temporary type and is, in most cases, the result of fire having destroyed the forest cover. . .In most cases, in from 5 to 10 years after the fire has consumed the timber, the brush takes possession of the land. . .after the brush has established itself, if seed trees are nearby, seedlings will get started and fight their way through the brush. It takes from 15 to 30 years for a seedling to get large enough to overtop the brush. . ."
Wu (1999)	San Juan Mts., Colorado	Tree regeneration concentrated within 20 yr after higher-severity fires
Baker (2017*b*)	Uncompahgre, Colorado	Tree regeneration sparse or lacking in a stand 24 yr after high-severity fire
Ehle and Baker (2003)	Front Range, Colorado	Tree regeneration concentrated within 20–25 yr after high-severity fires
Nagel and Taylor (2005:448)	Lake Tahoe Basin, California	"Tree regeneration into the chaparral stands was highest during the first two or three decades after the fire [6 fires in 1861–1882], but tree establishment continued for at least five decades after the last fire in all of the stands"
Lauvaux et al. (2016:82)	Southern Cascades, California	"Tree populations were multi-aged. Initial establishment [after 6 fires in 1864–1918] was slow and typically peaked five or more decades after the fire"
Duthie (1914:14)	Front Range, Colorado	Tree regeneration sparse or lacking for first 50 yr: "A careful reconnaissance of the region made in 1911 showed that there are over 10,000 acres of land from which all forest cover was consumed by these fires half a century ago, and upon which there has been practically no natural restocking"
Sherriff (2004)	Front Range, Colorado	Tree regeneration concentrated within 19–60 yr after high-severity fires
Huckaby et al. (2001:25)	Front Range, Colorado	". . .openings were created by a fire in 1851, and remained unforested 149 years later. . .the northern part of the area may have burned again in 1880, slowing tree regeneration"
Kaufmann et al. (2003:239)	Front Range, Colorado	". . .historical mixed severity fires and delays of regeneration into openings created by fire contributed to a very open, spatially complex and temporally dynamic landscape structure"
Pearson (1914:249)	Arizona and New Mexico	"A characteristic feature of the timbered mountains in Arizona and New Mexico at altitudes above 8000 feet is the occurrence of extensive burns. The original forests below 9500 feet were composed mainly of western yellow pine (*Pinus ponderosa*), Douglas fir. . ., limber pine. . ., Mexican white pine. . ., and white fir. . .The greater portions of the burns have grown up to quaking aspen. . ., but extensive areas are practically bare. Scattering trees of the original forest usually remain, and where this condition exists or where the burn is comparatively small conifers are generally restocking the land. . ."

conifers to regain dominance over aspen in mixed-conifer forests (Table 6). Historical high-severity fire rotations of 2–8 centuries (Baker 2015) would have often allowed full recovery to old growth before the next high-severity fire.

Fluctuating historical dry-forest landscapes of recovery had heterogeneous structure

Overall, historical dry-forest landscapes in the western United States fluctuated from infrequent large natural disturbances that included substantial severe fires, beetle outbreaks, and droughts that killed many trees, leaving a diversity of legacies, followed by 100–300 yr of natural recovery. Where tree density and basal area were reduced, vulnerability to droughts and beetle outbreaks often declined; where old trees persisted, vulnerability to severe fires was reduced. Slow, variable post-disturbance tree regeneration and growth made natural recovery after LIDs a dominant

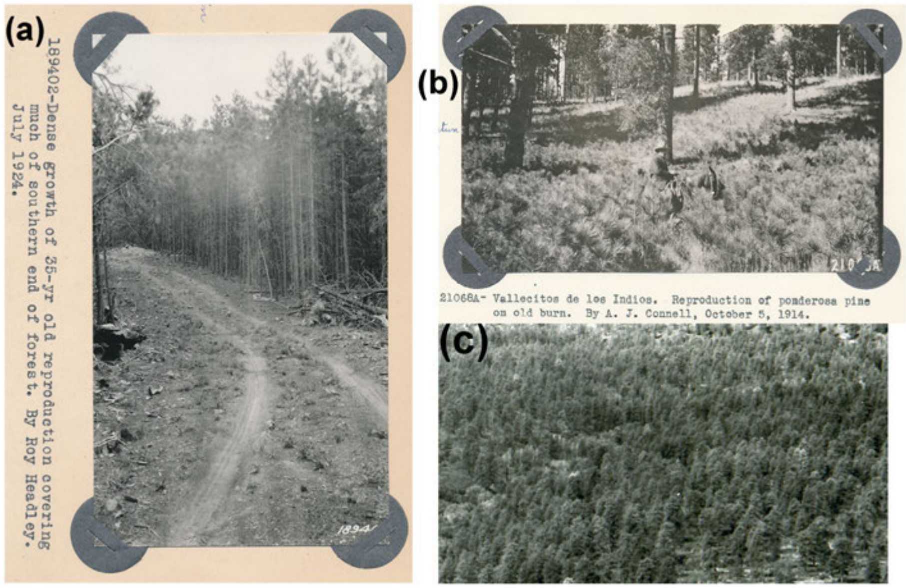

Fig. 4. Dense historical ponderosa pine regeneration after fire in the Southwest: (a) after likely large high-severity fire in the late 1800s in ponderosa pine forests, southern Coconino National Forest, Mogollon Plateau, Arizona, photograph taken in 1924 by Roy Headley, Historical Photo Collection, Region 3, U.S. Forest Service, Albuquerque, New Mexico; (b) after fire in the Jemez Mountains, New Mexico, photograph taken in 1914 by A. J. Connell, Historical Photo Collection, Region 3, U.S. Forest Service, Albuquerque, New Mexico; and (c) an example of a dense middle-aged historical forest, reproduced from a zoom of the right center of Fig. 2, an 1897 photograph by Whitman Cross.

ongoing process in most historical dry-forest landscapes. Episodes of LIDs across large areas meant that large land areas may have been synchronously recovering from natural disturbances. Infrequent disturbances and slow, variable natural recovery explain why historical dry-forest landscapes were spatially heterogeneous with a mix of old forests, middle-aged forests, recently disturbed forests, large and small openings with incipient or nearly completed regeneration, and more persistent openings, as documented by probabilistic landscape-scale studies (Table 2). This stand and landscape diversity conferred resistance, resilience, bet-hedging, and adaptation to diverse, unpredictable future disturbances, but substantial fluctuation still occurred.

Emerging Patterns of Transition to Committed Warming

Tree-mortality agents in dry forests over the last few decades

Increased tree mortality and regeneration decline or failure are expected during the transition. Increasing tree mortality is evident around the world (Allen et al. 2010). In dry forests, mortality is occurring from fires, beetle outbreaks, and directly from drought and temperature stress (Anderegg et al. 2013). Background rates of tree mortality (non-catastrophic, including all agents) increased significantly (3.3% per year, a doubling time of 22 yr), likely from warming, in the 15 old-forest plots most likely in dry forests, since they had short mean fire intervals (Van Mantgem et al. 2009: Table 1). In all plots censused from 1955 to 2007 across the western United States, 19% of trees died over the roughly 50-yr period (Van Mantgem et al. 2009), which is a 263-yr rotation (50/0.19). That would not lead to lasting loss of old forests, as 263 yr is ample time to regrow old trees, but if mortality doubled further, then it could become very limiting, and drought and heat stress could become the main cause of tree mortality (Allen et al. 2010).

Even with more severe (non-background) mortality from beetle outbreaks, droughts, and fires, there are survivors that play key stand-level roles

Table 5. Longer-term studies and observations of post-fire creation or maintenance of grasslands and shrublands after historical high-severity fires in dry-forest landscapes of the western United States.

Author(s)	Location	Years after fire	Observation
Guiterman (2016)	Jemez Mts., New Mexico	>115	Most of the area of 5 large patches (totaling 1142 ha) of mixed montane shrubland, dominated by Gambel oak (*Quercus gambelii*) that originated primarily in 1894–1900 remained largely unforested. Originating fires were likely mixed- to high-severity
Baker (2014)	Sierra Nevada, California	109–118	About 22% of montane chaparral, likely burned in high-severity fires in the late 1800s, did not become forested, and instead remained as montane chaparral, over periods of 109–118 yr
Nagel and Taylor (2005)	Northern Sierra, California	~120–140	About 38% of montane chaparral patches that originated after high-severity fires in 1861–1882 had not become forested by the 2000s
Lauvaux et al. (2016)	Southern Cascade Mts., California	~100–150	About 35% of montane chaparral patches that originated after high-severity fires in 1864–1918 had not become forested by the 2010s
Huckaby et al. (2001), Baker (2009:249)	Front Range, Colorado	~120–150	By about A.D. 2000 [120–50 yr after fires], some forests burned in high-severity fires in 1851 or 1880 had recovered to dense, middle-aged forests, but some openings were still unforested grasslands that were slowly reforesting
Baker (2017*b*)	Uncompahgre Plateau, Colorado	~130–150	About 40% of a large ponderosa pine and mixed-conifer landscape with evidence of high-severity fire in the late 1800s was nonforested (e.g., shrubs, small trees, grasslands); about half the nonforested area that was a mixture of grasslands, shrublands, recent burns, and areas with small trees was not forested by 2010, likely indicating at least century-scale stability after high-severity fires

in forest resilience (Table 3). In beetle outbreaks, most smaller trees survive as do some percentage of larger trees. A 1965–1978 MPB outbreak in the Colorado Front Range killed 25% of ponderosa pines of all sizes, especially 20–36 cm dbh, and reduced basal area by 38% (McCambridge et al. 1982). In British Columbia, a more severe 2005–2008 MPB outbreak, also with western pine beetle (*Dendroctonus brevicomis*), killed ~80% of trees, including 23–42% <15 cm dbh, 81% 15–30 cm, and 94% >30 cm over >175,000 ha, with little variation across a wide range of tree densities (Klenner and Arsenault 2009). In the Black Hills of South Dakota and Wyoming, an MPB outbreak over ~157,000 ha in 2004–2014 mostly killed ponderosas 23–43 cm dbh (Graham et al. 2016). Stands with <21 m^2/ha of basal area were little affected, but mortality increased up to 28–34 m^2/ha, where 74% of trees were killed, but 60% for >34 m^2/ha (Graham et al. 2016). Many trees survived, with means of 141 trees/ha of tree density and 11.7 m^2/ha of basal area. After beetle outbreaks, there were surviving trees of all sizes, especially small trees, as well as patches of surviving trees (Six et al. 2014). Dry forests were substantially renewed, and yet able to persist.

Mortality from droughts in dry forests has not been isolated, as beetles often ultimately kill many drought-affected trees. However, similar mortality patterns were evident with trees of all sizes killed and the highest percent mortality in larger trees (Ganey and Vojta 2011). Droughts put tall, old conifers especially at risk of replacement by shorter trees and shrubs (Bennett et al. 2015, McDowell and Allen 2015, McDowell et al. 2015), because taller trees are more physically vulnerable to failure to conduct water. A surprising 70% of a global sample of trees, in both dry and wet environments, operates with low physiological safety margins for escaping mortality from drought (Choat et al. 2012). Mortality consistent with these drought vulnerabilities is already occurring (Bennett et al. 2015). In contrast, larger trees generally better survive fires, because of thicker bark, elevated branches, and other adaptations (Baker 2009).

Table 6. Longer-term studies and observations of post-fire recovery to forest after historical high-severity fires in dry-forest landscapes of the western United States.

Author(s)	Location	Years after fire	Observations of post-fire succession in dry forests
MacKenzie et al. (2004)	Western Montana	60–100	Tree density/basal area approached pre-fire level within about 60–100 yr, basal- area increase slowed ~100 yr after high-severity fire
Baker (2014)	Sierra Nevada, California	109–118	About 78% of chaparral, likely burned in high-severity fires in the late 1800s, became forested over periods of 109–118 yr
Smith and Smith (2005), Baker (2017*b*)	Uncompahgre Plateau, Colorado	100–137	Conifers can begin to overtop aspen within about 100 yr, with mixed conifer–aspen stands at about 137 yr after high-severity fires
Nagel and Taylor (2005)	Northern Sierra, California	~120–140	About 62% of montane chaparral patches that originated after high-severity fires in 1861–1882 had become forested by the 2000s
Lauvaux et al. (2016)	Southern Cascade Mts., California	~100–150	About 65% of montane chaparral patches that originated after high-severity fires in 1864–1918 had become forested by the 2010s
Huckaby et al. (2001), Baker (2009:249)	Front Range, Colorado	~120–150	By about A.D. 2000 [120–150 yr after fires], some forests burned in high-severity fires in 1851 or 1880 had recovered to dense, middle-aged forests, but some openings were still reforesting
Baker (2017*b*)	Uncompahgre Plateau, Colorado	~130–150	About 40% of a large ponderosa pine and mixed-conifer landscape was nonforested (e.g., shrubs, small trees, grasslands) in the late 1800s; about half that area had become forested by 2010, likely indicating natural recovery after high-severity fires
Leiberg (1902:74)	Western Sierra, California	150	"The yellow pine on these tracts is mostly old growth; that is, the greater percentage of suitable size for mill timber is over 150 years of age"
Wu (1999:134)	San Juan Mts., Colorado	~150–200	"Even-aged stands still maintain their structure, such as a prominent post-fire cohort of aspen or ponderosa pine, 150 years after their last lethal fires, which occurred in the period from 1850 to 1880. . .therefore, this study estimates that all-age structure requires at least two hundred years to develop"
Kercher and Axelrod (1984)	Western Sierra, California	~250	Simulation suggested that about 250 yr would be required for Sierran mixed-conifer forests to recover and stabilize after severe disturbance
Baker (1925:89)	Central Rocky Mountains	≥250	"On the assumption that conifers found in the aspen zone will bear seed at 80 years, most areas ought to be well seeded in with reproduction in three tree generations or about 250 years in the Douglas fir-white fir zone. . .certain areas in the lower zones may require more than 250 years. . ."
Duthie (1914:14)	Front Range, Colorado	200–300	"It is estimated that two or three centuries would elapse before these burns would again be fully reforested if natural regeneration were depended upon to produce a satisfactory forest cover" (describing recovery after high-severity fires that occurred a half century earlier)
Zier and Baker (2006:261)	San Juan Mts., Colorado	Long periods	Over about a century, 40% of mixed-conifer forests visible in 25 scenes in early photographs showed increased conifers, while in 60%, there was no change in proportions of aspen and conifers, suggesting that ". . .long periods of time may be needed for conversion from aspen to conifers, if it occurs at all"

Given these vulnerabilities and documented mortality effects, what were recent sources of mortality; were severe fires, beetle outbreaks, or droughts the largest cause of non-background tree mortality over the last few decades? Details of analysis are in Appendix S1. Most important from this analysis is that insects-disease, on average, overall led to 2.1 times as much mortality area as did moderate- to high-severity fires, 1.7 times in ponderosa, and 2.6 times in dry mixed conifer (Table 7). Estimated rotations were 565 yr for moderate- to high-severity fires and 221 yr for insects-disease in dry mixed-conifer forests (Table 7). Rotations were 408 yr for moderate- to high-severity fires and 247 yr for insects-disease in ponderosa pine. These are similar to 2003–2012 mortality rotations of 500 yr for fire and 286 yr for beetles across all forests of the western United States from the inverse of annual mortality of 0.20% for fire and 0.35% for beetles, and the ratio of insects-disease to moderate- to high-severity fire of 1.75 is also similar (Berner et al. 2017). Under a hypothetical California-type drought scenario moving across dry forests (Appendix S2), an affected area of 5.5 million ha every six years would have a mortality area of 1.3 million ha (24%); if half from direct drought mortality, this would be a drought mortality rotation of 191 yr (6 yr/(0.65 million ha/20.7 million ha)). If so, droughts and insects-disease would likely account for about 3–4 times as much mortality area as severe fires.

Recent sizes and rates of beetle outbreaks, droughts, and moderate- to high-severity fire in dry forests are probably not yet outside the historical range of variability (Table 8), although evidence about historical variability is limited and some individual events have been exceptional locally (e.g., 2012–2016 California drought). Large beetle outbreaks have individually affected up to about 175,000 ha in dry forests, approaching the same scale as the 200,000- to 300,000-ha outbreak in the Black Hills in 1895–1909. The estimated recent beetle mortality rotation of 241 yr would not preclude full recovery of old-growth forests during or after the transition. The historical beetle-outbreak mortality rotation is too poorly known to be certain that this recent rate is or is not similar. Available evidence is insufficient to be able to assess historical vs. recent drought impacts on dry forests, but drought rates themselves are in general not outside historical variability in the western United States (Wuebbles et al. 2017; Appendix S3). However, if the frequency distribution of droughts does not change, $\sim 1°C$ elevated temperature alone will cause an increase in drought events sufficient to kill ponderosa pine seedlings by about 1.8 events by A.D. 2100 under RCP 2.6 (Adams et al. 2017). Larger recent moderate- to high-severity fires have individually affected about 30,000–60,000 ha, except for the 128,000-ha Rodeo–Chediski fire in Arizona (Table 8). Historical fire-size evidence is limited, in general, but the area burned at moderate to high severity on the Uncompahgre Plateau, Colorado, likely in 1879, was at the scale of about

Table 7. Affected area and estimated mortality area in dry forests across the western United States from 1999 to 2012 (n = 14 yr) from moderate- to high-severity fire and insects-disease.

Area and measure	Ponderosa pine	Dry mixed conifer	Total
Affected area			
Fire area (ha)	518,580	415,971	934,551
Insects-disease area (ha)	2,319,651	2,874,101	5,193,752
Fire rotation (yr)	265	367	311
Insect rotation (yr)	59	53	56
Ratio: insects-disease/fire area	4.5	6.9	5.6
Mortality area from multiplying affected fire area by 0.65 and affected insects-disease area by 0.24			
Fire area (ha)	337,077	270,381	607,458
Insects-disease area (ha)	556,716	689,784	1,246,500
Fire rotation (yr)	408	565	478
Insect rotation (yr)	247	221	233
Ratio: insects-disease/fire area	1.7	2.6	2.1
Fire area in 40 yr (% of total), if no change	9.8	7.1	8.4
Insects-disease area in 40 yr (% of total), if no change	16.2	18.1	17.2
Fire area in 40 yr (% of total), if projected	15.4	10.5	12.8
Total analysis area (ha)	9,825,679	10,910,705	20,736,384

Notes: Data on affected areas and total analysis areas are from Baker and Williams (2015). See Appendix S1 for an explanation of estimation of mortality area.

Table 8. Comparative sizes, durations, and rotations of recent large infrequent disturbances in dry forests and the expected mortality area during the 40-yr transition.

§ Klenner and Arsenault (2009).

¶ From Tree Mortality Task Force (2017) and Potter (2017).

\# From Worrall et al. (2013) for roughly the area of aspen decline affecting dry mixed-conifer forests.

‖ From MTBS data (www.mtbs.gov); the area is the sum of the moderate- and high-severity classes in the MTBS pdf map of each fire.

†† From the text, in the case of drought, and from Table 7, in the case of fire and insects-diseases; rotation is the time, in years, it is expected to take for these disturbances to affect land area equal to whole landscapes.

‡‡ The original rotation estimate of >80 yr for affected area is given in the text. The rotation for mortality area can be estimated by dividing by 0.24, which is the estimate from Hicke et al. (2016) used in Table 7.

§§ The original rotation estimate from Odion et al. (2014) was 235–319 yr for affected area, and the rotation for mortality area can be estimated by dividing by 0.65, as explained in the text and used in Table 7. After division, the original 235–319 yr range becomes 362–491 yr.

¶¶ From Table 7.

75,000–90,000 ha (Baker 2017*b*), thus similar to larger recent fires. The geometric mean higher-severity patch size was 47% lower in the recent than the historical period across 624,156 ha of dry forests in the Colorado Front Range (Williams and Baker 2012*a*). Moderate- to high-severity fire in dry forests was not operating from 1984 to 2012 at rates that exceeded historical rates, and the fraction of fires that burned at high severity had not increased (Baker 2015). The recent fire-mortality rotation for moderate- to high-severity fires of 478 yr is within, but toward the long end of the estimated historical rotation of 362–491 yr (Table 8).

Assuming no increase, in ponderosa pine, a resulting fire-mortality rotation of 408 yr would lead to expected mortality area of 9.8% over the 40-yr transition (Table 7). In dry mixed conifer, a fire-mortality rotation of 565 yr would lead to mortality area of 7.1%. In ponderosa pine, an insects-disease mortality rotation of 247 yr would lead to mortality area of 16.2% over the 40-yr transition (Table 7). Similarly, in dry mixed conifer, an insects-disease mortality rotation of 221 yr would lead to mortality area of 18.1% (Table 7). Under a California-type drought scenario, a 191-yr mortality rotation would lead to a mortality area of 20.9%. Overall, if no change in rates over the 40-yr transition, actual mortality area from fire and insects-disease would total ~26% of dry-forest area, 1/3 from moderate- to high-severity fires and 2/3 from insects-disease, a mortality rotation of 154 yr, which could still leave substantial area of old forests by the end of the transition. However, if a California-drought scenario ensued, an added 21% in 40 yr could lead to a total mortality area of $\sim$47%, a rotation of $\sim$85 yr, which could leave much less old forest, since it is particularly vulnerable to droughts and beetles.

Projecting possible increases in these disturbances during the 40-yr transition period is only roughly possible, and only for fire (Table 7; Appendix S3). There are no specific projections for only 1.5–2.0°C of warming on drought, fire, and insects. The U.S. Global Change Research Program reported low-to-medium confidence in a current anthropogenic climate-change effect on fire in the western United States (Wuebbles et al. 2017). Nonetheless, to estimate an upper bound on possible increases in moderate- to high-severity fire in dry forests, I used the midpoint of the low range of projected increases in area burned by A.D. 2046–2065 across 23 analysis areas under moderate emissions (RCP 4.5), which is 1.57 in ponderosa pine and 1.48 in dry mixed conifer (Baker 2015). These were the most recent area-burned projections, which are needed to estimate future mortality area. Using these, the percentage of mortality area from fire would increase from 9.8% to 15.4% in ponderosa pine and from 7.1% to 10.5% in dry mixed-conifer forests (Table 7). If combined with the hypothetical California-drought scenario, the total could reach about 51%.

Recent and projected tree regeneration in dry forests

Is there evidence of tree-regeneration decline in dry forests that could make the forest loss from tree mortality more permanent? Current rates and patterns of tree regeneration in all dry forests are relevant, but the only systematic monitoring is by the Forest Inventory and Analysis Program (FIA). Since 1995, FIA data are remeasured at 5- to 10-yr intervals on plots each representing about 2429 ha (Bechtold and Patterson 2005). Forest Inventory and Analysis data were used to analyze recent recruitment of juvenile vs. adult trees relative to climate in the western United States (Bell et al. 2014, Dobrowski et al. 2015). Ponderosa pine and Douglas-fir seedlings were much less likely to be present than were adults (28,177 plots), particularly along the warmer western and southern range margins of ponderosa pine (Bell et al. 2014). Similarly, for most conifers (13 species in 33,665 plots) in dry forests, juveniles occupied moister sites than did adults (Dobrowski et al. 2015). A caveat is that historical variability in tree regeneration was naturally high, as reviewed earlier, leaving in question whether these short periods of observation represent lasting trends.

These studies provide context, but tree regeneration after severe disturbances in dry forests is most relevant to the transition, since disturbances leave forests most dependent on regeneration. A focus has been on regeneration after high-severity fires; 24 studies, all I found, showed tree regeneration after these fires was almost universally heterogeneous (Table 9). Within the first 30 yr, substantial area lacked any conifer regeneration, while other area had adequate or dense regeneration (Table 9). Where studied, regeneration density was nearly always lowest in high-severity areas, relative to low- or moderate-severity areas. Ponderosa regeneration was commonly highest adjacent to the unburned margin of the fire and declined into the fire to low levels within 100–200 m, often attributed to seed-dispersal limitations, the hotter environment of open areas, or competition with shrubs or deciduous trees. Studies that analyzed topographic effects found regeneration especially deficient at low elevations and on south-facing slopes. Regeneration after high-severity fires in Colorado was concentrated in only three years with unusually high growing season precipitation over a 24-yr period, based on precisely dated seedlings (Rother and Veblen 2017). Less concentrated years of regeneration were evident in young adult trees, less precisely datable, after older New Mexico fires (Savage et al. 2013). Although regeneration was still sparse and favored near unburned margins at 28 and 45 yr post-fire, it was extrapolated to extend within $\sim$50 yr across the 28-yr-old high-severity burn (Haire and McGarigal 2010). Substantial declines in post-fire tree regeneration occurred from warmer and drier conditions since 2000, suggesting possible declines with warming (Stevens-Rumann et al. 2018).

Tree regeneration after recent high-severity fires was often considered unnatural or deficient, but historical evidence now does not support this. Dense regeneration was earlier considered hyperdense and outside the natural range of variability (Savage and Mast 2005). Since then, we have found (1) dense regeneration occurred

Table 9. Studies of tree regeneration up to 64 yr after high-severity fires in dry forests of the western United States arranged by the number of years since fire.

Author(s)	Location	Years after fire	Post-fire seedling/sapling density (trees/ha)
Bonnet et al. (2005)	South Dakota Black Hills	2	>700 ha^{-1} in burn (19 transects in 1 fire) within 12 m of unburned edge, declining inward, still some at 120 m, 180 m; positive effect, scorched needles on burned mineral soil; negative, high understory cover
Keyser et al. (2008)	South Dakota Black Hills	2–5	By year 5 (36 sites in 1 fire), >1000 ha^{-1} in unburned, low and moderate severity; little in high severity
Meigs et al. (2009)	Oregon Eastern Cascades	4–5	Range 0–62,134 conifers/ha (64 plots in 4 fires); no difference among unburned, low, and moderate severity. In ponderosa forests, no ponderosa regeneration in high-severity fires and in mixed conifer limited conifer regeneration in high-severity fires
Ouzts et al. (2015)	Northern Arizona–New Mexico	7–10	Range 0–1433 conifers/ha (46 plots in 8 fires); 2 fires had 0 conifers/ha 7–10 yr after fire, 5 fires had <50 conifers/ha, 1 fire had 1500 conifers/ha; litter cover positively associated with seedlings
Crotteau et al. (2013)	California Southern Cascades	9–10	Mean 2235 conifers/ha in unburned (60 units in 1 fire), 2252 conifers/ha in low-severity, 7868 conifers/ha in moderate-severity, and 733 conifers/ha in high-severity fire; *Abies concolor* dominated regeneration over pines in more severe fire areas
Dodson and Root (2013)	Oregon Eastern Cascades	10	Mean 362 conifers/ha (18 plots in 1 fire); Range 0–1807 with 0 in 5 of the 7 plots <1000 m elevation
Collins and Roller (2013:1807)	Northern California Sierra	2–11	Omitting plots with post-fire management (leaving 21 patches in 5 fires), "there was no pine regeneration in over 90% of sampled patches". No significant effect from distance to unburned forest. Negative effect from shrubs, low seed production or soil moisture
Welch et al. (2016: Fig. 5)	California Sierra, Klamath, Southern Cascades	5–11	Mean about 500 trees/ha in yellow pine (246 plots in 12 fires), about 2000 trees/ha in dry mixed conifer (489 plots in 10 fires), interpolated from a bar graph. Overall across all vegetation types, not just yellow pine and dry mixed conifer, 54% of plots had 0–1 conifers, in interiors of severe burns, in dry areas, where more shrubs
Hanson (2018)	California Sierra Nevada/San Bernardino Mts.	1–12	Mean 3803 conifers/ha at ≤50 m into fire (20 plots in 7 fires), 1850 ha^{-1} at 51–150 m into fire (15 plots in 7 fires), 798 ha^{-1} at 151–300 m into fire (22 plots in 7 fires), and 336 ha^{-1} at >300 m into fire (25 plots in 7 fires). More within 50 m, but no significant difference among other distances. Percent shrub cover not correlated with density of conifer regeneration
Kemp et al. (2016)	Idaho–Montana Northern Rocky Mountains	5–13	Mean 7047–8153 conifers/ha (182 sites in 21 fires); Range 0–127,500 conifers/ha, but 5% of 182 sites had 0 conifers within 500 m; seedling presence probable if within 95 m of live seed source, especially if high basal area; fire severity little effect as most burn area was within 95 m of live trees
Owen et al. (2017)	Northern Arizona	12–13	Mean 84.1 conifers/ha in edge plots (6 plots in 2 fires), 41.4 conifers/ha in interior plots having no surviving trees within 200 m (6 plots in 2 fires); Range 13.0–153.8 conifers/ha in edge plots, 12.0–124.0 conifers/ha in interior plots. Regeneration significantly lower in interiors. Some long-distance dispersal (>300 m) found
Rother and Veblen (2016)	Colorado Front Range	8–15	Mean 37–1424 conifers/ha (302 plots in 6 fires), nearly all lower than pre-fire density, and 59% of plots had 0 conifers in 100 m^2 plot, with 83% of plots having <370 conifers/ha. Few seedlings in hot, dry lower elevations or on south-facing slopes, more seedlings within 50 m of live seed source, also in more southerly locations with summer rainfall
Ziegler et al. (2017)	South Dakota, Northern Colorado	11–15	Mean 43.0 trees/ha (18 plots in 3 fires)
Foxx (1996)	Northern New Mexico	0–16	Two sites in 1 fire had no seedlings in year 1, 0 and 210 trees/ha in year 8, and 218 and 318 trees/ha in year 16
Haffey (2014)	Arizona–New Mexico	6–16?	Only 24% of plots (179 plots in 9 fires) had ponderosa pine regeneration; within 150 m of a seed source, 38% of plots had tree regeneration; no regeneration beyond 250 m from a seed source. Nearly half of ponderosa pine seedlings were near a nurse structure, most often a log or large branch
Roccaforte et al. (2012)	Arizona	1–18	Range 0–11,234 conifers/ha (399 plots at 14 sites in 11 fires); 8 sites had 0 conifers/ha 1–12 yr after fire, 3 sites had 37–74 conifers/ha, 2 sites had 297–336 conifers/ha, and 1 site had 11,234 conifers/ha. Deciduous regeneration was dominant at all but 2 sites

(Table 9. *Continued*)

Author(s)	Location	Years after fire	Post-fire seedling/sapling density (trees/ha)
Chambers et al. (2016)	Colorado Front Range	11–18	Mean 225 trees/ha (305 plots in 5 fires) across unburned, low, and moderate severity. Mean tree density lowest in high severity (118 trees/ha) and in only 25% of plots, whereas 60% of low- to moderate-severity plots had regeneration. Regeneration greatest at high elevations and adjacent to unburned, declining to 10 conifers/ha at 200 m
Shatford et al. (2007)	Southern Oregon–Northern California	9–19	Mean 1694 trees/ha (24 plots in 8 fires); Range 83–8188 trees/ha. Plots showed a wide range from immediate and rapid regeneration to slow and constant to chronically limited. No significant effect of distance from seed source on seedling density; up to 84–1100 trees/ha >300 m from a seed source. Positive effect of shrub and hardwood cover
Guiterman et al. (2015)	Northern New Mexico	20	Mean 11 conifers/ha (10 plots in 1 fire); conifers present in 4 of 10 plots; maximum distance from a ponderosa seedling to unburned edge was 77 m
Rother and Veblen (2017)	Colorado Front Range	8–23	Ponderosa pine and Douglas-fir regeneration was concentrated in years with especially high growing season precipitation (413 dated seedlings at 10 sites in 5 fires); for all sites combined, three years (1995, 1998, and 2009) in twenty-four (1988–2011) accounted for most of the post-fire regeneration. Regeneration lags after the 5 fires were 0–4 yr
Passovoy and Fulé (2006)	Northern Arizona	3–27	Range 0–1052 conifers/ha (210 plots in 7 fires). Four of seven fires in years 4–8 had <50 conifers/ha and one had 26 conifers/ha at year 27, the other two fires had 170 conifers/ha and 1052 conifers/ha in years 4 and 9, respectively
Haire and McGarigal (2010)	Northern Arizona–New Mexico	28, 45	Little within years 1–8 (68 plots in 1 fire) or 1–15 (79 plots in 1 fire); ~8000, 2000 trees/ha near low-severity edge; most within 200 m of low-severity edge, but some to 304 m, 410 m; could reach all of fire area within ~50 yr
Savage and Mast (2005)	Northern Arizona–New Mexico	25–54	Regeneration began within 1–2 yr at 7 sites, within 6–10 yr at 3 sites (300 plots in 10 fires); 5 sites <200 trees/ha, 5 sites >400 trees/ha
Savage et al. (2013)	New Mexico	47–64	Regeneration did not begin for 3–20 yr (5 fires); Range (from 150 plots in 5 fires) per fire: 96–443 adult conifers/ha (≥1.4 m height and >6 cm dbh), 94–1629 seedlings and sapling conifers/ha for a total of 201–2112 trees/ha

Note: ? indicates that the Years after fire entry is uncertain.

historically over 20–30% of dry-forest areas in Oregon, California, and part of northern Arizona (Baker and Williams 2015); (2) dense younger established forests were historically common in nearly all dry-forest landscapes, suggesting past regeneration had been successful and dense (Williams and Baker 2012*b*); and (3) very dense post-fire trees are shown here to have covered large area on the southern Mogollon Plateau in northern Arizona (Fig. 4a) and occurred in the understory of burned forest in the Jemez Mountains, New Mexico (Fig. 4b). Dense and even very dense regeneration, in general and after high-severity fires, was within the historical range of variability in dry forests.

Some also considered poor regeneration after high-severity fires to indicate potentially unnatural type conversion of forests to shrublands or grasslands (Savage and Mast 2005, Haffey 2014), possible indicators of emerging tipping points (Reyer et al. 2015). However, of 24 studies, 21 (88%) covered only up to 27 yr after high-severity fires (Table 9). In general, 27 yr is insufficient, as historical tree regeneration after high-severity fires in dry forests could extend over periods of up to 60 yr (Table 4). Some large areas could even lack regeneration for ≥50 yr (Table 4) in part because of few climatically favorable periods for tree regeneration (Savage et al. 1996, Rother and Veblen 2017). A way to offset insufficient post-fire records is to extrapolate spatially (Haire and McGarigal 2010), but this has not generally been done (Table 9). Evidence is insufficient to conclude that post-fire tree regeneration is outside historical variation.

Historical tree regeneration after high-severity fires in dry forests failed or was slow at times, creating forest openings (Tables 4, 5), but recent studies often did not show modern failure was outside historical variability (Lauvaux et al. 2016). Opening creation by high-severity fire is likely operating at or below historical levels, since high-severity fires are at or below historical rates in dry forests (Baker 2015). Some openings have declined (Coop and Givnish 2007); thus, creation of new openings by high-severity fires is likely restorative (Baker 2017*b*, Boisramé et al. 2017). Openings also enhance resistance to fire spread (Boisramé et al. 2017, Owen et al. 2017) and increase the heterogeneity of landscape structure (Kaufmann et al. 2003), enhancing resistance and resilience (Table 3); thus, added openings in the transition are generally beneficial.

In contrast, tree regeneration after beetle outbreaks and droughts is not currently thought to be declining, because advance regeneration continues. In the multi-decadal period that background tree mortality increased in dry forests as temperatures rose, tree recruitment was unchanged (Van Mantgem et al. 2009). In beetle outbreaks, (1) 75% of trees <20 cm dbh survived (McCambridge et al. 1982), (2) 77% of trees <7.5 cm dbh and 58% of trees 7.5–15 cm dbh survived a severe outbreak (Klenner and Arsenault 2009), and (3) >95% of trees survived in stands with <18 m^2/ha of basal area, about 170 trees/ha in trees up to 37 cm dbh (Graham et al. 2016).

Future regeneration of dry-forest trees in general, not just after disturbances, was projected. Dobrowski et al. (2015) modeled the recruitment niche of 10 dry-forest trees relative to minimum temperature, evapotranspiration, and climatic water deficit. They then projected recruitment prevalence across the West through A.D. 2100 under RCP 8.5 (high emissions) and found recruitment declines of only about 10% or less (estimated from graphs) by A.D. 2060, at the end of the transition. Petrie et al. (2017) modeled climatic effects on stages in ponderosa regeneration (Feddema et al. 2013, Savage et al. 2013) and then projected future conditions with a water-balance model under RCP 4.5 and 8.5. Regeneration potential would be increased by +50% $\pm$ 106%, at 47 sites across the West by A.D. 2020–2059, from more flowering, seed production, and germination, especially in Arizona, Colorado, and New Mexico. After A.D. 2060, at the end of the transition, tree regeneration would decline, due to lower seedling production and survival, especially in the Pacific Northwest (−67%), but less so in the Intermountain region (−29%).

In summary, background rates of tree mortality are increasing in dry forests, and major recent droughts and beetle outbreaks have killed many trees. Recent droughts and beetle outbreaks together account for perhaps 3–4 times as much tree mortality as do moderate- to high-severity fires. Together, natural disturbances could cause tree mortality over 26–51% of dry forests in the transition. Tree regeneration is not apparently outside historical variability and is projected to only slightly decline or even increase. Some opening creation from tree mortality followed by tree-regeneration failure could actually restore grasslands and other openings. Current dry-forest area is not all at risk, as 1/2 to 3/4 could escape substantial mortality under committed warming, and the remainder could have more resistant and resilient forests that persist more than expected.

Transitioning Dry-Forest Landscapes

Large, infrequent disturbances that will enact tree mortality during the transition are capable of rapidly affecting millions of hectares and are generally beyond control. The spatial extent (25.5 million ha) of dry-forest landscapes and associated human communities and infrastructure provides large inertia for preparations. Our ability to control LIDs by manipulating forest structure is limited, and structurally ideal or restored landscapes may help, but a broader tie-in strategy, with a refocus on bet-hedging to enhance resilience to natural-process management may be more feasible and effective.

Limited ability to directly prevent LIDs or reduce their impacts on dry forests in the transition

Our ability to directly prevent LIDs or reduce their impacts is limited. Graham et al. (2016) reviewed the long history of failed attempts at controlling bark beetles through direct suppression or indirect manipulation of forest structure. At best, evidence suggests thinning, the most common manipulation, might modify the extent and pattern of tree mortality over limited area. Fettig et al. (2014) found thinning treatments to reduce tree mortality from MPB were costly and did not work during outbreaks without added direct control; thinning worked in some cases in ponderosa pine forests but had no significant effect in others. Six et al. (2014) also found thinning could possibly work at times, but failures occurred during outbreaks, and unthinned stands may actually have more survivors. Droughts are not directly controllable. Some drought treatments aim to protect particular trees by reducing competition (McDowell and Allen 2015), but this will likely ultimately fail under hotter droughts (Bennett et al. 2015). Fuel treatments to reduce fire spread and severity have also not been very effective: "Mechanical fuels treatments on U.S. federal lands over the last 15 yr (2001–2015) totaled almost 7 million ha. . .but the annual area burned has continued to set records" (Schoennagel et al. 2017:4586). Schoennagel et al. (2017) explained that treatments can reduce fire severity and increase low-severity fire in some dry forests, but the probability of having an effect is low, as only about 1% of treatments actually experience wildfire each year. Thinning treatments have been ineffective for LIDs in dry forests, in general, and are best as short-term, small-area holding actions (Six et al. 2014).

Can ideal or restored landscapes discourage LIDs from crossing tipping points?

Evidence that ideal or restored landscapes can discourage tipping points is also limited. To maintain MPBs in an endemic condition, discouraging an outbreak, Graham et al. (2016:157) suggested, based on high tree survival in an outbreak: ". . .heterogeneous landscapes composed of stands with heterogeneous structures and containing densities in the neighborhood of 80 feet^2 [18.3 m^2/ha] of basal area are resistant to MPB infestations. . ." However, they said forests in the late 1800s were dominantly in that condition when the largest known MPB outbreak in ponderosa pine forests occurred, the 200,000- to 300,000-ha 1895–1909 outbreak in the Black Hills. Thus, ideal landscapes might only be resistant to some beetle outbreaks. Lundquist and Reich (2014:472) said: "Existing models show that diverse composition and configuration is the best and possibly only long-term, large-scale approach to bark beetle management. . ." For droughts, ideal stands and landscapes have not emerged, and there is little historical evidence. For wildfires, low-density stands with large, old ponderosa pines and few understory trees and shrubs are most resistant and resilient to subsequent wildfires (Allen et al. 2002). However, probabilistic studies (Table 2) have shown this structure was a significant, but not dominant component of most historical dry-forest landscapes, which had more heterogeneous stands across heterogeneous landscapes (Table 2). Thus, historical and ideal landscapes appear congruent, and achievable through restoration, for droughts and beetle outbreaks, and at least partly for fires.

Idealized and historical stand and landscape structures are unlikely to prevent LIDs from causing substantial tree mortality, some tree-regeneration failures, and some opening creation, as these were natural components of historical processes of disturbance and recovery in dry forests. Large, infrequent disturbances occurred in historical dry-forest landscapes and led to substantial landscape change and large fluctuations. Dry-forest landscapes appear to have been capable of general recovery after LIDs (Table 6), but some nonforest, created by disturbance, persisted for 100–150 yr or more (Table 5). Whether tipping points were crossed or this simply represents slow natural recovery is uncertain, but in either case dry-forest landscapes were dynamic and subject to large fluctuations that created and renewed resistance and resilience features that fostered bet-hedging (Table 3).

Natural fluctuation means that restoration and management in dry forests are less a matter of restoring and managing forest structures (Table 3) and more a matter of restoring and managing natural disturbance and recovery processes. Most structures are inherently ephemeral, persisting for only years or decades, and are quickly recreated by disturbances, and thus do not warrant intentional restoration. Widespread micro-management of fuel loads and forest structures after LIDs, based on fears of hypothetical mass fires (Stephens et al. 2018), is likely a waste of resources, because extensive structure management to reduce severe fires has been ineffective (Schoennagel et al. 2017). However, old trees and their associated stand- and landscape structures could persist for centuries, are not recreated by disturbances, and have been lost to excessive logging. Structure restoration and management make sense for these long-persisting structures not created quickly by disturbances, but process management, and associated facilitative structures (e.g., bet-hedging) now make sense for most landscape restoration and management.

A tie-in strategy using bet-hedging and process management of disturbances in the transition

Given substantial uncertainty and limited ability to control LIDs, a broad tie-in strategy, using actions beneficial for people and nature no matter what occurs, could likely facilitate more forest persistence in the transition. Suggested actions include (1) refocusing intentional ecological restoration on bet-hedging using historically congruent structures that provide resistance and resilience to diverse future disturbances (Baker and Williams 2015), (2) expanding development of fire-safe landscapes for people and infrastructure (Schoennagel et al. 2017), (3) expanding managed fire, and (4) accepting that LIDs will beneficially revise resistance, resilience, and genetic adaptation (Six et al. 2014). Restoring forest structure is costly, and resistance structures may fail, favoring structures that facilitate more process-based restoration (Millar et al. 2007).

Droughts and beetle outbreaks are likely to be 3–4 times as important as fires during the transition, which means that abundant small trees and high tree species diversity are now the more important resistance and resilience structures for transitioning dry forests (Table 3). Most large restoration programs (Reynolds et al. 2013, Addington et al. 2018) are likely to be ineffective, as they are focused on structures resistant to fire, when it is more likely that drought and beetles will determine the structures that persist in the transition. These programs to thin forests to resist damage by moderate- to high-severity fires have unfortunately reduced the small trees and diverse tree species that most provide resilience to droughts and beetle outbreaks. These programs could be quickly modified to instead retain small and diverse trees. In forests already deficient in small and diverse trees, if only one prescribed fire occurs before managed wildfire for resource benefit ensues, that last fire will likely stimulate some tree regeneration to repopulate small trees. If low-severity fires are generally managed to mimic historical spatial and temporal variability, opportunities will likely occur for diverse trees to repopulate (Baker 2017*a*).

The unpredictability of future disturbances suggests hedging bets (Millar et al. 2007, Baker and Williams 2015) in stand-level restoration by maintaining large and small trees and available tree species diversity. After restoration, most stands, even open low-density stands, can have numerical dominance by small trees of all available species, but also sufficient replacement larger trees of all available species. Early land surveys across 1.7 million ha of dry forests showed small trees (typically <40 cm dbh) were, on average, 62% of total trees (Baker and Williams 2015). Given loss of large trees to logging, retaining all large trees, and mid-sized trees that are their future replacements, is sensible. After disturbances, successful tree regeneration is favored by large surviving trees that provide seed within about 100–200 m (Table 9). Larger trees may later be lost to hotter droughts and beetle outbreaks. However, if there were 20–50 larger (>40 cm dbh) trees per ha, and >5% survived, that could provide needed surviving large trees. Bet-hedging in restoration leaves abundant trees of all species and sizes with small trees dominant.

At the landscape scale, diverse historical forest structures could reduce the spread and effects of natural disturbances (Table 3) and bet-hedging at this key scale of LIDs is very important now. For fires, areas of large fire-resistant trees, openings, and naturally moist areas or shaded fuels provide resistance and favor survivors that aid post-fire resilience. For beetle outbreaks and droughts, diverse tree species and smaller trees provide the most important resistance and resilience. Recovering younger to middle-aged forests were common historically, based on studies in Table 2, and naturally conferred resistance and resilience to beetles and droughts. Kautz et al. (2017:534) found that "...more than 60% of global forests are in various stages of recovery from a past disturbance at any given time." Protecting young, naturally recovering forests is thus feasible, congruent with historical forests, and a key landscape part of a process-restoration approach (Baker 2017*b*). Young forests can survive beetle outbreaks and possibly droughts at much higher rates than older forests (Graham et al. 2016). To maximize bet-hedging, mixtures of diverse resistance and resilience structures across landscapes, with much more focus on beetle outbreaks and droughts, in addition to fire, are now more congruent with expected LIDs.

It would benefit both people and nature to rapidly increase protection of infrastructure, homes, and communities from increased wildfires, and this would also enable more managed use of natural disturbances. With ~7 million ha of fuel-reduction treatments, but fires still burning homes (Schoennagel et al. 2017), we need to prevent the expansion of developments into fire-prone settings and finish full fire protection around all homes, infrastructure, and communities. Effective ways to reduce vulnerability and live with wildfire have been articulated (Cohen 2000, Baker 2009, Calkin et al. 2014, Moritz et al. 2014, Smith et al. 2016, Schoennagel et al. 2017). Tools include fire-safe construction, zoning, building codes, incentives, easements, growth boundaries, insurance policies, and other means (Kennedy 2006, Baker 2009, Schoennagel et al. 2017). Homeowners can use fire-safe construction focused on the home-ignition zone (Cohen 2000). Possibly most effective is for communities and developments to designate growth boundaries that enclose a wide margin of open, fire-resistant land uses that can serve as an effective fire break (e.g., ball fields, wetlands, irrigated agricultural fields), whether they are already in place or require construction. This alone would definitively stop expansion into fire-prone vegetation, protect key concentrations of people and infrastructure from fire, and make it more feasible to manage wildfires for resource benefit on adjoining public lands (Baker 2009).

Among LIDs, using more managed fire for resource benefit would be effective wherever it is safe and feasible, especially in the early part of the transition. Moderate- to high-severity wildfire has the longest recent rotation (Table 8) and is the only LID that can be directed. Prescribed fires are typically not sufficiently intense for effective restoration (Van Wagtendonk and Lutz 2007, Baker 2014), but prescribed burning once across landscapes and near homes and infrastructure is best before initiating managed fire (Baker 2017*a*). Managed wildfires can accomplish more renewal and enhancement of resistance and resilience, and also help prepare communities for future LIDs (Schoennagel et al. 2017). Expanding managed fire is scientifically supported (North et al. 2015, Schoennagel et al. 2017), and solutions to institutional barriers are identified (Stephens et al. 2016). Managed fires early in the transition are especially important to reduce tree density and basal area, which can lower vulnerability to droughts and beetle outbreaks more likely with higher temperatures later in the transition. Early managed fires could also stimulate tree regeneration, when it is favored (Petrie et al. 2017). Recovering small trees and entire stands recovering after fires provide resilience to droughts and beetles and foster asynchrony in tree populations that can slow disturbance spread (Millar et al. 2007, Seidl et al. 2016). If openings or low-density patches are created by early disturbances, those could also reduce later vulnerability. Openings are less likely to ignite (Baker 2009), may slow fire, and could hinder beetle spread.

Acceptance of the benefits of LIDs and protection of the post-LID environment are sensible, since we cannot prevent LIDs in the transition. For example, bark-beetle outbreaks may naturally thin and diversify forest structures (Oliver 1995, Graham et al. 2016), updating resistance and resilience, while increasing biodiversity and furthering genetic adaptation to emerging climates and LIDs (Six et al. 2014, Beudert et al. 2015). Large, infrequent disturbances also provide selection against individual trees not resistant to the LID or post-LID environment (Six et al. 2014). Survivors and post-disturbance regeneration can revise tree adaptations to both emerging climate and patterns of LIDs. Rapid evolutionary response to extreme climatic events is possible, even in long-lived trees (Grant et al. 2017). For example, MPB outbreaks favor survival of slower-growing ponderosa pines, even though faster-growing trees may outcompete them at other times (De la Mata et al. 2017). Also, since post-LID tree regeneration is favored within 100–200 m of surviving trees (Table 9), and LIDs can leave isolated patches of surviving trees that, by chance, have different gene frequencies, the opportunity for locally adapted genetic change is high. As Howe (1976:263) said: "Prevention of major conflagrations... would eliminate the ingredients for drift, i.e., the replacement of large, continuous populations by tiny islands of isolated interbreeders from which most ensuing regeneration would emanate..." To preserve genetic adaptation of trees to emerging climate and LIDs, it is important to not prevent LIDS, not plant trees, and not log post-disturbance survivors (Lindenmayer et al. 2008). Genetic adaptation to committed warming could enhance possibilities for more dry-forest persistence in the transition and during the extended period of adjustment after the initial transition to committed warming.

Conclusions

Limiting warming, as with the Paris Agreement, should enable more persistence of current dry forests in the transition to committed warming than projected by models. Here, I reviewed evidence that (1) LIDs historically produced diverse forest stands and landscapes that naturally provided resistance and resilience to subsequent disturbances; (2) LIDs cannot be generally prevented through direct control or indirect manipulation of forest structure; (3) fires, droughts, and beetle outbreaks are not yet having effects in dry-forest landscapes that appear outside historical variability; (4) in the last few decades, droughts and beetle outbreaks have caused roughly 3–4 times as much tree mortality as fires; (5) primary opportunities to enhance forest persistence are from expanded bet-hedging at stand and landscape scales focused on resistance and resilience to droughts and beetle outbreaks, and facilitating adaptation as disturbances occur; and (6) 1/2 to 3/4 of dry-forest area could possibly escape most mortality during the transition.

RESEARCH ARTICLE

Restoring and managing low-severity fire in dry-forest landscapes of the western USA

William L. Baker*

Program in Ecology/Department of Geography, Dept. 3371, 1000 E. University Ave., University of Wyoming, Laramie, Wyoming, United States of America

* bakerwl@uwyo.edu

Abstract

Low-severity fires that killed few canopy trees played a significant historical role in dry forests of the western USA and warrant restoration and management, but historical rates of burning remain uncertain. Past reconstructions focused on on dating fire years, not measuring historical rates of burning. Past statistics, including mean composite fire interval (mean CFI) and individual-tree fire interval (mean ITFI) have biases and inaccuracies if used as estimators of rates. In this study, I used regression, with a calibration dataset of 96 cases, to test whether these statistics could accurately predict two equivalent historical rates, population mean fire interval (PMFI) and fire rotation (FR). The best model, using Weibull mean ITFI, had low prediction error and $R^2_{adj} = 0.972$. I used this model to predict historical PMFI/FR at 252 sites spanning dry forests. Historical PMFI/FR for a pool of 342 calibration and predicted sites had a mean of 39 years and median of 30 years. Short (< 25 years) mean PMFI/FRs were in Arizona and New Mexico and scattered in other states. Long (> 55 years) mean PMFI/FRs were mainly from northern New Mexico to South Dakota. Mountain sites often had a large range in PMFI/FR. Nearly all 342 estimates are for old forests with a history of primarily low-severity fire, found across only about 34% of historical dry-forest area. Frequent fire (PMFI/FR < 25 years) was found across only about 14% of historical dry-forest area, with 86% having multidecadal rates of low-severity fire. Historical fuels (e.g., understory shrubs and small trees) could fully recover between multidecadal fires, allowing some denser forests and some ecosystem processes and wildlife habitat to be less limited by fire. Lower historical rates mean less restoration treatment is needed before beginning managed fire for resource benefits, where feasible. Mimicking patterns of variability in historical low-severity fire regimes would likely benefit biological diversity and ecosystem functioning.

Introduction

Low-severity wildfires significantly shaped dry forests in the western USA, but historical rates (e.g., mean interval, area burned) of these fires remain uncertain in a time of altered and further changing fire regimes. Low-severity fires periodically burned the understory of historical dry forests, changing fuel loads, composition, diversity, and ecosystem processes without killing most canopy trees [1–2]. Dry forests in the western USA cover 25.5 million ha and include dry pine forests, dominated by ponderosa pine (*Pinus ponderosa*) or other dry pines, and dry mixed-conifer forests that also have firs (*Abies concolor*, *A*. *grandis*, *Pseudotsuga menziesii)* and other trees [3]. Past reconstructions of low-severity fire in dry forests, using tree-rings, focused on long records of dated fire years in small plots, and most were not intended to accurately estimate key rate parameters of low-severity fire [1–2] needed to restore and manage low-severity fire across large landscapes. These small-plot reconstructions have known inaccuracies and biases if inappropriately used for this purpose [1, 4–11]. Fortunately, new landscape-scale and small-plot reconstruction methods [1, 11] overcome many known inaccuracies and biases in estimating historical low-severity fire rates, but limited new estimates are available.

This situation leaves a weak current basis for restoring and managing low-severity fire, using historical rates as a guide, across dry-forest landscapes. Here I: (1) develop regressions for estimating mean historical rates of low-severity fire from past reconstructions using a calibration dataset, and then (2) apply these regressions to estimate mean historical rates of low-severity fire for a large dataset of past reconstructions across the western USA, and (3) assess the applicability of these new estimates across dry-forest landscapes. These new estimates are directly usable in restoring and managing low-severity fire in the parts of dry forests of the western USA where low-severity fire was historically predominant, and provide a West-wide perspective on variability in historical mean rates of low-severity fire in these parts of dry forests. As discussed later, variability around mean rates is also an essential attribute of a low-severity fire regime.

Estimated mean historical rates of low-severity fire need to be fairly accurate, for restoring and managing low-severity fire, because key effects of fires on biological diversity, ecosystem functioning, and post-fire recovery operate significantly differently across a narrow range of mean rates. For example, understory fuels in dry forests, reduced by a single fire, often recover to pre-fire levels in about 7–25 years [12–14]. If mean fire intervals for low-severity fires were 10–15 years, understory fuels would often have been kept at relatively low levels, but if mean intervals were 25 years or more, then understory fuels would more often have been fully recovered and generally higher. Fires that are too frequent can reduce the ecological roles of the forest floor in replenishing soil nutrients and organic matter, enhancing absorption of water and nutrients, and providing habitat for microbial communities, potentially reducing long-term forest productivity [15]. Habitat for wildlife that use snags or down wood could be adversely affected by fire that is too frequent [15], which can also reduce understory plant species richness, possibly due to depletion of soil nitrogen [16]. Native shrubs, historically abundant in some dry forests, may also be reduced by fire at intervals less than about 20–30 years [17]. However, fire-stimulated shrubs in the understory of dry forests may also decline if low-severity fire rates are too low [18]. Insufficient low-severity fire can allow tree density or other understory shrubs to increase, reducing nutrient cycling and understory diversity, and increasing fire severity [16, 19].

Maintenance of tree populations in dry forests also depends on the balance between tree natality and mortality, a balance strongly shaped by rates and patterns of fires. Fire intervals for successful tree regeneration were likely long relative to historical mean intervals, as fires at short intervals can kill most small trees [6]. Patchy surface fires could alone allow survival of small trees in unburned areas [20]. Also, seedlings regenerating in openings may produce limited fuels, enhancing fire patchiness that favors seedling survival [21]. Where fire kills overstory trees, a resulting mineral seedbed and reduced competition with grass can enhance tree regeneration, if other factors (e.g., seed production) co-occur [22]. A fire-quiescent period is also needed [23]. Long intervals may occur over large areas in wet periods, or stochastically from variability in fire. In contrast, mortality of larger trees from single low-severity fires can reach 7–8%; if repeated every 10 years, larger trees could be reduced by half in a century, but, assuming the same 7–8% rate repeated every 50 years, larger trees would be halved in 500 years [17]. Thus, tree populations, both young and old trees, are sensitive to rates and patterns of low-severity fire.

Rates and patterns of low-severity fire also affect how resistant and resilient dry forests are to future fire, drought, and beetle outbreaks [24]. Open, low-density forests relatively free of shrubs and small trees can be produced by repeated low-severity fires, and may be more resistant to subsequent higher-intensity fires than are denser forests, with more shrubs and small trees [25]. Forests subject to repeated low-severity fires could even be self-limiting, if the rate of fires is high, possibly promoting continuing low-severity fire rather than higher-severity fires [26]. However, if a deficiency in tree regeneration occurs because of too-frequent fires, dry forests would be vulnerable to subsequent regeneration lags or failures after droughts and beetle outbreaks that are a higher current risk than are severe fires [24]. Too little low-severity fire could increase fire severity, but too much could reduce higher-severity fires that enhance spatial heterogeneity, a key source of forest resilience to future disturbances [3].

Research has enhanced understanding of the importance of rates and patterns of low-severity fire to biological diversity, ecosystem functioning, and sustainability of dry forests, but estimated historical rates and patterns of low-severity fire remain uncertain. Newer methods for accurately reconstructing rates of historical low-severity fire promise to eventually resolve uncertainty, but improved estimates, the focus here, might be possible from past research.

Measures and estimators of mean rates of low-severity fires

Terms and measures

A *low-severity fire* in this study is a fire that burns in the understory of a forest, and is often defined as causing mortality or topkill of no more than about 20% of stand basal area [27–28]. These fires are not usually burning in the canopy independently, instead torching upwards from surface fuels into single or small groups of trees. These fires could also be called low-moderate severity to reflect some canopy mortality, but the extent of canopy mortality from these fires is poorly known [17].

Several measures of mean rates of fire also need explanation. At a point in a landscape, the average interval between fires is the point *mean fire interval* (point MFI). The average MFI across multiple points in a landscape provides a sample estimate of the *population mean fire interval* (PMFI) for a particular landscape, which is the grand mean fire interval across the landscape [6]. Fire-interval data at points have interval distributions that often are skewed, not normally distributed. Alternative measures of central tendency, such as the median, can characterize these distributions. These distributions often can also be fit by the flexible two- or three-parameter Weibull distribution, which has a shape parameter that describes the form of the distribution (e.g., lognormal), a scale parameter that represents the 63rd percentile of the distribution, and a shift parameter to set the location of the distribution [29]. The mean and median of the fitted Weibull distribution, which can offset unusual values in actual data [29], are useful alternative measures of central tendency. Descriptors of variation (e.g., standard deviation) are relevant for all measures. The *fire rotation* (FR) is the expected time for fire to burn an area equal to the area of a landscape of interest [17]. The FR for a landscape is equivalent to the PMFI, which was shown analytically [6] and through simulation [7–8]. Fire-interval data at points can be used to estimate the PMFI, or area-burned data across a landscape can be used to estimate the FR. PMFI estimates at points and FR estimates across areas are the fundamental, equivalent estimators of mean rates of fire, as they show how often points experience fire and the equivalent time it takes for fire to burn across a landscape.

Estimators of the Population Mean Fire Interval (PMFI)

For reconstructions of mean low-severity fire rates in the pre-EuroAmerican period, which are predominantly derived using tree-ring and fire-scar methods, the actual intervals needed for estimating PMFI can be sampled and processed in several ways. Fires do not physically leave a scar on every tree that burns [30], and the scarring fraction (SF), the fraction of live trees that receive a scar from a fire, may be moderate or even low. The intervals derived from scarred trees are thus simply estimators of the actual fire intervals that occurred at a point.

The most widely used fire-interval estimator is the mean composite fire interval (mean CFI), often also called the mean fire-return interval (MFRI) or even, to confuse matters, the MFI itself, which is not the estimator but instead what is being estimated. This estimator seeks to offset the fact that SF is < 1.0 by compositing scar records across a set of nearby trees, which together are expected to contain a more complete record of fires that burned the point. To calculate mean CFI, the user creates a pooled "composite" list of fire years that burned any tree in a set of sample trees, then the estimated intervals are those between fire years in the composite list. However, this composite list of all fires may contain small spot fires that have little ecological effect, and users often also report estimates for larger fires that scarred more than 10%, 25%, or another percentage of scarred trees. Various measures of central tendency can be calculated, including the mean, median, and Weibull measures. I distinguish variants here using combined terms, such as mean CFI-all fires, mean CFI-10% scarred, or median CFI-25% scarred. Mean CFI-10% scarred, for example, is the mean composite fire interval for fires recorded on $\geq$ 10% of scarred trees.

Another commonly used estimator is the mean individual-tree fire interval (mean ITFI). This estimator is calculated in two steps. First, the intervals between fires on an individual scarred tree are used to estimate the MFI for that tree. Second, the grand mean of each tree's estimated MFI is calculated across a set of sample trees. In this case, restrictions (e.g., 25% scarred) are not used, but alternative measures of central tendency are, so there are fewer variants.

Finally, we developed an estimator, the mean all-tree fire interval (mean ATFI), which seeks to offset SF < 1.0 by using an estimated SF to predict the total number of scars that would have occurred if SF was 1.0 [7–8, 11]. This estimator has been shown to be the best available estimator of PMFI [11], but it is not used in this paper because few ATFI estimates are currently available.

Estimators of the Fire Rotation (FR)

Area-burned estimates for calculating FR can be derived from three main sources: (1) area burned in recent fires from agency polygon fire records or fire-atlas records or from remotely sensed data, (2) historical area burned from fire-year maps reconstructed from scarred-tree or plot locations, or (3) historical area burned reconstructed using a ratio method and scarred-trees or plot records, or comparable data in a table or graph.

Polygon fire records or fire-atlas records are available from public land-management agencies, and are most complete and accurate after about A.D. 1980. Early data are often from fire perimeters sketched on a map, but later data may have been from remotely-sensed data [31]. Small fires were not always mapped. Accuracy of boundaries of fires in fire-atlas data, relative to tree-ring reconstructions and remote-sensing data, was moderately high in one study, sufficiently accurate to use in some research [31]. In another study, tree-ring methods underestimated fire extent relative to fire-atlas maps, which also had some errors [32]. A larger study showed closer agreement between fire-atlas data and tree-ring reconstructions of fires [1].

Fire-year maps are typically reconstructed from tree-ring and fire-scar data collected at a grid of points or a set of random points. Fire scars near the points are dated, dates are displayed on a map or in GIS, and a fire perimeter is placed around the points common to a fire year [33–34]. The boundary is positioned using a set of fire-spread principles [35], Voronoi polygons centered on the points [1], convex hulls [32], fuzzy-set methods [36], inverse-distance weighting [23, 33], or indicator-kriging [33–34]. If grid points are close, unburned area may be most accurately mapped, but a larger grid spacing is often needed to allow sufficient area to be sampled, leading to less precision in boundaries and unburned areas [34]. Smaller fires also will be missed more often with larger grid spacing. Larger fires that contribute most to fire rotation are mapped the best. Fire rotation has been shown to be estimated within about 10% of the value obtained from fire-atlas data [1, 11].

A non-spatial ratio method estimates area burned within a study area as proportional to the percentage of sample trees scarred in a particular fire year or the percentage of plots in which a particular fire year is recorded on sample trees. The equation [37] is:

$$A_i = (AT^* NS_i)/(NST - NRE) \quad (1)$$

where A_i is area burned in year i, AT is the study area size, NS_i is the number of scarred trees or plots recording a fire in year i, NST is the total number of scarred trees or plots, and NRE is the number of scarred trees or plots eliminated by subsequent fires. This method is most accurate when the number of scarred trees or plots is large and these are well distributed across a sample area [1, 37]. However, scarred trees are often clustered [30], which could lead to ratio estimates that are biased and too short. Because the location of scarred trees or plots is not used, unburned area may also be underestimated. In a large modern corroboration study, the ratio method accurately estimated area burned of larger fires (> 100 ha), that accounted for 97% of total area burned, and fire rotation from total plots was 89% of fire rotation from fire-atlas data [1].

FR can be calculated, using any of the three sources of data, by the equation [17]:

$$FR = (ObservationPeriod/FractionBurned) \quad (2)$$

where FR is fire rotation, in years, $ObservationPeriod$ is the period, in years, for which there are mapped or reconstructed records of fire, and $FractionBurned$ is the fraction of the study area estimated to have burned during the observation period, obtained by summing the areas of fires or the estimated fraction burned from ratio estimates.

Perspectives on estimating PMFI/FR and interpreting mean CFI

A central area of analysis and discussion by our research group has been about whether past mean CFI and ITFI estimates from small plots accurately estimate PMFI/FR. Other studies (e.g. [38]) were more focused on reconstructing a long history of dated fire years across a network of locations, not so much accurate rates of fire across landscapes. I continue the rate focus here. An earlier review suggested mean CFI is too short and mean ITFI is too long as an estimator of PMFI/FR [6]. This study suggested mean CFI was often too short from compositing across too much area or samples and mean ITFI was too long, as it does not offset unrecorded fires that occur because SF is < 1.0 [6].

Reflecting a need for rate estimates, some studies mostly used mean CFI as comparable to, or effectively an estimator of FR [39–40]. Others also used historical median CFI as an estimator of historical FR [41]. Another compared estimated median CFI, ITFI, and FR, found median ITFI was closest to FR, and suggested median ITFI might be used to estimate FR in low-severity fire regimes [42]. In contrast, other studies suggested fire scars provide estimates of the PMFI/FR that are generally too long: ". . . our findings clearly demonstrate that analysis of fire scars will likely underestimate past fire occurrence" ([10]:1500). However, when compositing fire-scar records over larger areas and more trees, mean CFI declines toward 1.0, a fire every year [1, 43], an estimate of PMFI/FR that is nearly always too short. Given uncertainty about estimators of low-severity fire rates, some studies suggested that summary statistics, such as mean CFI or FR, should not even be used in restoring and managing low-severity fire (e.g. [44]).

Other studies suggested that multiple descriptors of fire regimes (i.e., including mean CFI) are desirable (e.g. [1]). Studies, that favored mean CFI and ITFI as one of multiple statistics, suggested they must be interpreted correctly. For example, regarding mean CFI-all fires, one study said it was not designed to estimate area burned, and if it does not, that is not a problem in mean CFI, but an error in interpreting it [1]. Other studies also suggested it is a problem if mean CFIs are interpreted as indicating how often the entire stand burned ". . . since fires are quite variable in burn patterns" ([2]:1091). Similarly, other studies suggested managers need to recognize that fires indicated by mean CFI burned in variable spatial and temporal patterns, including unburned areas [45]. A study in California said: ". . . the composite MFIs are not equivalent to average point fire intervals, population means [sic] fire intervals or natural fire rotation. They are an estimation of average intervals between fires of any size, or of an estimated size class, occurring anywhere within a study area" ([46]:52). That mean CFI declines with increasing sampling area is also interpreted by some not as a fundamental flaw [6], but instead as an added descriptor of a fire regime [47–49]. Complex power-function patterns across spatial scales, observed as mean CFI declines toward 1.0 with more samples, are thought in this study to elucidate cross-scale spatial properties of fire regimes. Thus, ". . . measures of fire frequency are area dependent, and . . . fire return intervals cannot be described by a single number independent of spatial scale" ([48]:820). However, scale-dependent values are only known for CFI measures, not other rate measures. In summary, there is now general agreement that mean CFI and its variants (e.g., median CFI) and ITFI are not intended to estimate the PMFI/FR. Mean CFI is accepted to not indicate area burned, the pattern of the fire, or PMFI/FR.

Accurate estimators of the PMFI/FR are still needed. Fortunately, recent modern calibrations have validated new methods for estimating PMFI and FR that do not need to use mean CFI or ITFI and have promising accuracy [1, 11]. However, it may be decades before better estimates from these new methods become sufficiently common to be able to guide restoration and management of low-severity fire. In the meantime, past mean CFI and ITFI plot estimates are abundant, and required large efforts to gather and process. Moreover, plot data on fire history likely will remain a fundamental sampling component of spatial fire histories, and could provide detail about spatial variability in FR and MFI across landscapes. Mean ITFI is less studied; it remains unclear how it might perform as an estimator of PMFI/FR, but it may suffer from the unrecorded fire problem, so that mean ITFI may be too long [6]. Now that there are more spatial estimates of FR, further analysis of the relationships of CFI, ITFI, and PMFI/FR is warranted, to see whether a variant of CFI or ITFI may estimate PMFI/FR.

Materials and methods

I assembled two datasets for analyzing the relationships of CFI, ITFI, and PMFI/FR in dry forests of the western USA (Fig 1) using an analysis of bias and inaccuracy followed by regression analysis. I also recorded and analyzed fire-history sampling measures (e.g., number of samples) and their effects on these relationships.

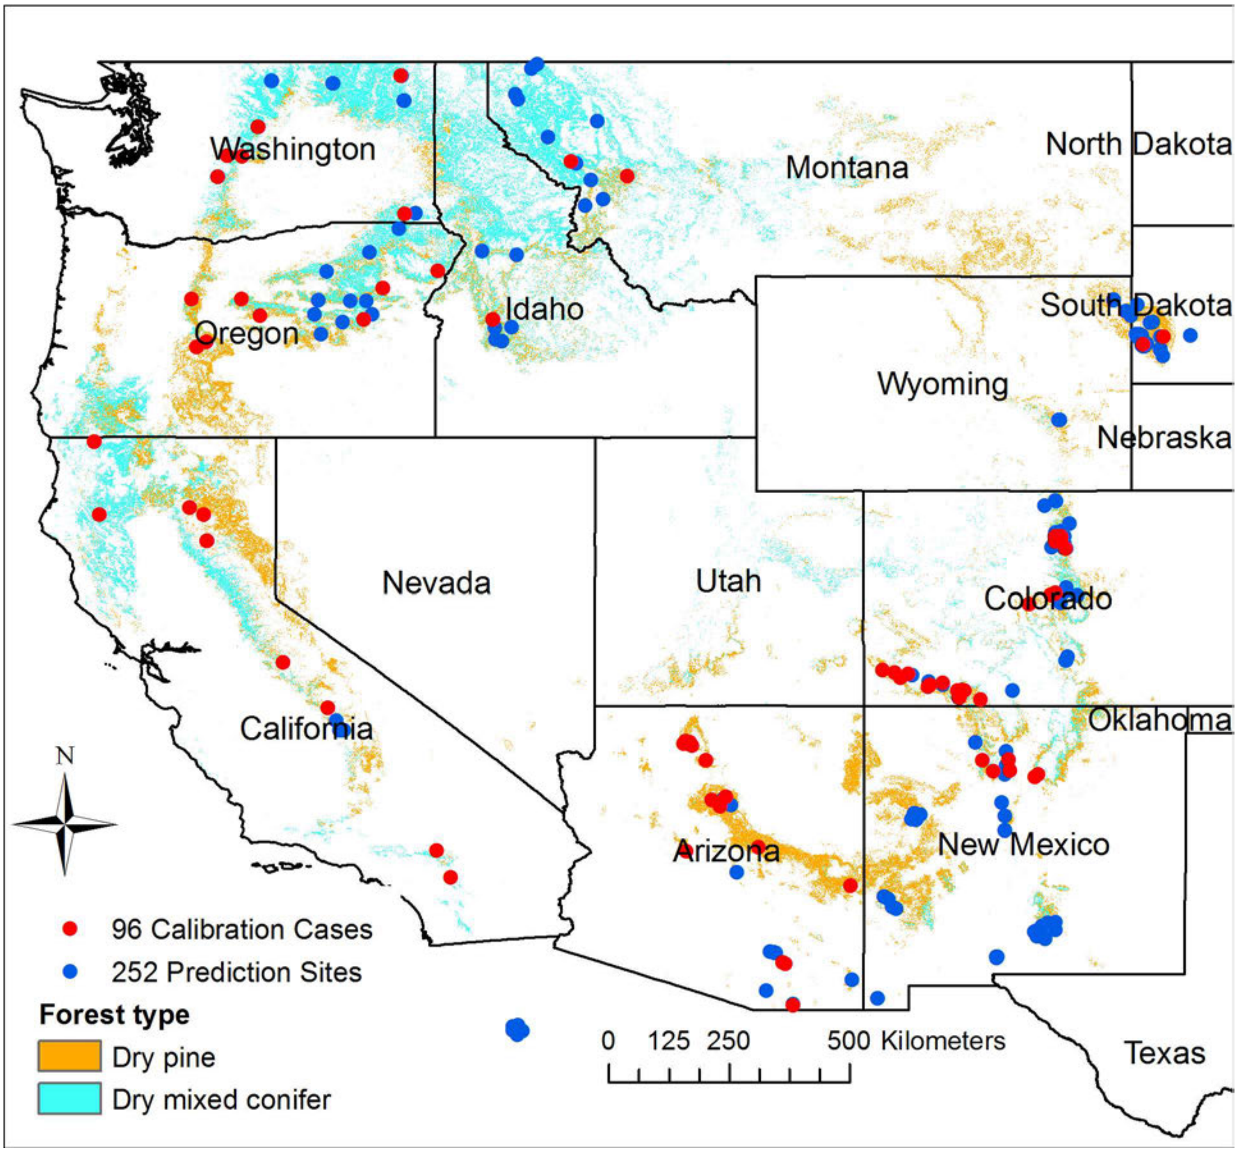

Fig 1. The 96 calibration cases and 252 prediction sites from the International Multiproxy Paleofire Database. Note that multiple plots were often done near one site, thus the number of dots is fewer.

doi:10.1371/journal.pone.0172288.g001

The 252-site fire-history dataset

To obtain a large sample of fire-history sites in dry forests to use to analyze methods and estimators in common use, I searched the International Multiproxy Paleofire Database (IMPD) (https://www.ncdc.noaa.gov/data-access/paleoclimatology-data/datasets/fire-history) for all fire-scar sites between 102˚ and 125˚ west longitude and 30˚ and 60˚ north latitude, finding 436 sites. I excluded 77 sites not clearly in dry pine or dry mixed-conifer forests. Some were also excluded because their FHX file (containing the fire-history data) in the IMPD was not usable (n = 26), the dataset was too small (n = 6) or calculations could not be completed (n = 12). I also removed 63 sites usable in a calibration dataset, described next, which left 252 sites. I left in 9 sites from Mexico and one from Canada that are nearby and relevant to the western USA.

I downloaded from the IMPD an FHX file containing fire-history records for each site and used the Fire History Analysis and Exploration System (FHAES; frames.nbii.gov) Version 2.0.2 [50] to calculate CFI and ITFI estimators. To reduce differences in the period of record, I restricted calculations for all sites to the period extending from the earliest fire to the latest fire within the A.D. 1600–1900 period. The purpose of restricting analysis to fire-to-fire periods is that scar-to-scar fire intervals are traditionally used. I did not want to introduce a possible confounding variable by using an arbitrary period. After restriction, I omitted sites with < 50 years of record, an arbitrary criterion aimed at minimizing short records.

For each case, I also recorded ancillary information, from the original publication reporting the study or from the FHX file, including the sample area, the number of sampled scarred trees, the total number of fire scars across all sampled trees, the analysis years used. and the types of targeted sampling used, including: (1) seeking the best information/longest record, (2) seeking multi-scarred trees, (3) seeking clusters of scarred trees, (4) seeking scars on dead wood, or (5) placing plots or selecting study areas in areas with many scarred trees or in old forests with long records of fire. I also recorded whether fire severity was studied, and I recorded the location of the samples found in the FHX file or publication.

The 96-case calibration and analysis dataset

To analyze the relationship of CFI and ITFI estimators and FR, I searched for and found 44 fire-history studies with 96 fire-history reconstructions and alternative calculations of fire rates in dry forests in which the study: (1) estimated CFIs and/or ITFIs and (2) in areas of at least 80 ha, also estimated FR or provided data sufficient to allow FR to be calculated from data in the paper or in an FHX file (S1 Table). The purpose of this dataset was to analyze whether CFI and ITFI estimators can predict FR. I included all sites from the IMPD, meeting the criteria defined earlier, for which sample area was given and was ≥ 80 ha, and for which there was a usable FHX file. Other sites > 80 ha were included that did not have an FHX file, but were documented in a publication. If area was reported as a range, I used the midpoint. The 80-ha minimum is an arbitrary limit to increase the area used for estimating FR. Analysis periods did not need to be pre-EuroAmerican or identical among sites, but had to have ≥ 50 years of record. If measures were not calculated in the study, I restricted analysis to scar-to-scar intervals, beginning with the first scar after ≥ 10 samples had accumulated, and ending with the last fire.

FR was calculated in the study, or by me if the study did not do this, using the previously-described area-burned estimates: (1) area burned from agency polygon fire records (n = 1) or fire-atlas records (n = 2), (2) estimates of area burned from fire-year maps reconstructed from scarred-tree or plot locations (n = 24), or (3) estimates of area burned from the ratio method and scarred-tree or plot locations (n = 63), or data in a table or graph (n = 6). For published studies, I recorded whether FR was estimated from total number of scarred trees/plots or recorders. In a few cases, this was uncertain and I recorded the most likely. A recorder is a tree scarred at least once, which increases the probability of recording fires [30]. If the study did not estimate FR, I used FHAES and Minitab to estimate FR from fire-history data in the IMPD for sites for which an FHX file was available and usable. I copied the summary table, provided in FHAES for each FHX file, into Minitab 17 [51] to do calculations. I made ratio estimates, and calculated them separately based on both total number of scarred trees and number of recorders. Sites were included more than once if different methods to calculate FR were provided in the study or could be calculated. As in the case of the 252-site dataset, I obtained and recorded ancillary information for each site.

The 342-site merged dataset

To allow calculation of histograms for particular attributes across all the sites, I merged sites in the two datasets. I removed post-EuroAmerican sites from the 96-case calibration dataset, then merged it with the 252-site prediction dataset, yielding a dataset of 342 sites (S2 Table). These include some alternative estimates from the same site or area by different studies or from using different methods, data sources, time periods or with different boundaries or other differences.

I did a rough analysis of whether sampled stands were old forests in the pre-EuroAmerican era. Old-growth dry forests are generally at least 150–200 years old, but also have attributes other than age [52], so here I call forests older than 150–200 years just "old forests." To roughly estimate the age of sampled forest stands, I used the beginning year of analysis for each stand, as defined in the study (first fire year if not). Stands with beginning years before A.D. 1700 were likely generally $\geq$ 200 years old in A.D. 1900, thus would have been old forests in the pre-EuroAmerican era. Although some could have been younger, if the oldest sample trees were not abundant, often the beginning year of analysis was defined by a minimum number of sample trees (e.g. [10]). Although imprecise, this should roughly estimate sampling in old forests. I also reviewed GLO-survey and aerial-photo reconstructions of fire severity to assess the percentage of historical landscapes with a history of predominantly low-severity fire. The GLO reconstructions use a calibrated and validated low-severity fire model [53]. The calibrated model predicts low-severity fire where historical tree density was $<$ 178 trees/ha, percentage of large trees was $>$ 29.2%, and percentage of small trees was $<$ 46.9% [53].

Can CFI and ITFI measures predict PMFI/FR?

The calibration dataset included 21 estimators of the rate of low-severity fires based on CFI, ITFI, and PMFI/FR and three sample-size variables. Sample-size variables included sample area (ha), total number of scarred trees, and scar density, expressed as total scarred trees per 100 ha (e.g. [54]). These variables are included because previous analyses found that CFI estimators were related to sample size [6]. The 21 estimators of the rate of low-severity fires included five measures of central tendency (mean, median, Weibull scale, Weibull mean, and Weibull median) for CFI-all fires, CFI-10% scarred, CFI-25% scarred, ITFI, plus the PMFI/FR based on recorders.

These 21 variables are used to individually predict PMFI/FR based on total scarred trees/plots, not based on recorders, for several reasons. Most of the best available estimates, from fire-year maps and ratio estimates using plots in a grid, are based on fires from total scarred trees in the plot. For ratio estimates from just scarred trees, recorders or all scarred trees each have strengths and limitations (S1 Text), summarized here. The use of all scarred trees is consistent with most plot-scale fire-year estimates. Recorders are two to three times less abundant than single-scarred trees, so area burned is inherently less detailed if only recorders are used, likely generally inflating area burned and shortening the estimated PMFI/FR. However, recorders do have a higher probability, than do unscarred trees, of recording a fire or of documenting it did not burn at a particular point [30]. Recorders are also multi-scarred trees, that inherently omit unscarred and single-scarred trees, that can indicate where fires did not burn, also inflating area burned and shortening PMFI/FR. PMFI/FR estimates from targeted trees (typically multi-scarred) were reduced to about 86–95% of estimates from equal-size probabilistic samples [55], supporting this expected effect. Also, about 1/3 of fires may be missed if only recorders are used [S1 Text]. More research is needed on using unscarred trees, single-scarred trees, recorders ($\geq$ 2 scars), or all scarred trees to estimate area burned, but all scarred trees likely provide the best estimates.

To understand the direction and magnitude of differences between the 21 estimators and the PMFI/FR, I calculated bias and inaccuracy for the 21 estimators relative to PMFI/FR-total scarred trees/plots for the calibration dataset. Bias is quantified by relative mean error (RME):

$$RME = \sum_{i=1}^{n} [(M_i - FR_i)/FR_i]/n \tag{3}$$

where M_i is value i of n total available estimates for CFI or ITFI estimator M of the 21 estimators and FR_i is the corresponding estimate of PMFI/FR-total scarred trees/plots [56]. RME measures relative bias as sample sizes differ. I also calculated the standard error of each mean and tested the null hypothesis that mean bias is zero using a one-sample *t*-test in Minitab 17 [51]. Inaccuracy or error was also calculated using a relative measure, relative mean absolute error (RMAE):

$$RMAE = \sum_{i=1}^{n} [|(M_i - FR_i)|/FR_i]/n \tag{4}$$

where symbols are as above. This quantifies the difference or error between the 21 estimators versus PMFI/FR-total scarred trees/plots as a percentage of this PMFI/FR estimate [56]. I also calculated the standard error of each mean and then tested the null hypothesis that mean inaccuracy is zero using a one-sample *t*-test in Minitab 17 [51].

Can bias and inaccuracy be overcome by adjusting estimators using regression models? Scatter plots showed that PMFI/FR-total scarred trees/plots versus CFI and ITFI estimators were generally linear (e.g., Fig 2A), thus I fit linear regression models, using the lm function in R version 3.2.3 [57], to predict PMFI/FR-total scarred trees/plots from each of the 21 estimators. Sample size differed among the regressions, because individual estimators were not available for all 96 cases. After initial fitting, for each measure I removed 1–2 outliers with the largest studentized residuals (i.e., > 3.0). After refitting, I examined a plot of residuals versus fitted and a normal probability plot to identify trends in residuals, which were lacking for all models.

To estimate prediction error, which is useful itself but also provides a model-selection criterion, I completed a 10-fold cross-validation using the cv.lm function in the DAAG package in R. The output is the mean square error (MSE) of predicted estimates, and its square root is the root mean square error (RMSE), a prediction analog of the standard error of the estimate in fitted regression equations. Prediction error from cross-validation is asymptotically equivalent to Akaike's information criterion (AIC), a commonly applied model-selection criterion [58], but low prediction error is most germane for this application.

Do sample-size variables improve these models? To test this, I redid the regressions with three sample-size predictors (sample area, total scarred trees, scarred trees/100 ha) in addition to each of the 21 estimators in the previous models. This time I used best-subset regression in Minitab 17 [51], and the best predictor models were chosen by the lowest Mallow's C_p statistic, where each included variable also had to be significantly ($\alpha = 0.05$) related to FR-total scarred trees/plots. I again removed 1–2 outliers based on studentized residuals and examined histograms of residuals and normal probability plots, but found no trends in residuals.

Results

Bias, inaccuracy, and regression models to estimate PMFI/FR

Bias was significantly different from 0.0 for all estimators except mean ITFI and inaccuracy was significantly different from 0.0 for all estimators (Table 1). Mean RMEs of -69% to -75% for CFI-all fires, -60% to -69% for CFI-10% scarred, and -38% to -49% for CFI-25% scarred estimators, combined with low standard errors, show that CFI measures all lead to estimates of PMFI/FR that are consistently too short (Table 1). Bias diminished from CFI-all to CFI-25%, but all estimators, except mean ITFI, were still biased. Inaccuracy for CFIs had similar

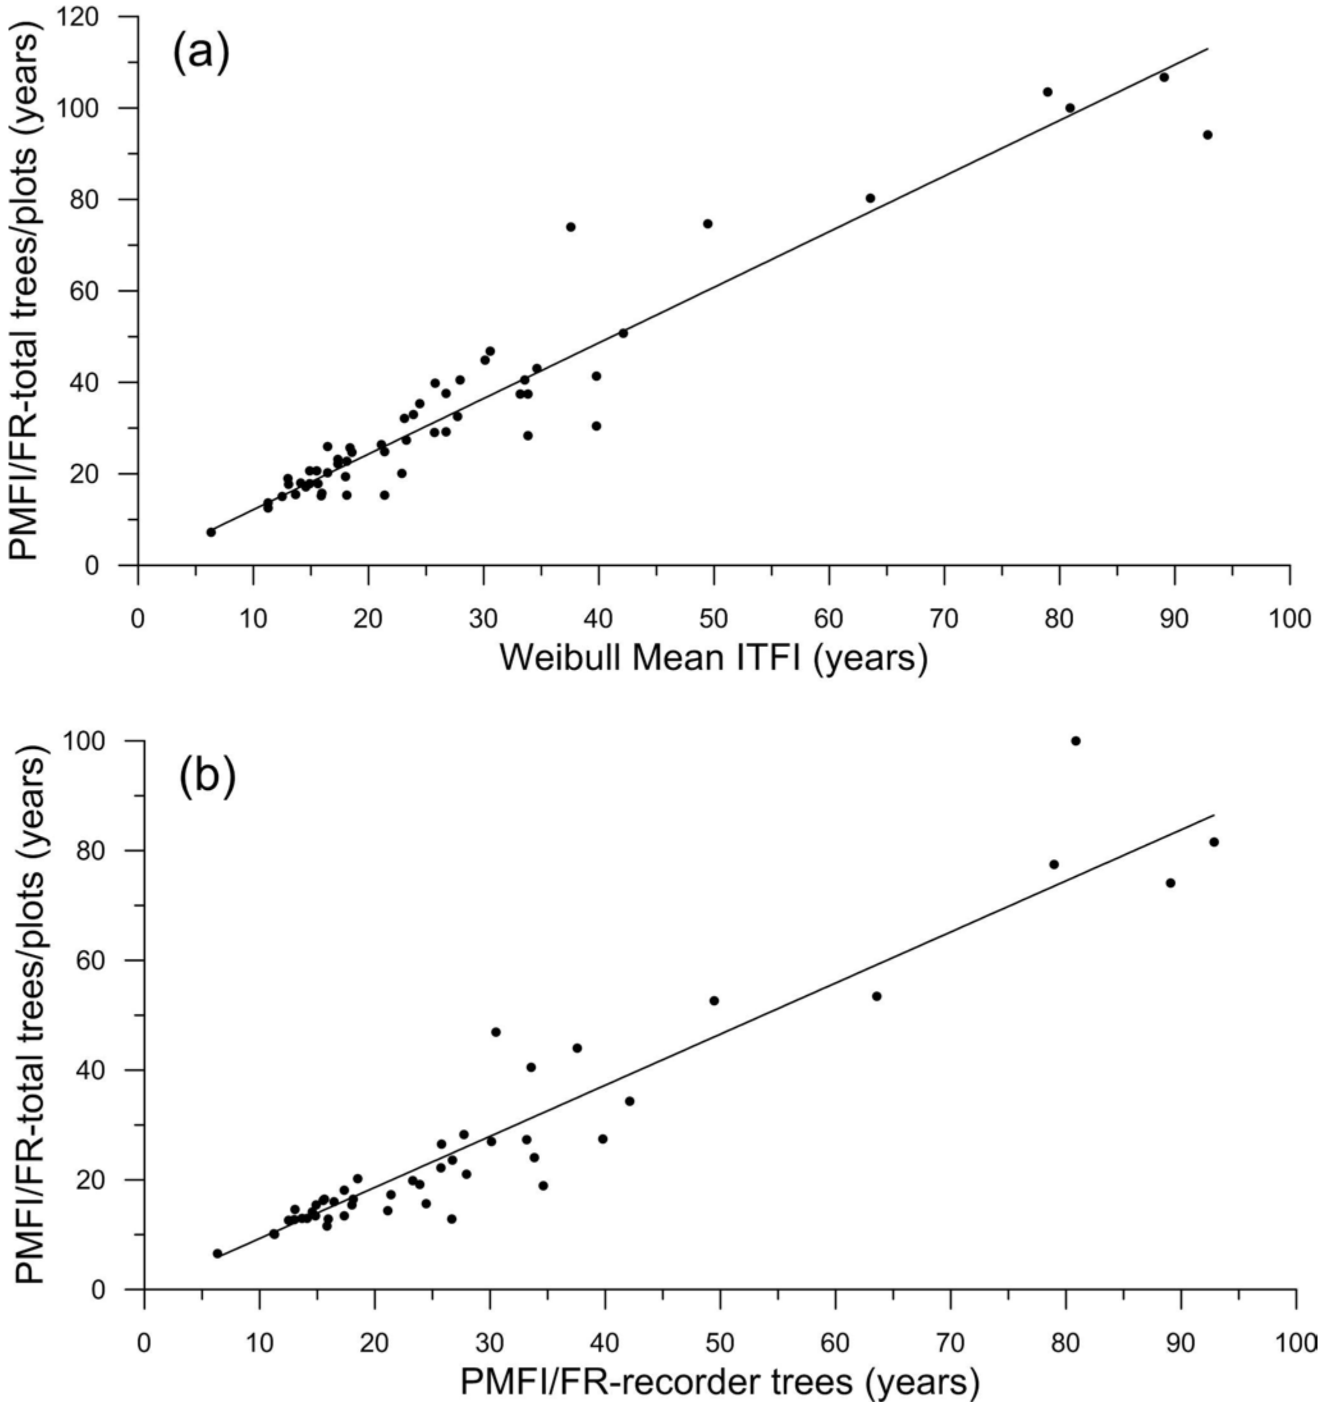

Fig 2. Scatterplots showing the linear relationships between: (a) Weibull mean ITFI and fire rotation-total trees/plots, and (b) Fire rotation-total trees/plots and fire rotation-recorder trees.

doi:10.1371/journal.pone.0172288.g002

magnitudes, patterns, and trends, with the best still having inaccuracies of 40–50%. ITFI estimators had lower bias and inaccuracy than CFI measures, with bias ranging from -3 to -30% and inaccuracy ranging from 16–33%. Only mean ITFI was unbiased, but still had 30% inaccuracy. FR-recorders also produced significantly biased and inaccurate estimates of FR, averaging 27% too low.

Table 1. Bias and inaccuracy in composite fire interval (CFI) and individual-tree fire interval (ITFI) estimates if used to estimate fire rotation-total trees/plots within the 96-case calibration dataset.

Measure	Test of bias					Test of inaccuracy			
	n	Mean RME (%)	s.e. of mean (%)	t	p	Mean RMAE (%)	s.e. of mean (%)	t	p

doi:10.1371/journal.pone.0172288.t001

Prediction error and fit show that the best regression models to predict PMFI/FR-total scarred trees/plots (Table 2) were from ITFI estimators, particularly Weibull mean ITFI (RMSE = 7.52, R^2_{adj} = 0.972), Weibull scale ITFI (RMSE = 8.04, R^2_{adj} = 0.970), and Weibull median ITFI (RMSE = 9.46, R^2_{adj} = 0.958), although the mean ITFI model was also good (RMSE = 10.30, R^2_{adj} = 0.944). Models based on CFI-25% scarred measures had moderately low prediction errors (RMSE from 11.0–13.7) and high R^2_{adj} values of 0.870–0.929. Models using CFI-10% had higher prediction errors and somewhat lower fit (Table 2). The poorest models were from CFI-all measures (Table 2). Weibull mean models consistently had lowest prediction errors and highest R^2_{adj} compared to models based on mean, median, Weibull scale, or Weibull median (Table 2).

Sample-size variables were not significant in most models (Table 3). The few models with significant sample-size variables had R^2_{adj} values generally improved only slightly, averaging higher by only 0.006–0.010 except for the model for mean CFI-all fires, which was 0.086 higher (Tables 2 and 3). Thus, simpler models in Table 2 should suffice for estimating PMFI and FR, except that the sample-size model may be worth using in the case of mean CFI-all fires (Table 3).

Using prediction error (RMSE) as the criterion, supplemented by fit (R^2_{adj}), the best model (Table 2) is based on Weibull mean ITFI, which had the lowest RMSE of 7.52 years and the highest R^2_{adj} of 0.972 (Table 2). The Weibull mean ITFI model was thus used for all PMFI/FR estimation for the 252-site dataset. Given its 7.52 year RMSE, 15–20 year bins are appropriate for reporting estimates, as about 68% of predictions are expected to be within the ± 1 RMSE of 7.52 years. Models other than the Weibull mean ITFI model (Tables 2 and 3) can also be used for deriving estimates from CFI and ITFI estimates, assuming prediction error and fit are acceptable.

Estimated historical PMFI/FRs across the 342-site dataset

Overall, estimated historical PMFI/FR across the 342 sites had a mean of about 39 years and a median of about 30 years (Table 4). Mean PMFI/FR did not differ significantly between dry pine forests and dry mixed-conifer forests (Table 4; $t\,(181) = -0.34$, $p = 0.731$). Maps and histograms show that shorter historical PMFI/FRs (< 25 years) were concentrated in Arizona and New Mexico, but also were scattered across parts of all other states, except for few in South Dakota, Wyoming, Colorado, and Mexico (Figs 3 and 4). Historically long PMFI/FR (> 55 years), in contrast, were common only in a band from northern New Mexico to western South

Dakota, and were otherwise only scattered in a few locations in California, Oregon and Washington, with no occurrences in Idaho and Montana (Figs 3 and 4). Variability in historical PMFI/FRs was substantial but generally modest within a state, with coefficients of variation (CV) typically between about 30–60%, although California had a high CV and Arizona had a low CV (Table 5). Minima were typically 7–15 years except 20–30 years in South Dakota, Wyoming, and Mexico. Maxima were not very indicative, as a few long PMFI/FR were not uncommon (Fig 4). However, the 3rd quartile of about 93 years in Colorado, 56 years in Wyoming, and 50 years in South Dakota suggests that long historical PMFI/FRs were common in the southern Rocky Mountains and Black Hills (Table 5, Fig 3). At the state level, Colorado stands out in having the greatest variability and total range in historical PMFI/FRs (Fig 4I), and Arizona stands out as having the lowest variability and total range (Fig 4A).

Another pattern is that in the most mountainous areas with the steepest environmental gradients and topographic diversity, the full range (all four classes) in historical PMFI/FRs often was found in a small area (Fig 3). This high diversity occurred in northeastern Washington, the central Sierra Nevada, northern New Mexico, southwestern Colorado, north-central Colorado, and in western South Dakota, but not in Arizona, Idaho, Montana, or Oregon (Fig 3). However, even in these areas, with the exception of Arizona, some diversity in historical PMFI/FR was found over relatively short distances (Fig 3), suggesting the importance of local factors in addition to the large trends evident across the western USA.

Most studies of low-severity fire in dry western forests were conducted in forest stands that were mostly old forests in the pre-EuroAmerican era (Fig 5). Stands with beginning analysis years before A.D. 1750 were likely generally ≥ 150 years old, and stands with beginning analysis years before A.D. 1700 were likely generally ≥ 200 years old, in A.D. 1900, thus meeting the age criterion for old-growth forests (Fig 5). A history of predominantly low-severity fire in the century before the late-1800s was found across about 34%, on average (ranging from 2.5–62.4%), of eleven dry-forest landscapes across the western USA (Table 6). Thus, estimated historical PMFI/FRs apply primarily to old forests, which were likely concentrated historically in the 34% of overall dry-forest landscapes with a history of predominantly low-severity fire.

Discussion

Limitations of CFIs and ITFIs if used to estimate PMFI/FR

Researchers in the past commonly sampled fire scars and trees to generally increase the length of the fire-history record, minimize physical damage to trees, and maximize efficiency [55]. Unfortunately, these methods also produced CFI and ITFI estimates that are biased and

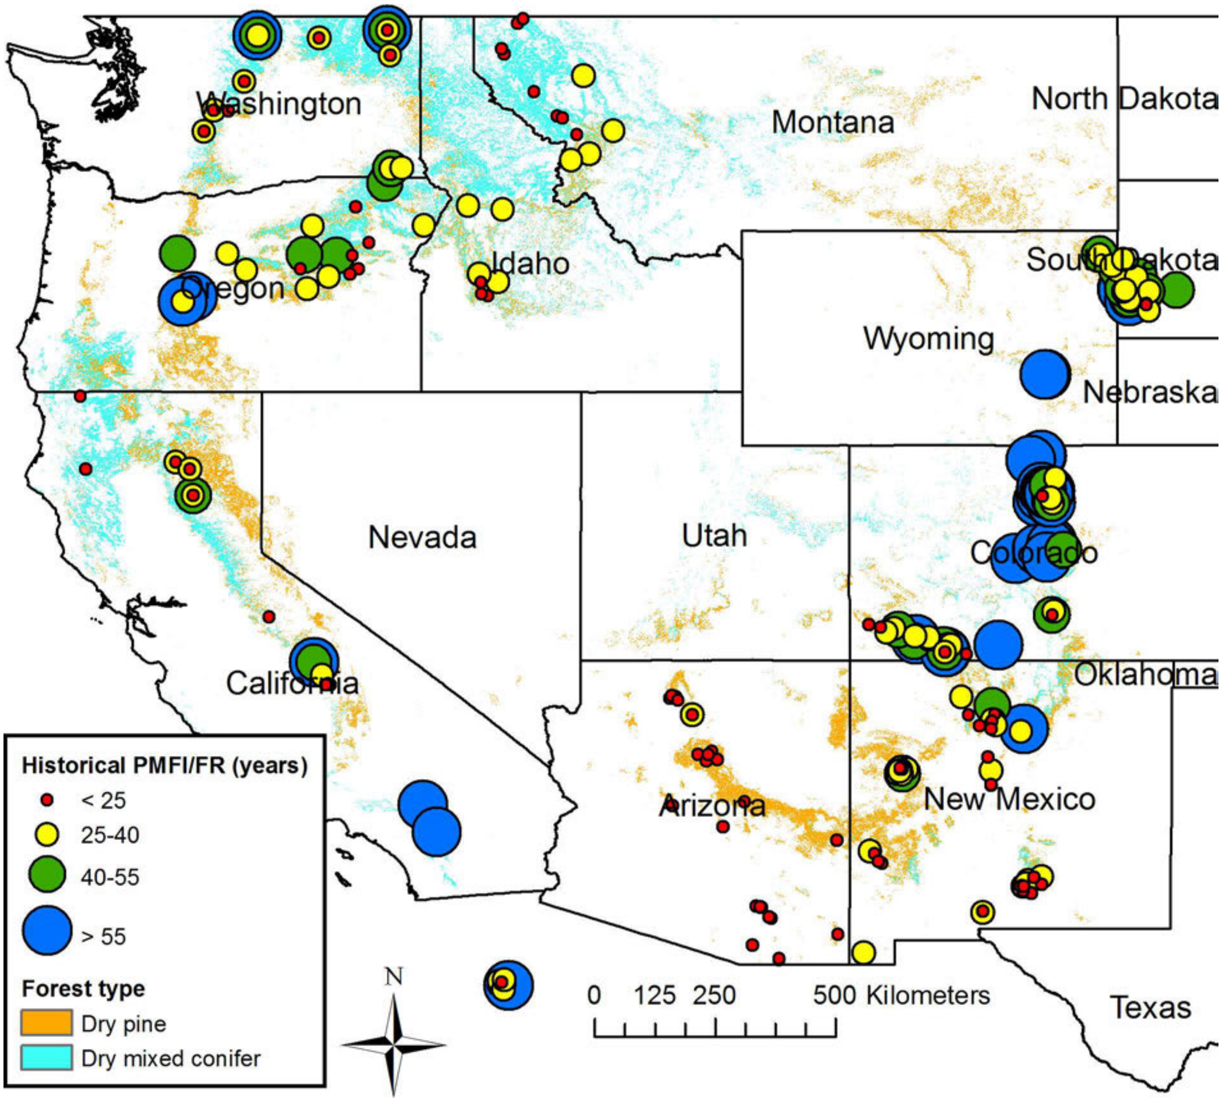

Fig 3. Estimated historical low-severity population mean fire interval/fire rotation (PMFI/FR) for the combined set (n = 342) of calibration cases and prediction sites in dry forests of the western USA.

doi:10.1371/journal.pone.0172288.g003

inaccurate if used to estimate the PMFI/FR (Table 1), as also found from modern calibration [11], and this is now accepted to be an inappropriate use. However, it is possible to estimate PMFI/FR accurately from past CFI and ITFI estimates using linear regression (Table 2).

Further discussion of the limitations of past measures as estimators of the PMFI/FR is thus generally moot, but for those interested, I include further analysis in S1 Text and a summary here. The main factors unique to underestimation of PMFI/FR by CFI measures likely include: (1) overcompensation—sampling and compositing across too large an area, (2) loss of long real fire intervals to the compositing process, and (3) restriction rules that do not omit enough small fires. ITFI measures do not use compositing and have lower bias and inaccuracy, but still are biased and inaccurate (Table 1). Both CFI and ITFI measures must be missing longer intervals from a sampling bias, because their estimates are low relative to PMFI/FR. Major factors likely are targeting trees and sampling areas with the most scars, excluding trees with no or one scar, and censoring intervals at the beginning and end of a tree's record (S1 Text).

Fig 4. Histograms showing the variability in historical PMFI/FRs (342 sites). These are shown among: (a-i) the eleven western states and (j) overall. In (j) the numbers above the bars indicate the percentage of the distribution that exceeds the lower limit of each bin. For example, 59% of the distribution had historical PMFI/FR > 25 years. Idaho and Montana were combined, as were South Dakota and Wyoming, because of insufficient samples and similarity of histograms within these pairs of adjoining states. Colors indicate similar histograms, with the shortest historical PMFI/FRs predominating in Arizona, New Mexico, and Idaho-Montana, intermediate in Washington, California, Oregon, and Mexico, and the longest in South Dakota-Wyoming and Colorado.

doi:10.1371/journal.pone.0172288.g004

Targeting can also reduce estimated PMFI/FR itself (S1 Text), and needs to be avoided in new landscape methods.

Inference space for the PMFI/FR estimates

Studies of new probabilistic landscape methods for reconstructing PMFI/FR encourage ". . . clearly defining the inference space, not extrapolating to unrepresentative areas . . ." ([55]:1030), and this is also important for estimates of PMFI/FR from regression. The dataset of 342 sites spans dry forests in the western USA (Fig 1). The set of published studies corresponding to this dataset (S2 Table) includes many of the studies of low-severity fire in dry forests in the western USA, but other studies exist. This dataset and these other studies likely are not a probabilistic sample of historical dry forests, however, as many studies targeted old forests or forests with concentrations of fire scars (S1 Text) and occurred in forests that likely were old in the pre-EuroAmerican era (Fig 5). Old trees were historically dominant in some dry-forest landscapes and old trees were not uncommon in many forests, but young to middle-aged forests historically dominated most dry-forest landscapes [24, 62, 63]. Based on the GLO reconstructions and early aerial photographs (Table 6), the PMFI/FR estimates here apply most clearly to no more than about 34% of dry-forest landscapes, particularly in old forests. That leaves about 66% of dry-forest landscapes without PMFI/FR estimates. It is possible that some estimates do apply to parts of these other forests, possibly representing the low-severity parts of mixed-severity fire regimes on sites that had not recently burned at high severity. However, it is impossible to determine this from data in FHX files or for the 74% of studies that did not reconstruct fire severity (S1 Text).

Several studies, that targeted old forests to obtain long fire records, indicated that younger forests had few fire scars and, because these studies were focused on long and complete records of fire years, they avoided sampling younger stands. In El Malpais, New Mexico: "The most abundant, best preserved fire-scarred samples were found at sites on the northwestern and western peripheries of the malpais . . . We found no fire-scarred samples on the kipukas in the northern and eastern portions of the malpais, and found few samples in the southern portions. These areas contained ponderosa forests that appeared younger than elsewhere, perhaps due to more recent, intense stand-replacing fires . . ." ([64]:136). Sampling was concentrated in

areas with abundant fire-scars, but later this targeting was forgotten, and these areas were portrayed as representing the whole El Malpais landscape: "These increased fuel loadings in malpais forests have essentially changed the trajectory of fire behavior to one that now favors the occurrence of high-intensity, stand-replacing fires in contrast to the low-intensity, stand-maintenance fires that occurred prior to Euro-American settlement . . ." ([64]:234). Similarly, no fire scars were found in 5 of 12 transect locations in mixed-conifer forests in northern New Mexico [65]. The study sampled scars on relatively flat ridges nearby, where scars were abundant, and composite fire intervals from these sites were assumed to apply to the whole mixed-

conifer forest [65]. This was also the pattern in northern Colorado: "Most of the 67 fire-scarred trees that were sampled were found on ridges or in open areas (Fig 1). It was uncommon to find scarred trees in dense stands" ([66]:138).

These observations suggest low-severity fire was likely less frequent or even rare in younger and denser historical dry forests, that likely were common in the 66% of dry forests lacking a history of exclusive low-severity fire (Table 6). However, specific studies of rates of low-severity fire are lacking for stands $\leq$ 150–200 years old in the pre-EuroAmerican era (Fig 5), that are the predominant forests today. Because they are not in the inference space for past fire-history studies in dry forests, it is not valid to infer that today's young to middle-aged forests would have been subject to low-severity fires at the historical mean rates in the 342-site dataset or in other comparable published fire-histories for dry forests.

Historical dry forests not predominantly frequent-fire forests

Dry pine and dry mixed-conifer forests have been described as frequent-fire forests, an attribute still supported for only about 14% of overall dry-forest area, with multidecadal low-severity fire likely historically over about 86% of overall dry-forest area in the western USA. Only about 41% of the old, dry forests, which were likely concentrated in about 34% of western USA dry forests (41% of 34% = 14% of overall dry forest), had frequent fire, with a historical PMFI/FR $<$ 25 years (Fig 4J). Old forests with frequent fire were historically concentrated in Arizona and found at scattered sites across the West (Fig 3), particularly in New Mexico, Washington, Idaho, Montana, and California (Fig 4A–4E). In contrast, about 59% of cases in old forests and thus about 20% of dry forests in the western USA (59% of 34% = 20% of overall dry forest) had a historical mean PMFI/FR $\geq$ 25 years (Fig 4J). Low-severity fire was likely even less frequent in the remaining overall 66% of dry-forest landscapes lacking a history of exclusive low-severity fire (Table 6). Altogether roughly 14% of dry forests in the western USA historically had frequent (PMFI/FR $<$ 25 years) low-severity fire and 86% of dry forests in the western USA historically instead had multidecadal low-severity fire.

Even in the 34% of dry-forest landscapes with an exclusive history of low-severity fire, the overall mean PMFI/FR was 39 years, half the cases had PMFI/FR $>$ 30 years, and a quarter of cases had PMFI/FR $>$ 46 years (Table 4). These old forests are better described overall as having diverse rates of low-severity fire, spanning the range from frequent to multidecadal. This diversity in rates varied on two scales, first across large regions from predominantly multidecadal (median $>$ 40 years), in Colorado, South Dakota, and Wyoming, to predominantly frequent in Arizona, New Mexico, and Idaho-Montana, with other states having broader mixtures, ranging from frequent to multidecadal (Figs 3 and 4). Second, individual smaller areas often contained a diversity of rates over short distances, particularly in mountain ranges, often spanning or nearly spanning a broad range from frequent to multidecadal (Fig 3).

Estimated historical PMFI/FR mean rates are relevant, because many ecological processes and structures change across a narrow range in rates. In the roughly 86% forests with PMFI/FR $\geq$ 25 years, fuels that required about 7–25 years to build back up after a low-severity fire [12–14]. would, on average, have been fully recovered for an extended period before the next fire. Shrubs would likely have been able to fully recover and dominate for substantial periods. Small trees that rely on seed (e.g., ponderosa pine) would also have been able to regenerate and become common in forest understories, as documented in several historical dry forests [24]. The role of the forest floor in replenishing soil nutrients and organic matter, enhancing absorption of water, and fostering microbial communities [15] would not have been limited by too-frequent fires. Greater opportunities for trees to regenerate and less mortality from low-severity fire also help to explain dense areas of dry forests that occurred historically across substantial parts of many dry-forest landscapes (e.g. [53, 59]). Natural fuels, less limited by low-severity fire, would have favored higher-severity fires via ladder fuels. Adverse effects on habitat for wildlife that use snags or coarse down wood [15] would be less because of less low-severity fire, and fires of higher intensity would likely increase snags and coarse dead wood.

In contrast, in the roughly 14% of historical dry forests with historical PMFI/FR < 25 years, levels of fuels, including shrubs and small trees, would have been more consistently kept low (Fig 3). Frequent low-severity fires would likely have fostered a diversity of grasses and forbs, but would have limited shrubs and small trees. In these settings, lower-density forests would have been favored and higher-severity fires would have been discouraged, at least by fuel conditions [19, 53]. Potential adverse ecosystem and wildlife effects of frequent low-severity fire [15] would remain a natural historical characteristic of these primarily southwestern frequent-fire forests (Fig 3). However, high local and regional diversity in rates (Fig 3) meant that a diversity of processes, rates, and structures occurred across even the old-forest part of many dry-forest landscapes, within both small areas and across the western USA.

Limitations and error in calibration and prediction PMFI/FRs

The calibration cases (S1 Table) are from larger land areas and include estimates of PMFI/FR that are directly usable as a guide for restoration and management in old, dry forests. The appropriate estimate in S1 Table is FR-YrsTot, which was directly estimated in the study in many cases. Where a direct estimate was not made, I estimated PMFI/FR-YrsTot from PMFI/FR-YrsRec using the equation in Table 2 and Fig 2B.

The 252 prediction cases (part of S2 Table) are from single-plot samples in smaller plot areas, and likely have more error. The estimated prediction error for PMFI/FR in a small plot was a 7.52 year RMSE, which suggests bins about 15-years wide, as in Fig 3, would likely contain about 68% of observations. Bins about 30-years wide would contain about 95% of observations. Smaller plots used at the 252 sites also may not individually provide an adequate sample of a forest area. In an accuracy study, estimates from small plots required averaging across 5–6 plots representing 600–1000 ha to achieve mean relative errors $< 30\%$ in estimating PMFI/FR [11]. The estimated PMFI/FRs from the available set of small plots cannot be pooled to decrease this error, as they are not necessarily samples from one population. The problem for small plots is inherent stochastic variability in realized fire intervals, even from a fixed fire regime in a particular land area [67], and errors in the sample and estimators. Thus, the PMFI/FR estimates are a significant improvement over using CFI and ITFI, but greater accuracy can be expected from larger studies in the calibration dataset and also from future landscape-scale reconstructions.

Most of the 342 estimates are likely low estimates for two reasons. Targeting multi-scarred trees reduces CFI and ITFI estimates, but also reduces estimated PMFI/FR by not sampling trees with one scar or no scar that can indicate areas that did not burn in a particular fire (S1 Text). Thus, the area burned by each fire may be inflated and the PMFI/FR too short. Because 94% of 250 cases with evidence did target multi-scarred trees (Table A in S1 Text), this affects almost all estimates of PMFI/FR. Targeted sampling of individual trees led to PMFI/FR estimates reduced to about 86–95% of estimates from equal-sized probabilistic samples [55]. This would mean that PMFI/FR estimates here need to be multiplied by 1.05–1.18. Also, both calibration and prediction PMFI/FR estimates are low estimates in many cases because PMFI/FR could not be estimated separately for low-severity fires in the 74% of cases where fire-severity was not studied. Even where fire severity was studied, the study did not report separate rates, instead only rates for fire severities combined (S1 Text). Because estimates are for old forests with a history of low-severity fire, the higher-severity component was likely not large, but could affect longer estimates (Table B in S1 Text). Combining these two factors likely would increase estimated PMFI/FR, but more research is needed to narrow and validate the needed corrections before they are applied. In contrast, FR estimates in the calibration are from all trees, not recorders, and regression equations applied to the predicted dataset are from all trees. Estimates from recorders would be lower, but I explained earlier why the truth is likely closer to FR-all trees. Further research is warranted, and could possibly resolve all remaining uncertainties, leading to improved equations and estimates.

PMFI/FRs as a guide to restore and manage low-severity fires

In spite of these limitations, these new PMFI/FR estimates are the best available and usable estimates of historical mean rates of low-severity fire to use as a guide in restoring and managing low-severity fire in dry forests of the western USA. Past CFI and ITFI estimates were not intended to estimate PMFI/FR and would be misapplied, with adverse impacts on biological diversity and ecosystem functioning, if used directly for this purpose, as is shown by their biases, inaccuracies, and needed adjustments using regressions (Tables 1, 2).

Estimated historical PMFI/FRs specify how long, on average, it took to burn across a land area (the FR), and how long the intervals were, on average, between fires at points in the land area (the PMFI). They can be estimated at multiple scales, from small plots to large land areas, although with greater accuracy over larger land areas. Congruent estimates of modern and historical low-severity PMFI/FR can be made, and directly compared. Modern estimates can be made using digital fire maps (e.g., Monitoring Trends in Burn Severity at: http://www.mtbs.gov) or other sources. All that is needed is to add up the areas of fires that burned in a particular landscape of interest at low severity over a particular period, calculate the area of the landscape, and use Eq 2. Temporal and spatial variability in PMFI/FR can be estimated as well, using subareas or sub-periods (e.g. [23]). Comparison of modern and historical rates of low-severity fire facilitates monitoring the effectiveness of restoration and management programs, and analysis of trends in rates of modern relative to historical fires [3].

Fire-size distributions are also important, but those from small plots have inherently limited value. At this point, distributions of annual area burned, which approximate fire sizes, can be shown for some larger study areas in dry forests (Fig 6). I compiled data for these histograms from graphs or tables in the sources. Note that this is area burned at all severities, not just low severity, and is not restricted to old-forest parts of landscapes. Several graphs show that the most fire years were in the smallest size class, with decreasing abundance in larger size classes. Historical fire sizes could reach at times into the 5,000–11,000 ha size classes, at least in three study areas (Fig 6C, 6F and 6G). In many study areas, the maximum area burned reached the size of the study area (Fig 6B, 6C, 6D, 6E and 6F), suggesting fires could have been larger.

In an Arizona dry-forest landscape, 5.1% of total fires, that were the largest fires, contributed 97% of total burned area [1]. This pattern, common in forests [17], also suggests that in dry forests most of the burned area is from infrequent large fires, with frequent small fires not adding much to total burned area. This pattern of variable fire sizes and infrequent large fires is important to mimic, as it fosters diverse times since fire, at any instant, across a landscape, which allows species with different responses to fire to all remain viable across landscapes [16].

Low-severity fires can kill up to about 20% of basal area [27–28], and it is usually expected that this mortality is from torching or passive crown fires that kill individual trees or small groups of trees. However, little is known about the size and distribution of patches of mortality in low-severity fire regimes. Only about 23% of reconstructions of low-severity fires analyzed fire severity and even these provided little information about this topic (S1 Text), as it is difficult to reconstruct the size of mortality patches. Early historical observations provide some

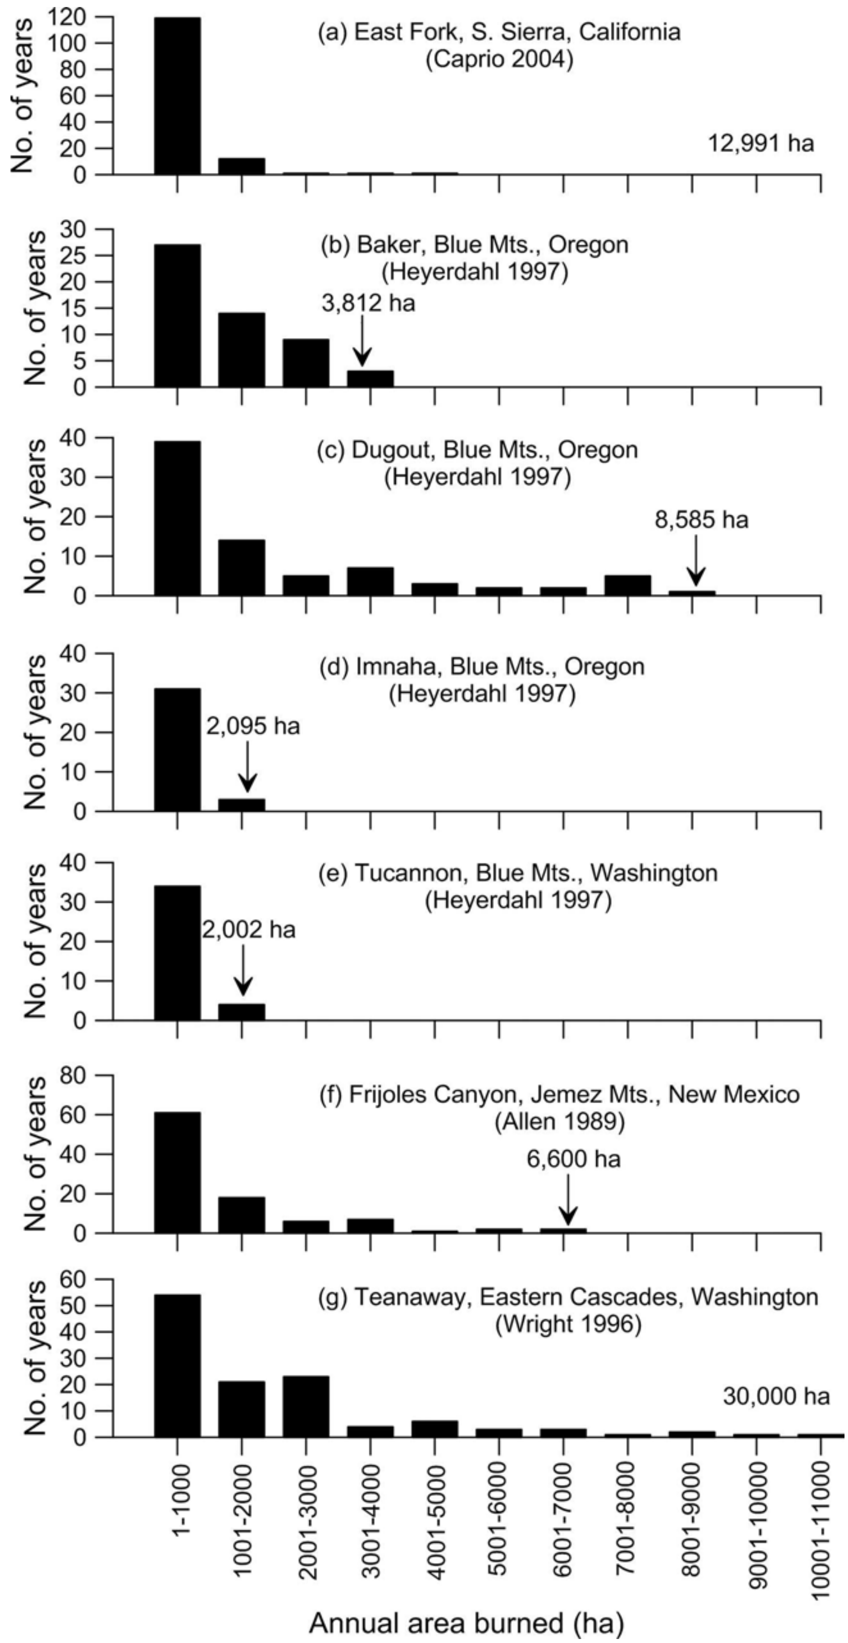

Fig 6. Size distribution for historical annual area burned in seven large study areas in dry forests of the western USA. Study area size is given above arrows or at the right of the x-axis.

doi:10.1371/journal.pone.0172288.g006

evidence. For example, generally low-severity fires in Sierran mixed conifer forests were observed to also have about 15% high-severity fire in small patches [20]. Small high-severity patches from low-severity fires in these forests were described [68] as mostly < 2–4 ha ([61]: Table A1 Q18-Q25). More research is needed on early historical observations of canopy mortality from low-severity fires, but some is historically congruent and expected from low-severity fires in modern forests.

Unburned areas within the perimeters of fires are also important for biological diversity and natural recovery, as these areas serve as refugia for less fire-tolerant plants or those that regenerate by seed, facilitating survival in these areas and natural recovery within the burned area [69]. This study found 35% average unburned area inside 154 modern fire perimeters in Yosemite National Park, California, which included substantial dry-forest area. Unfortunately, little is known about the extent of unburned area in historical low-severity fires in dry forests. It is known that prescribed burning that fully blackens burn units can reduce spatial heterogeneity in fire that promotes coexistence of multiple species [16]. Also, as reviewed in the introduction, unburned areas historically were locations where tree regeneration to replace tree mortality could survive. Thus, including unburned area within burn units, rather than blackening the whole unit, is ecologically important to restore and maintain tree populations and biological diversity.

The extent of needed burning to restore and manage old dry forests and the rest of dry forests is lower than previously thought. Earlier estimates were largely based on the assumption that reported mean CFI estimates represent PMFI/FR, which they do not (Tables 1, 2) and apply to all dry forests, which they also do not. Estimated historical rates of low-severity fire in dry forests in the U.S. Landfire program, for example, typically incorrectly use reported mean CFI estimates as though they represent PMFI/FR, although some actual PMFI/FR estimates are also used. These are applied to all dry forests, not just old forests. Both misapplications likely have adverse effects on biological diversity and ecosystem functioning. Prescribed burning in U.S. national forests, national parks, and on other public lands, where Landfire or other estimates from mean CFIs have been used as a guide, is likely too much by 1.6–3.3 times, depending on the CFI measure used (See *ß* inTable 2) in the roughly 14% of dry-forest area that was historically old forest with frequent fire (PMFI/FR < 25 years). Mean rates are likely too high by > 1.6–3.3 times in the 86% of the area of dry-forest landscapes that historically had multidecadal low-severity fire.

A need for less low-severity fire in restoration and management of dry forests is good news, because costs of prescribed burning and other restoration treatments are high, effects on invasive species, ecosystem processes, and biological diversity are a concern [15, 70], and the feasibility of restoring and managing low-severity fire is higher with longer rates. Longer rates also mean that completed treatments may have already been sufficient in many old-forest areas, and further management of low-severity fire can be redirected to using managed fire for resource benefit [71]. Where initial treatment is incomplete, one prescribed fire should suffice before a managed-fire program can begin. At that point, managers can monitor low-severity fire using historical mean PMFI/FR rates, fire-size distributions, and other attributes (e.g., unburned area) as a guide.

In locations where managed fire for resource benefit is infeasible, and an ongoing prescribed-burning program must be used, burning at rates longer than the mean PMFI/FRs reported here and using a diversity of rates and patterns of prescribed fires would be congruent with the findings. First, substantially lower rates (longer PMFI/FR) are warranted, if forests are not old forests, because estimated rates here apply mostly to old forests and the prevailing younger forests today likely burned historically at longer PMFI/FR. Second, the rates reported here are likely somewhat too short, as explained in "Limitations and errors. . ." Finally, lower rates would likely reduce the spread of invasive species and adverse effects on ecosystem processes and biological diversity. Also, historical rates varied substantially within small areas, particularly where there was topographic diversity, but also because of natural variability over time. It makes sense to similarly vary prescribed burning rates within local areas, leaving some areas unburned for longer periods. An approximation of the percentage of western USA old-forest parts of landscapes that experienced longer historical rates of fire is in Fig 4J. More local data can be derived from S2 Table, which lists PMFI/FR by state.

Data presented here can generally be used, with other evidence and tools, to create more comprehensive and spatially informative local understanding about mean historical PMFI/FR to guide local restoration and management of low-severity fire in old-forest parts of landscapes. Data in S2 Table have latitude and longitude and other ancillary information, and can be downloaded (S2 Dataset) and used directly or be read into a GIS program, where topography, land ownership and other information can be added for context. As new data are added to the IMPD, an FHX file for each new site can be downloaded and read into FHAES. Weibull mean ITFI can be calculated, which can then be used (Table 2) to estimate historical PMFI/FR, if not already provided in the study. Geographical coordinates, usually in the FHX file, allow new data to be added to the database (S2 Dataset) for use in GIS. Estimates of historical mean CFI and ITFI are available in the published scientific literature for other sites, not in the IMPD, which can also be used to estimate historical PMFI/FR using the equations in Tables 2 and 3, then added to the dataset (S2 Dataset) and input into GIS for local analysis. Of course, these estimates usually apply to only old-forest parts of historical landscapes.

Dry-forest landscapes until recently were thought to have historically been primarily old-growth forests, with a history of frequent low-severity fire, across their extent (e.g. [72]), but this has been refuted by GLO reconstructions and early aerial photographs (Table 6), paleo-ecological evidence [24], and early forest-reserve reports and other evidence [63, 73]. Even in Arizona, which had abundant old forests with frequent fire (Fig 3), denser forests and high-severity fire were extensive at certain times and in certain places, as on Black Mesa and parts of the Mogollon Plateau [60, 73]. It is sensible to restore low-severity fire to its former dominance in the parts of dry-forest landscapes with a history of primarily low-severity fire, historically averaging about 34% of western dry-forest landscapes (Table 6). Estimated mean PMFI/FRs here provide a guide for restoration and management of low-severity fire in extant old-forest parts of landscapes. For most dry-forests today, which are not old, using frequent fire (PMFI/FR $<$ 25 years) in restoration is not supported, and fuels do not need to be substantially reduced, because historical PMFI/FRs naturally allowed historical shrubs and small trees to fully recover after fires. Restoration of low-severity fire is still needed. The most appropriate approach, given likely long but uncertain mean rates of historical low-severity fire, is for most dry forests today to receive at most one prescribed fire, followed by managed fire for resource benefit, with the goal of mimicking mean historical PMFI/FRs and variability in fire (fire-size distributions, unburned area) as forests reach old age.

Acknowledgments

This project could not have been completed without the prior work of many scientists in collecting and analyzing fire history across the western USA. I appreciate the contribution of the team that developed the FHAES software. This article was substantially improved by the thoughtful comments of anonymous reviewers.

Dry forests are particularly subject to wildfires, insect outbreaks, and droughts that likely will increase with climate change. Efforts to increase resilience of dry forests often focus on removing most small trees to reduce wildfire risk. However, small trees often survive other disturbances and could provide broader forest resilience, but small trees are thought to have been historically rare. We used direct records by land surveyors in the late-1800s along 22,206 km of survey lines in 1.7 million ha of dry forests in the western USA to test this idea. These systematic surveys (45,171 trees) of historical forests reveal that small trees dominated (52–92% of total trees) dry forests. Historical forests also included diverse tree sizes and species, which together provided resilience to several types of disturbances. Current risk to dry forests from insect outbreaks is 5.6 times the risk of higher-severity wildfires, with small trees increasing forest resilience to insect outbreaks. Removal of most small trees to reduce wildfire risk may compromise the bet-hedging resilience, provided by small trees and diverse tree sizes and species, against a broad array of unpredictable future disturbances.

Keywords: dry forests, wildfires, insect outbreaks, droughts, climate change, resilience, land surveys, bet-hedge

INTRODUCTION

Dry forests globally may be particularly vulnerable to climatic change, because their setting is prone to wildfires, insect outbreaks, and droughts; these disturbances may increase, and post-disturbance tree recruitment is often poor. Recruitment limitation in forests is a widespread concern (Clark et al., 1999), particularly where moisture is limiting, as in *Pinus* forests in drier parts of precipitation gradients (Dorman et al., 2013). For example, dry forests of the western USA (Figure S1), which include montane ponderosa pine (*Pinus ponderosa*) forests and dry mixed-conifer forests also with firs (*Abies* spp.) and Douglas-fir (*Pseudotsuga*), can have poor tree recruitment that limits their recovery after fires, insect outbreaks, and droughts. Tree recruitment in dry *P. ponderosa* forests of the western USA over the last century has been poor, concentrated in episodic pluvials (Savage et al., 1996), and spatially variable (Stein, 1988; Roccaforte et al., 2012). Mortality of *P. ponderosa* at their ecotone with lower-elevation woodlands during a 1950s drought (Allen and Breshears, 1998) also indicates vulnerability. Rising temperatures and drought could further reduce tree recruitment in dry forests (Anderson-Teixeira et al., 2013). Climate envelopes of seedlings vs. established trees of *P. ponderosa* suggest general recruitment failure is underway, possibly a precursor to broader range contraction (Bell et al., 2014).

In contrast, paleoecological research shows that dry forests of the western USA persisted for thousands of years in the face of wildfires, insect outbreaks, and droughts (Jenkins et al., 2011), suggesting recruitment was not generally deficient and historical forests were resilient. However, this persistence appears incongruent with the hypothesis that these dry forests historically had low abundance of seedlings, saplings and small trees (Covington and Moore, 1994; Allen et al., 2002). This hypothesis is based in part on tree-ring reconstructions, which show that large trees were historically dominant in most sampled stands (Williams and Baker, 2012a). However, small trees could have been common, but missed in tree-ring reconstructions because small trees had high mortality rates and may decompose by the time of reconstruction (Allen et al., 2002). Also, tree-ring reconstructions are not located systematically across landscapes and plot-level size-class distributions are often averaged, masking variability (Williams and Baker, 2013). Nonetheless, frequent surface fires were thought to have limited small trees, and some early accounts do suggest low abundance of tree recruitment (Leiberg et al., 1904; Covington and Moore, 1994; Allen et al., 2002). Today, large trees are likely less abundant and small trees more abundant than historically (Covington and Moore, 1994), but our focus is only on historical abundance of small trees, not current abundance. The common hypothesis is that low-severity fires historically limited small trees, so they were a low percentage of total trees and were found across a low percentage of land area.

We use a previously untapped historical source, the General Land Office (GLO) land surveys, which provide spatially extensive direct empirical data on historical tree recruitment (seedlings/saplings, small trees). We use seven study areas that span dry forests of the western USA (Figure S1) to test the hypothesis that dry forests historically had little tree recruitment. We formalize this for the two data sources from the GLO surveys and two components of recruitment abundance: H_1: Small trees were <20% of total trees, and H_2: Seedlings and saplings (trees < 10 cm diameter) were present on <20% of forest area.

Past specific estimates of percentages were lacking; we used test values that conservatively represent the hypotheses. Small trees are ≥10 cm dbh, with an upper size limit of 30–50 cm, defined for each study area (Williams and Baker, 2012a). We measured and compared recent risks of higher-severity wildfires and insect outbreaks in dry forests, separated into ponderosa pine forests and dry mixed-conifer forests, across the western USA using government data. We reviewed the role of tree recruitment in recovery after these disturbances. We suggest a strategy to maintain the resilience of dry forests to future disturbances, based on our findings.

MATERIALS AND METHODS

Data from the public land survey system, conducted by the U.S. General Land Office, have been widely used in the USA to reconstruct historical vegetation (Schulte and Mladenoff, 2001). Surveys in the study areas were generally done in the late-1800s before widespread expansion of EuroAmerican land uses. The system consists of 9.6 × 9.6 km townships containing thirty-six 1.6 × 1.6 km sections. Surveyors marked quarter corners at the 0.8 km mark and section corners at the 1.6 km mark along section lines. Surveyors were required to record azimuth, distance, species, and diameter of two bearing trees at quarter corners and four trees at section corners. Here we used surveyors' direct estimates of tree diameters. In an accuracy study, we found surveyors estimated diameters with sufficient accuracy to place trees in 10-cm diameter bins (Williams and Baker, 2010). After applying an empirical correction, diameter distributions from bearing trees were 87–88% similar to distributions from plot data (Williams and Baker, 2011), thus are quite accurate. Bearing trees are a statistically valid sample, as they have low bias and error (Williams and Baker, 2010).

We also used section-line data recorded by surveyors. Surveyors in forests were required to record, in order of abundance, the dominant overstory trees and understory plants, often including small trees (seedlings and saplings) and shrubs (Williams and Baker, 2012a). Surveyors also often recorded qualitative estimates of understory tree density. Not all surveyors followed the instructions, thus we limited analysis to the set of surveyors who did so for at least one section-line. The section-line data represent a statistically valid line-intercept estimate of cover (Butler and McDonald, 1983).

To provide data to test hypothesis H_1, we totaled small and large trees in each of the seven study areas and for the composite (**Table 1**, **Figure 1**). Small trees were defined as ≥10 cm but ≤40 cm, except ≤30 cm in the Colorado Front Range, where tree growth is slower (Williams and Baker, 2012a) and ≤50 cm in the western Sierra, where tree growth is faster (Baker, 2014).

Table 1 | Study areas, corresponding number of trees and section-line length in forested area, and the percentage of forest section line-length with seedlings and saplings.

[e] *Seedling/Sapling pines, firs, oaks, and other trees may be overlapping, as a line can have, for example, both pines and firs.*

[f] *Degrees of freedom = 1 and N = the number of 1-km line-lengths, for all chi-square tests.*

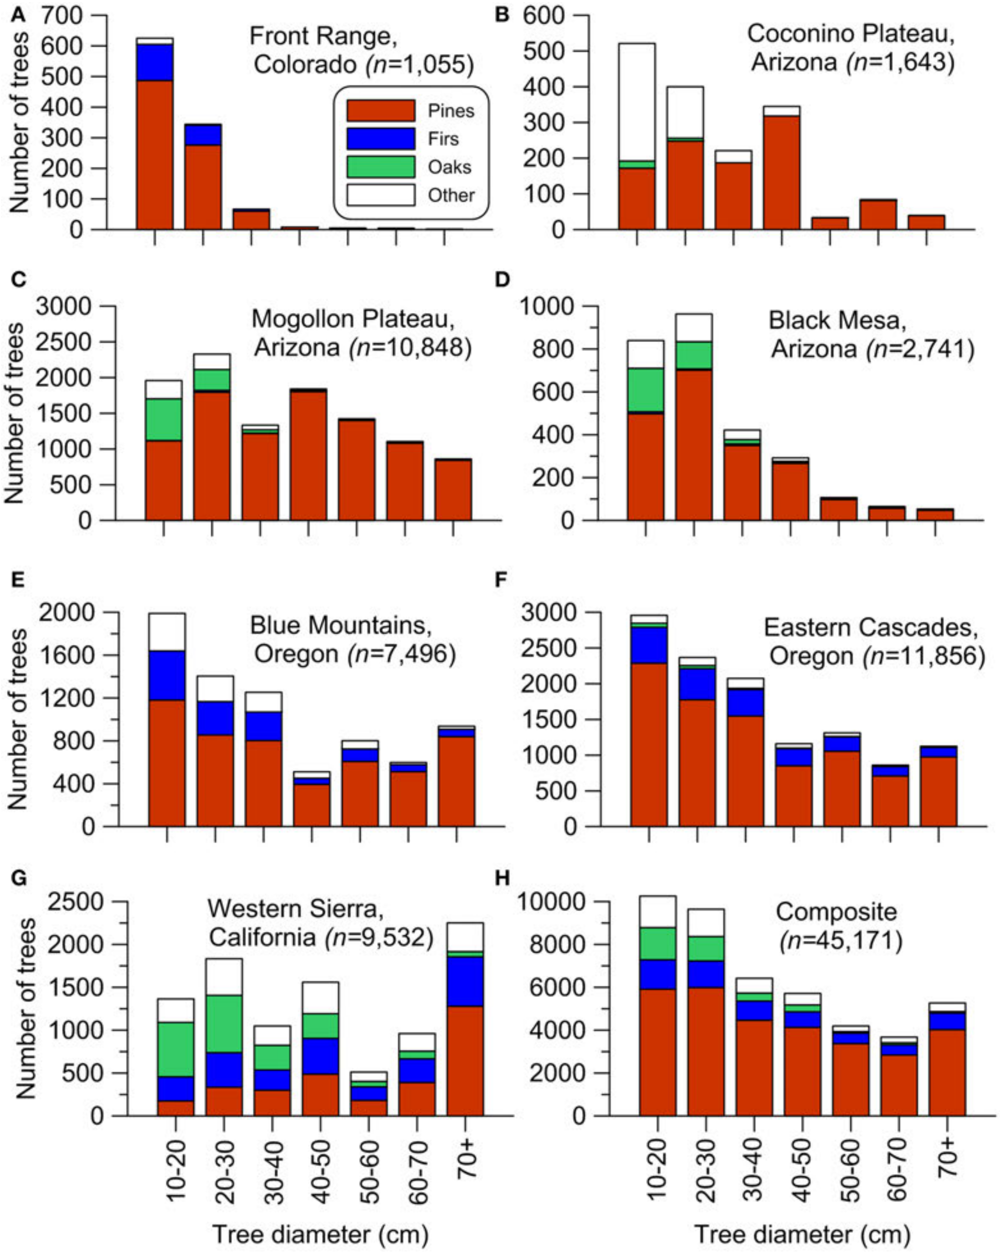

FIGURE 1 | Historical tree size-class distributions for the seven study areas and a composite across all the study areas: (A) Front Range, Colorado, (B) Coconino Plateau, Arizona, (C) Mogollon Plateau, Arizona, (D) Black Mesa, Arizona, (E) Blue Mountains, Oregon, (F) Eastern Cascades, Oregon, (G) Western Sierra, California, (H) The composite of all areas. Distributions use 10-cm bins compatible with the accuracy of diameters measured by the surveyors (Williams and Baker, 2011). Other trees, not found in every area, include *Pinus edulis* and *Juniperus* spp., *Calocedrus decurrens*, *Populus tremuloides*, and *Larix occidentalis*. As in **Table 1**, small trees were defined as trees ≥10 cm but ≤40 cm diameter, except ≤30 cm in Colorado **(A)** and ≤50 cm in California **(G)**.

These diameters generally represent trees that are less than about 140 years old (Bright, 1912; Baker, 2012, 2014; Williams and Baker, 2013). Trees this size today are often thought to have widely established after EuroAmerican settlement because of logging, livestock grazing, and fire exclusion (Covington and Moore, 1994; Allen et al., 2002; Franklin and Johnson, 2012), and thus may be removed in restoration treatments. To test H_1, we used a chi-square goodness-of-fit test of a null hypothesis that small trees were 0.2 of total trees and large trees were 0.8 of total trees. If this null was rejected, we rejected H_1 if small trees were <0.2 of total trees. To control error rates, we Bonferroni-corrected $\alpha = 0.05$, for 8 planned tests, one per study area and one for the composite (**Table 1**, **Figure 1**), to $\alpha = 0.00625$.

To provide data to test H_2, we totaled 1-km section lines for which surveyors recorded understory trees in each of the study areas and for the composite. Similarly, to test H_2, we used a chi-squared goodness-of-fit test of a null hypothesis that the area with seedlings/saplings was 0.2 of the total forested area and the area without seedlings/saplings was 0.8 of the total forested area. If this null was rejected, we then rejected H_2 if seedlings/saplings were found across <0.2 of total forest area. We also Bonferroni-corrected an initial $\alpha = 0.05$ for 8 planned tests.

We used maps of ponderosa pine and dry mixed-conifer forests from Landfire Biophysical Settings (www.landfire.gov). Wildfire area and severity were from raster maps of actual burned area, not fire perimeters, from the Monitoring Trends in Burn Severity (MTBS) program (http://www.mtbs.gov). Insect-caused mortality was from the US Forest Service Forest Health Technology Enterprise Team (http://foresthealth.fs.usda.gov/portal/Flex/IDS). Insect outbreaks were detected using annual aerial surveys. To limit analysis to dry western forests, aerial survey polygons and wildfires were both clipped by the maps of ponderosa pine and dry mixed conifer. The annual sample area varied, but averaged about 9.8 million ha of ponderosa pine and 10.9 million ha of dry mixed-conifer forests (Table S1), about 80% of the 25.8 million ha area of western dry forests.

Comparison of wildfire and insect outbreaks was done for each year both datasets were available. We compared moderate- and high-severity wildfire area, which are the severities with substantial tree mortality, with areas where tree mortality from insects was also substantial, as it was visually detected from aerial surveys. We calculated the rate of wildfire using the fire rotation, which is the number of survey years divided by the fraction of the survey area impacted by fire in those years. The rate of insect outbreaks was determined similarly. Some outbreak areas appeared to overlap in subsequent years and potentially be cumulative. We performed a union and spatial dissolve in GIS to derive a conservative estimate of total area impacted by insect outbreaks over the analysis period. Additional details are in Supplementary Methods.

RESULTS

SMALL TREES HISTORICALLY ABUNDANT AND DOMINANT

Hypothesis H_1 is rejected across all seven study areas and the composite (**Table 1**). Small trees generally dominated historical dry forests, ranging from 51.8 to 91.8% of total trees across the seven study areas and equaling 61.6% of trees in the overall composite (**Table 1**, **Figure 1**). Small trees can be suppressed older individuals, but were predominantly <140 years old (Bright, 1912; Williams and Baker, 2012a). Small trees were somewhat diverse, with pines most abundant, but also firs, oaks and other conifers and hardwoods (**Figure 1**). Hypothesis H_2 is rejected for study areas in California and Oregon, but not in Arizona and Colorado (**Table 1**).

HIGHER RECENT THREAT FROM INSECT OUTBREAKS THAN FROM WILDFIRE

Data from government agencies show that insect outbreaks were recently a more significant threat to dry forests than were moderate- to high-severity wildfires; similar data are not available for droughts. It is conservatively estimated (i.e., consolidating all areas of spatial overlap) that insect outbreaks caused substantial detectable tree mortality in 5,193,752 ha of western dry forests over the 1999–2012 period for which spatial data were available, which is 5.6 times the 934,551 ha impacted by moderate- to high-severity wildfires (Table S1). Mean ratios of insect to fire impact were 4.5 in ponderosa pine and 6.9 in dry mixed-conifer forests (Table S1). At the rates during 1999–2012, it would require 311 years for moderate- to high-severity wildfires to burn once across an area equal to the area of western dry forests, but only 56 years for insect outbreaks to impact this area (Table S1). Rotations for fire varied from 265 years in ponderosa pine to 367 years in dry mixed-conifer forests, and for insects from 53 years in dry mixed-conifer to 59 years in ponderosa pine forests (Table S1).

DISCUSSION

NATURAL DISTURBANCES FOSTERED HISTORICALLY ABUNDANT SMALL TREES AND DIVERSE TREE SIZES

Historical dominance of small trees in dry forests (**Figure 1**) does not support the hypothesis that surface fires generally kept small trees rare. Small trees had successfully recruited and were dominant in all dry-forest areas (**Figure 1**). These small, established trees are given more weight, than smaller, more ephemeral seedlings/saplings, for which evidence is more mixed. Seedlings/saplings were abundant in the majority of areas, except two southwestern landscapes (Black Mesa, Mogollon Plateau) and the Colorado Front Range (**Table 1**). Early scientific sources corroborate limited seedlings/saplings in these areas (Leiberg et al., 1904; Williams and Baker, 2012b). Early foresters emphasized preserving advanced recruitment during logging (Pearson, 1923). Thus, recent high-severity fires do not have unprecedented poor recruitment (Savage and Mast, 2005). Seedling/sapling populations in these landscapes must have fluctuated, since small trees had been able to recruit and dominate all dry forests (**Figure 1**). Particular sequences of fires, droughts, and other disturbances may explain fluctuating seedling/sapling populations (Dugan and Baker, in press), and reinforce the historical role of advanced recruitment.

Dominance of small trees, and even ephemeral seedling/sapling populations in most areas, indicates more imperfect limitation of tree recruitment by historical low-severity fires than previously thought. Other disturbances, including droughts, insect outbreaks, and more severe fires likely killed canopy trees and increased tree recruitment, particularly if followed by pluvials (Savage et al., 1996; Dugan and Baker, in press). The Colorado Front Range and Black Mesa (Williams and Baker, 2012a) had the greatest dominance of small trees (**Figures 1A,D**), and our reconstructions showed these areas had more higher-severity fires (Williams and Baker, 2012a,b). Historical abundance of small trees and importance of higher-severity fires in structuring tree populations across dry-forest landscapes are supported by an independent dataset of tree ages (Odion et al., 2014). Higher-severity fires likely interacted with other disturbances to produce diverse tree sizes that were together more resilient to disturbance than would have been the case if only low-severity fires had occurred and large trees had dominated. Historical dominance by small trees and diverse trees sizes are consistent with long-term persistence and resilience of dry forests after disturbances (Jenkins et al., 2011).

ABUNDANT SMALL TREES AND DIVERSE TREE SIZES CONFER RESILIENCE IN MODERN FORESTS

Modern observations also document key, but contrasting roles for advance recruitment and surviving larger trees in forest resilience after fires, insect outbreaks, and droughts. Higher-severity fires may be followed by variable recruitment, including poor recruitment, lags in recruitment, or abundant recruitment in some areas (Roccaforte et al., 2012), with large, surviving trees and proximity to them important (Bonnet et al., 2005; Haire and McGarigal, 2010).

About a dozen bark-beetles, that kill trees over large areas of dry forests in the western USA, are the major outbreak insects (Bentz et al., 2010; Weed et al., 2013). In this case, larger trees are differentially susceptible, which often leaves smaller surviving trees as the key source of post-outbreak recruitment. Vulnerability of larger trees to bark beetles is related to greater food resources (Raffa et al., 2008). In a 1970s outbreak of mountain pine beetle (*Dendroctonus ponderosae*) in ponderosa pine in Colorado, tree survival was substantially higher for trees <20 cm diameter (McCambridge et al., 1982). Similarly, western pine beetles (*Dendroctonous brevicomi*s) kill relatively few trees <40 cm (Miller and Keen, 1960). However, *Ips* in Arizona preferentially kill smaller trees (Negrón et al., 2009). Nonetheless, advance recruitment generally dominates post-outbreak recruitment. After spruce beetle (DeRose and Long, 2010) and mountain pine beetle outbreaks (Astrup et al., 2008), small trees present before outbreaks dominated post-outbreak recruitment. Since these small trees were more diverse than pre-outbreak canopy trees, post-outbreak forests may have greater resilience to future outbreaks (Diskin et al., 2011; Kayes and Tinker, 2012).

Drought often also differentially kills the largest, oldest trees, with less mortality in small and mid-sized trees (Allen et al., 2010), thus also leaving advance recruitment. Drought effects on tree mortality can be widespread and affect forests for centuries (Allen et al., 2010). Drought also influences the occurrence of wildfires, insect outbreaks, and regional tree mortality (Allen et al., 2010), thus it is difficult to parse the impacts of drought alone.

The upshot is that both small trees and surviving larger trees and a diversity of tree species provide resilience to disturbances. Surviving larger trees are particularly important after higher-severity fires and abundant small trees are particularly important after insect outbreaks and droughts.

RESTORING AND MAINTAINING THE BET-HEDGING RESILIENCE OF HISTORICAL FORESTS

Current restoration strategies that seek to increase forest resilience focus predominately on impacts from severe wildfires, but bark-beetle outbreaks and other insects affected 5.6 times the area of western dry forests impacted by moderate- to high-severity fires over the most recent 14-year period (1999–2012). Current rates of moderate- and high-severity fire, with a combined rotation of 311 years (Table S1), would likely not prevent recovery of old-growth forests in the interlude between fires, but rates of insect outbreaks, with a rotation of 56 years (Table S1), could prevent recovery of most older dry forests. Previous research, using the same data sources, in a more limited and lower-elevation area in the southwestern United States, found that beetle-outbreaks affected 2.5–4 times as much area as moderate- to severe wildfires (Williams et al., 2010). Both wildfires (Dennison et al., 2014) and beetle-outbreaks (Bentz et al., 2010; Weed et al., 2013) are increasing in parts of the western United States. Future outcomes are uncertain and complex, however, as beetle-outbreaks can affect wildfire probability (Simard et al., 2011), and as tree mortality occurs, both beetle outbreaks and wildfires could become self-limited (Williams et al., 2010).

Ecological restoration of public dry forests in the western USA is increasingly a goal, because these forests were altered by unsustainable logging, livestock grazing, and fire exclusion that allowed abundant small trees to recruit (Covington and Moore, 1994). Retaining older trees, while removing most small trees up to ages or sizes of trees recruited since EuroAmerican settlement (Figure S2A), is thus often a restoration focus (Covington and Moore, 1994; Allen et al., 2002; Abella et al., 2006; Franklin and Johnson, 2012). Typical upper tree age and size limits are 120–150 years old or 30–50 cm diameter (Abella et al., 2006; Franklin and Johnson, 2012).

We show here, however, that these small trees were the tree sizes historically dominant in these forests (**Figure 1**, **Table 1**), thus removing most small trees so they are no longer dominant is not ecological restoration. There are also efforts underway to increase resilience of forests to droughts by removing most small trees and lowering stand density. However, stand density does not appear to play a major role in level of tree mortality from drought (Ganey and Vojta, 2011). Thus, strategies to reduce most small trees are neither restorative nor very effective.

We suggest diverse historical tree sizes and abundant and dominant small trees long provided bet hedging in dry-forest landscapes subject to unpredictable disturbances. These forests can be more effectively restored and their resiliency to future disturbances increased by maintaining or restoring the historical abundance, dominance, and diversity of small trees, while also restoring large trees depleted by logging (Figure S2B). This can be achieved with historically congruent diversities of forest structures across landscapes, based on GLO and other spatial reconstructions. This bet-hedging landscape approach to ecological restoration is consistent with long-term persistence of historical forests, the high current threat from insects, and would likely confer more resilience to disturbances, that may all increase in the future, than would just retaining larger or older trees across large areas.

ACKNOWLEDGMENT

This research had no specific funding source, and builds on datasets from previous research.

S1 Text. Why CFIs and ITFIs underestimate PMFI/FR

Since both mean composite fire interval (CFI) and mean individual tree fire interval (ITFI) typically underestimate the population mean fire interval or fire rotation (PMFI/FR), it is logical to infer that both methods are missing longer intervals because of biased estimates (Table 1 main text). Compositing alone could explain nearly the whole bias in CFI measures, as explained below, but ITFI measures are not composites and are still biased, although less so. The most likely explanation for bias in ITFI measures, and also a contributor to bias in CFI measures, as estimators of PMFI/FR, is targeted sampling. These potential sources of bias are reviewed in detail here.

Compositing overcompensates, destroys long fire intervals, and restriction rules do not remedy this

Scarring fraction, compositing, and widespread over-compensation

The purpose of compositing is to compensate for the incomplete scar record on individual trees, since trees can often resist scarring even if burned (Baker and Dugan 2013). Scarring fraction (SF) is the fraction of burned live trees that survive a fire but receive a scar. Studies of SF are few (e.g., Collins and Stephens 2007, Stephens et al. 2010). A study of 16 fires in ponderosa pine forests in northern Arizona found a mean SF of 0.375, ranging from 0.121 to 0.728 across 52 plot samples (Baker and Dugan 2013).

Given a particular SF, how many trees must be sampled or composited to compensate for SF < 1.0 (Baker and Dugan 2013)? The minimum is to have a sample size that has a high probability of recording each fire on at least one scarred tree. The probability, P, of at least one tree scarring in a sample of n live trees, for a scarring fraction, SF, is given by:

$$P = 1.0 - (1.0 - \text{SF})^{n} \quad (1)$$

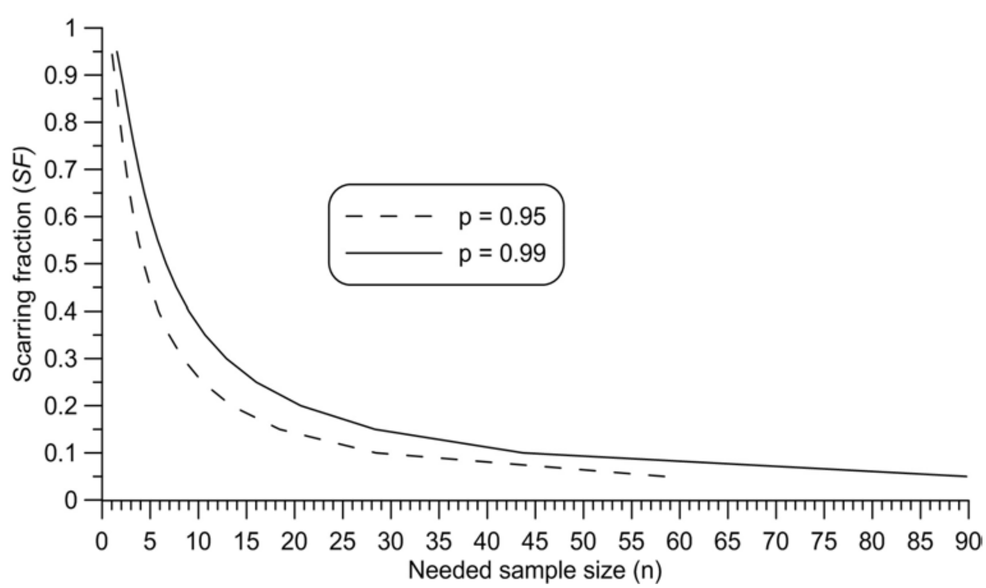
and the corresponding estimate of n, for a particular SF, is given by:

$$n = \log(1.0 - P) / \log(1.0 - \text{SF}) \quad (2)$$

The necessary sample sizes to achieve a probability ≥ 0.95 or 0.99 of detecting a fire are modest, typically < 20 trees, whether scarred or not, to detect fires with SF < 0.25 (Figure A).

However, this equation does not adjust for scar healing. Scars can, but do not always, heal from the sides and disappear under new bark unless subsequent fires occur (Baker and Dugan 2013). However, Fiegener (2002) examined over 8,000 stumps and snags in a Sierran mixed-conifer forest and found only 2% with scars. An empirical study of scar healing after fires in northern Arizona ponderosa pine forests

Figure A. Scarring fraction and its effect on the sample size needed to have either a 0.95 or 0.99 probability of scarring at least one tree.



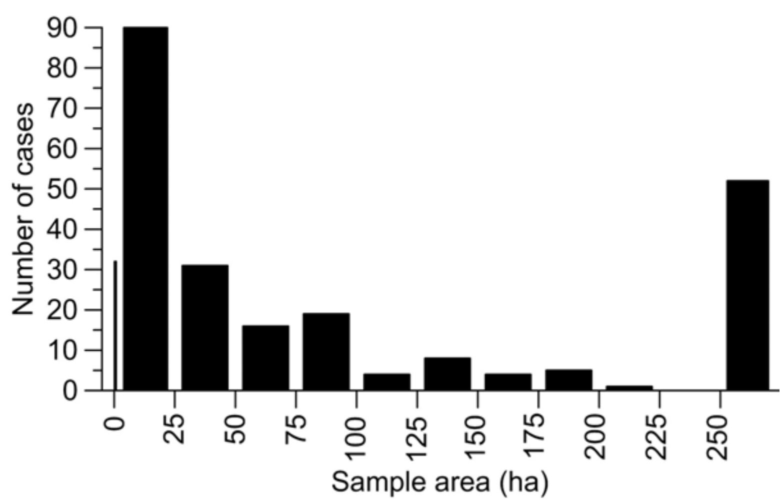
showed that larger initial scars have longer expected healing times and subsequent fires increased healing times of all scars (Baker and Dugan 2013). Healing rates from this study can be used to estimate the needed sample size to find at least one unhealed scar for a fire after 100 years, or another time since fire, using an equation developed from forests differing in time since fire:

$$\text{Effective mean SF} = \text{Initial SF} \times \exp(-0.0125 \times \text{Time since fire}) \qquad (3)$$

For example, if expected mean SF is 0.400, then six sample trees would likely ($P = 0.95$) contain at least one scar (using Eq. 2 or Figure A) from a fire burned recently. In contrast, the effective mean SF if that same fire had burned 100 years ago, and scars had healed since then, would be 0.115, from Eq. 3, thus requiring a sample of about 26 trees each > 100 years old (Eq. 1, Figure A). Similarly, a lower SF of 0.200 would require 51 trees > 100 years old for a fire 100 years ago. These calculations suggest that sufficient trees to detect fires in historical landscapes could likely be obtained from unlogged areas that are on the order of about 1 ha in area or even less.

In contrast, most compositing is from areas far too large for the area and number of sample trees usually needed to compensate for SF < 1.0. In the merged dataset of 342 sites, only 262 reported area sampled. Of those, only 32 (12.2%) were from areas < 1.0 ha (Figure B). One concern is whether SF rates estimated in this study are higher than they would have been in historical forests, because fire exclusion increased fuel loads in modern forests, likely increasing SF. Some effect is likely, but the effect would not change the general pattern of widespread overcompensation. First, if a preceding fire occurred within 30 years, then SF was reduced from a mean of 0.393 to 0.324, only an 18% reduction, in the Baker and Dugan (2013) study. This would have a minor effect of increasing the number of needed sample trees from 26 trees to 31 trees, having almost no effect on the widespread pattern of over-compensation evident in Figure B. Second, even in the extreme case of a 0.05 mean SF in historical forests, assuming a historical fire rotation of < 10 years (Stephens et al. 2010), only 208 trees, whether scarred or not, would be needed after 100 years to achieve a probability ≥0.95 of detecting a fire. This could be obtained in most historical dry forests in < 2-3 ha. Even at this extreme level of SF, only 18.7% of the 262 sites were from areas < 3 ha, thus 81.3% of studies were over-compensating.

Figure B. Number of cases (n = 262 total) by sample area (ha). Many cases did not report area. The first bin is from 0-1 ha, the remainder are 25-ha wide, and the last bin is for areas > 250 ha.



This over-compensation particularly biases CFI estimates toward values that are too short, since mean CFI declines as sample area or number of sample trees increases (Arno and Petersen 1983, Baker and Ehle 2001, Everett 2003, Kou and Baker 2006a, b). ITFI and FR estimates, in contrast, do not systematically decline with larger samples, and may even become more precise. Compositing records across an area or number of trees that is too large could explain why CFI estimates are too short relative to FRs, but cannot explain why ITFI estimates, which do not use compositing, are also too short.

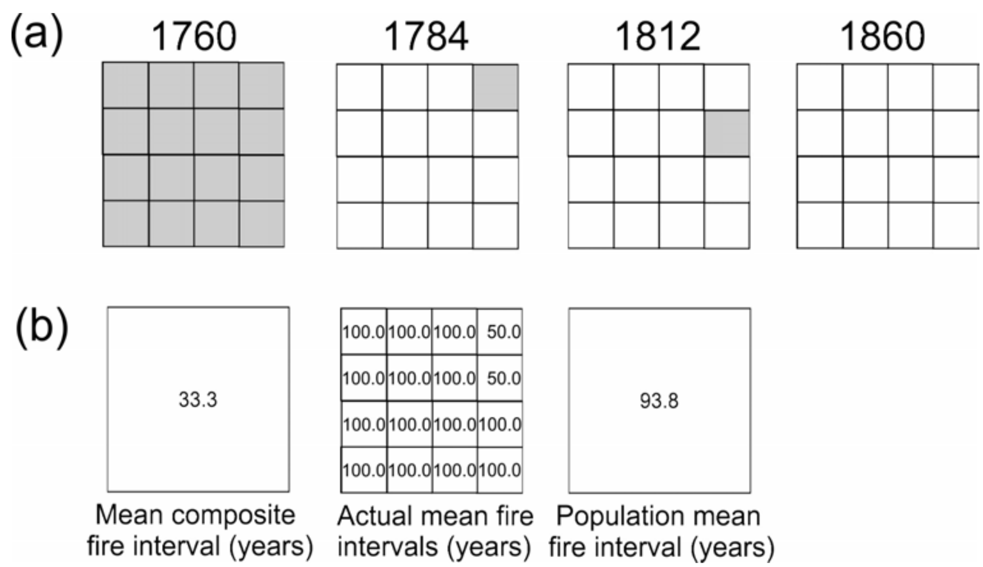
Compositing not only over-compensates, but also destroys long fire intervals that are real

Compositing is a processing step, separate from finding and collecting an adequate sample. Several methods can be used to process sample data, including calculating mean ITFI (Dugan and Baker 2014), or estimating FR, thus the compositing step is not essential. How does the compositing step contribute error if used to estimate PMFI/FR? Most fires are small and only a few are large (Baker and Ehle 2001). When a composite list is created, and intervals are calculated among fires in the list, each small fire year counts the same as a large fire year. Even though some compositing might offset incomplete evidence, at the same time it destroys other evidence. Longer fire-free intervals that are real occur in unburned parts of landscapes adjacent to where small fires occurred, and some long intervals that are false because scarring is incomplete also occur. However, all these long intervals, whether real or false, are erased across the whole sample area when a composite list is created, rather than disappearing only in the area where a small fire occurred (Figure C). Since longer intervals, some of which are real, are all lost to compositing, this in part explains why mean CFI underestimates PMFI/FR.

CFI restriction rules are ad hoc, inconsistent, and likely insufficient in excluding small fires

Some suggest that there is only a problem with mean CFI and its use if it is presented without omitting spot fires: "...this becomes a problem only if the fire chronology is presented with all fires, even the smaller spot fires, and is interpreted by the reader as if the chronology indicates how often the entire stand burned" (Stephens et al. 2003 p. 1091).

Figure C. How compositing destroys long fire intervals that are real: (a) a landscape that burned (shaded area) in each of three fire years between 1760-1860, and (b) the actual mean fire intervals (center panel), the mean composite fire interval for the landscape (left panel) calculated from a composite list of fires (1760, 1784, 1812, ending in 1860), thus three intervals in 100 years = 33.3 years, and the PMFI (right panel), which is the grand mean of the actual mean fire intervals (1500 years/16 = 93.8 years). Note that the reason that the mean CFI underestimates the PMFI is that compositing treats the 1784 and 1812 fire years as though they burned the same land area as the 1760 fire year, which also eliminates the 100.0-year fire intervals that occurred over most of the landscape.



Restriction rules are traditionally applied to filter out fires, like spot fires, that are small, using the number of fire scars or the percentage of total scarred trees that record a fire year (e.g., 10%, 25%). However, no way is known to objectively identify a spot fire or other small fire that should be omitted, since fire-size distributions are typically nearly linear on a log-log plot and have no natural breaks (Kou and Baker 2006b). Also, distributions vary in slope among forest types and environments (Kou and Baker 2006b), so imposing a particular filter (e.g., 25%) has varying effects. This means that restriction rules are ad hoc and inherently inconsistent in their effects.

Moreover, 10% and 25% filters that are typically applied, may be insufficient to limit the fires that should be included in a composite list, if the goal is that mean intervals between fires in the list estimate the PMFI/FR. In a spatial reconstruction of fire sizes in dry forests, Farris et al. (2010) found that 414 total fires occurred in their study area from 1937-2000, but only 21 fires (5.1% of total fires) accounted for 97% of total burned area. This suggests a restriction rule would have to exclude 95% of fires to limit a composite to the fire years that account for most of the total burned area, which would more likely accurately estimate PMFI/FR. Together, the ad hoc, inconsistent, and insufficient extent of traditional restriction rules in part explain why mean CFI underestimates PMFI/FR.

Censoring incomplete fire intervals leaves out long intervals in both CFI and ITFI estimates

Fire-history data contain incomplete intervals at the beginning and end of a period of record unless those periods begin and end with fires (Polakow and Dunne 1999). Incomplete intervals can be included or omitted ("censored") in analysis of fire-interval data (Polakow and Dunne 1999). Censoring (i.e., using only scar-to-scar intervals) biases both mean CFI and ITFI by omitting incomplete intervals at the beginning or end of a tree's record. Incomplete fire intervals occur on most trees, but longer intervals have more chance, than shorter intervals, of appearing as incomplete intervals, indicated by no scars or one scar on a tree (Kou and Baker 2006a). Simulation has shown that in a landscape subject to low-severity fires at modest intervals (e.g., 50 years), actual intervals at some locations may be several times longer (Kou and Baker 2006a) and even up to an order of magnitude longer than the mean interval (Parsons et al. 2007). These are real intervals that occur by chance, not an artifact of incomplete scarring. Censoring is biased against these expected long fire intervals and leads to estimates of PMFI/FR that are too short and have reduced variability, since longer intervals are omitted (Kou and Baker 2006a). These effects from censoring were also found in two studies in Mediterranean shrublands, in which censoring reduced the scale parameter (indicator of length of fire intervals) of a Weibull fire-interval distribution and also reduced estimated variability in fire intervals (Polakow and Dunne 1999, Moritz et al. 2009).

These censoring effects have ecological implications in dry forests subject to periodic fires, since most composited fire-scar records, which are traditionally censored, lack evidence of the long intervals needed for tree regeneration and survival of fire-intolerant species. We suggested that the interval before the first fire scar (origin-to-scar interval--OS) on individual trees may record the fire-free period needed for trees to successfully regenerate (Baker and Ehle 2001), since both wide-area and local processes producing long intervals should be recorded as OS intervals. Mean OS intervals are, in fact, usually much longer than mean scar-to-scar intervals in the same stands, and many are sufficiently long to allow tree regeneration (Baker and Ehle 2001). Mean OS intervals in ponderosa pine forests were 51 years in the Black Hills (Brown et al. 2008), 55.4 years in Rocky Mountain National Park (Baker and Ehle 2003), 81 years across five studies (Baker and Ehle 2001), and 101.5 years in one case in northern Arizona (Van Horne and Fulé 2006). Arguments can be made for and against including the OS interval in CFI estimates (e.g., Baker and Ehle 2003, Van Horne and Fulé 2006, Stephens et al. 2010). However, long intervals that are real do occur and are directly censored by traditional use of only scar-to-scar intervals in CFI and ITFI estimates, contributing to underestimation of PMFI/FR by CFI measures.

Targeted sampling likely a significant source of underestimates of PMFI/FR by ITFI, as well as by CFI

<u>Why researchers target fire-history evidence and why it remains a concern for estimating PMFI/FR</u>

Researchers target fire-history evidence to increase the length of record and maximize the data obtained with minimal physical effort and damage to trees (Farris et al. 2013). If only 50 scarred trees can be sampled, more fire years per scarred tree and a longer mean length of record will nearly always be obtained from 50 trees selected by targeting than from a random sample.

Unfortunately, targeting fire-history evidence at the scale of individual trees, sampling areas, and landscapes produces biased estimates of fire history (Lorimer 1985, Johnson and Gutsell 1994, Baker and Ehle 2001). The consequences are generally that estimates of historical PMFI/FR are too short and fire-severity is underestimated. The magnitude of targeting and its effects is now better known. Targeting remains common in fire-history studies, as illustrated in Table A, which shows that targeting of individual trees, particularly multi-scarred trees and old trees, was widespread, almost universal for multi-scarred trees, and almost 1/3 of studies placed study plots where there were concentrations of scarred trees and old trees.

Table A. Percentage of 342 sites in which various types of targeting sampling were used.

Targeting type and measures	**Yes**	**No**	**No explanation**
1. Target trees to get best information or longest record of fires?			
Number of cases	114	68	160
Percentage of yes/no (%)	62.6	37.4	-
2. Target multi-scarred trees?			
Number of cases	235	15	92
Percentage of yes/no (%)	94.0	6.0	-
3. Target clusters of scarred trees?			
Number of cases	37	9	296
Percentage of yes/no (%)	80.4	19.6	
4. Target scars on dead wood?			
Number of cases	270	27	45
Percentage of yes/no (%)	90.9	9.1	
5. Target tree species thought to better record fire			
Number of cases	12	13	317
Percentage of yes/no (%)	48.0	52.0	
6. Target plot locations in old forests and concentrations of scars			
Number of cases	73	153	116
Percentage of yes/no (%)	32.3	67.7	
7. Target study areas in old forests and concentrations of scars			
Number of cases	18	168	156
Percentage of yes/no (%)	9.7	90.3	

Specific studies of some of these types of targeting are now available (Baker and Ehle 2003, Van Horne and Fulé 2006, Kou and Baker 2006a, Brown et al. 2008, Farris et al. 2010, 2013), but the most significant types are less studied. Studies whose findings supported targeted sampling (e.g., Van Horne and Fulé 2006) for some purposes did not study using targeted sampling for estimating PMFI/FR, the focus here, thus targeted sampling has not been supported for this purpose.

Targeting individual trees

Targeting individual trees typically includes a bias component and a non-random sampling component. The bias component is from omitting trees with no scars or one scar and preferentially or exclusively using trees with multiple scars. The non-random sampling component comes from purposely choosing particular multi-scarred trees rather than randomly sampling them.

Significant bias is likely from omission of trees with no or single scars, which are traditionally omitted because only scar-to-scar intervals provide estimates of complete fire intervals. However, no scars or single scars on a tree may be false, because fires do not scar every tree that burns, but no or single-scarred trees also include real but incomplete fire intervals. No or single scars that represent real, incomplete long fire intervals are more likely where fire intervals also are longer (Kou and Baker 2006a). More long intervals and more of the length of long fire intervals are inherently present on unscarred or single-scarred trees, assuming tree ages are similar to those of multiple-scarred trees. Since longer fire intervals are more likely to be omitted by individual-tree targeting, all types of estimators (i.e., CFI, ITFI) from multi-scarred trees are biased toward being too short (Kou and Baker 2006a). FR estimates are also biased toward being too short if only multi-scarred trees are sampled, because trees with no scar or one scar can indicate places where a fire did not burn, and these omissions inflate area burned for that fire year, and shorten the estimated FR.

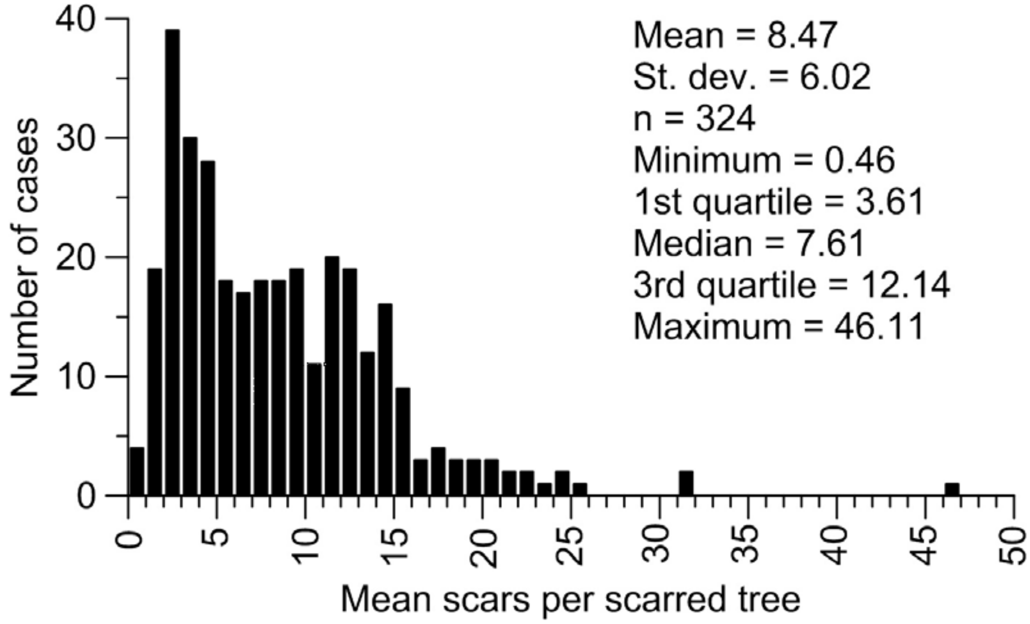
How does targeting trees with more than one scar (multi-scarred trees, recorder trees, and open-scarred trees) lead to CFI and ITFI values that underestimate PMFI/FR? Trees have visible, open scars because they are the trees that have had fires often enough to prevent healing. We found that the time for a fire scar to heal had a median of 38 years and was <100 years for 89% of scars (Baker and Dugan 2013). Longer fire intervals, that are real, have a high probability of not being selected by targeting trees with > 1 scar, because longer intervals often are expressed as no scars or one scar. Of course, long intervals can be an artifact of incomplete scarring, so that including all of them would lead to bias, but excluding all of them does too. Targeting trees with > 1 scar omits trees most likely to have long real fire intervals and selects trees with short fire intervals.

The substantial numerical dominance of unscarred and single-scarred trees in dry forests suggests omission of longer real fire intervals by individual-tree targeting of trees with > 1 scar could be among the most significant sources of bias in CFI estimates and possibly the main source of bias in ITFI estimates. In a sample of 906 pre-EuroAmerican trees we collected on 8 transects in northern Arizona, near Flagstaff and in Grand Canyon National Park, 779 trees had no scar (86%), 111 had one scar (12%), and only 16 trees had two or more scars (2%). In a mixed-conifer forest in the western Sierra, 98% of nearly 8,000 stumps and snags examined for scars did not have any scars, only 13 (0.2%) had one scar, and 48 (0.6%) had two or more scars (Fiegener 2002). Multi-scarred trees are rare in modern landscapes.

The magnitude of effects of omitting trees with no or one scar is unstudied, but within the set of multi-scarred trees with ≥2 scars, the effect of restricting fire history to increasing levels of multiple-scarring was studied (Fiegener 2002). To gauge how relevant this study is to multi-scarred sets of trees actually used in fire histories, I analyzed the number of scars per tree found by studies in the merged dataset, although data were available for only 324 cases. First, I calculated mean number of scarred trees, over each site's sample period, which is less than the total number of sample trees, since trees usually each cover only part of the sample period. Then, I calculated mean number of scars per scarred tree as total number of scars/mean number of scarred trees from the summary table for the FHX file in FHAES.

A histogram of mean scars per scarred tree had a mean of 8.47 scars/sample tree and a median of 7.61 scars/sample tree (Figure D). Fiegener (2002) found that restriction to ≥3 scars reduced ITFI from 17.4 years to 16.8 years (to 96.6%). This is above the minimum of 0.46 scars/tree in the distribution (Figure D). Restriction to ≥4 scars, just above the 1st quartile in the distribution, reduced ITFI to 15.8

Figure D. Histogram of the ratio of mean scars per sample tree in the 342-case merged dataset, and parameters of the distribution. Mean scars could not be calculated for 18 cases.



years (to 90.8%), restriction to ≥7 scars, just below the median, reduced ITFI to 14.6 years (to 83.9%), and restriction to ≥10 scars, below the 3rd quartile, reduced ITFI to 13.2 years (to 75.9%). These responses show that the more scars on a multi-scarred tree, the shorter is the mean ITFI estimate.

Roughly the median level of multi-scar targeting (≥7 scars), which reduced ITFI to 83.9%, or by 16.1%, closely matches the -16.64% bias in Weibull mean ITFI relative to PMFI/FR-total scarred trees/plots (Main text--Table 1). Other ITFI measures have biases of -2.71 to -29.71 (Main text-Table 1), so the close match with the Weibull Mean ITFI could possibly be a coincidence. Mean CFI-10% scarred also declined from 6.7 years to 5.7 years (85.1%) with restriction to ≥3 scars, but fluctuated or increased with higher levels of restriction (Fiegener 2002). Thus, the response of ITFI to targeting multi-scarred trees could explain much of why ITFI underestimates PMFI/FR, but the response of CFI estimators was inconsistent, suggesting it is possible too, but also may not be a main effect for CFI measures.

Mean CFI, ITFI, and FR estimates are further biased and shortened by non-random sampling of multi-scarred trees. Van Horne and Fulé (2006) found a statistical difference, using 95% confidence intervals, between mean CFI for an individual-tree targeted sample and a large census. Comparison of a random sample and a targeted sample, each of 40 trees, shows that mean CFI in the targeted sample was 79.1% (2.23/2.82) of the mean CFI in the random sample for all fires, 98.4% (3.00/3.05) for mean CFI-10%-scarred, and 86.9% (5.43/6.25) for mean CFI-25%-scarred. Farris et al. (2013) re-analyzed the Van Horne and Fulé (2006) dataset and added two other datasets, which together showed targeted samples had a mean CFI-all fires that was 78.9-112.5%, a mean CFI-10% scarred that was 93.5-131.4%, and a mean CFI-25% scarred that was 80.0-96.1%, of the corresponding mean CFI from a probabilistic sample. In Brown et al. (2008), a target-supplemented sample (their Figure 4d) had a mean CFI that was 88.9% (24/27) of that from a systematic plot sample (their Figure 4c). ITFI and FR estimates from recorders are similarly affected. Van Horne and Fulé (2006) found that mean ITFI in a targeted sample was 83.3% of mean ITFI in a random sample. Everett (2003) sampled fire-scarred trees using a grid at two sites and chose the closest fire-scarred tree, thus a probabilistic sample without targeting multi-scarred trees. No comparable estimate from non-random sampling and a targeted sample was made, but Everett's estimated ITFIs were in the 3rd and 4th quartiles of the distribution of estimated ITFIs in the 96-case calibration dataset, consistent with the possibility that ITFIs were long because of lack of targeting.

Farris et al. (2013) showed that individual-tree targeting and non-random sampling even led to ratio-based estimates of FR at three sites that were reduced to 85.5%, 88.3%, and 94.8% of FR estimates from equal-sized probabilistic samples. As suggested earlier, this may be because places with long fire intervals that are real are omitted. These omissions may be places that particular fires did not burn, thus fire size for those fire years is inflated, leading to FR estimates that are too short.

Another impact of individual-tree targeting is reduced completeness of the fire record and over-representation by small, low-severity fires. Fiegener (2002) found that targeting trees with ≥ 5 scars reduced detected fires from 76 to 68 (to about 89.5%), but reduced detection of larger fires to 77%, thus increasing the proportion of small fires in the sample. Baker and Ehle (2003) also found that targeting multi-scarred trees identified and emphasized more small, low-severity fires, including one-tree fires that are another central source of bias in CFI estimates (Baker and Ehle 2001). A non-targeted sample did as well or better at identifying large, low-severity and mixed-severity fires (Baker and Ehle 2003). Also, 18% of 60 total fires and 30% of the most ancient fires (pre-1700), including a significant high-severity fire, found in a non-targeted sample would have been missed if only trees with ≥4 scars were sampled (Baker and Ehle 2003). Targeting multi-scarred trees thus leads to an incomplete fire record, missing significant fires, and a bias toward small fires that produce CFI and ITFI estimates that are too short.

A related type of individual-tree targeting focuses only on "recorder" trees with at least one previous fire scar (thus ≥2 fire scars), which are thought to preferentially record fires, leading to a more complete fire record. To have increased the probability of receiving a subsequent scar, these trees had to have been effectively open, with a scar lacking bark, at the time of the next fire. Previously scarred trees do have a much higher probability of receiving a new scar than do unscarred trees (Baker and Dugan 2013). However, they are much less common than unscarred trees, and unscarred trees appear to typically be scarred at a sufficient rate in a fire to outnumber scars on recorder trees. For example, in a single fire, 73% of scarred trees were first scars and only 27% were recorders that had a previous scar (Stephens et al. 2010), suggesting previously scarred trees were poorer recorders of the fire, in terms of number of scars per unit area, even though scarred at a higher rate. In a larger Rocky Mountain National Park (RMNP) study (Baker and Ehle 2003), for 24 fires that showed up both as first scars and on recorders, 62% of the scars documenting these 24 fires were not on recorders, while 38% were on recorders, a significant difference ($\chi^2 = 4.76$, $p = 0.029$) and lower rate per unit area for recorders, just as in the Stephens et al. study. Moreover, we found 60 total fires, and 32% of these fires showed up only as first scars while 28% of the 60 fires showed up only on recorders, suggesting neither source alone provides a complete fire history. However, there was not much difference in the ability of more numerous unscarred and less numerous recorder trees to record complete histories of fire. Moreover, recorders have the same additional biases, as estimators of PMFI/FR, as do other multi-scarred trees, as reviewed above.

Targeting open-scarred trees often aims at trees with a cat-face or deep semicircular wound, which typically also means they are multi-scarred trees and qualify as recorders. In a study of a single fire in a California Sequoia grove, 68% of open-scarred trees were scarred in a 1797 fire, but only 20% of intact trees were scarred (Kilgore and Taylor 1979). Across many fires, in a California study, a significantly greater mean fraction (0.22) of oaks with open scars at the time of a fire had scars from the fire than did intact trees (0.09), but twice as many intact trees on the sites had scars since there were 5.5 times as many intact trees as trees with open scars (McClaran 1988). This pattern is similar to that of recorders. Mean CFI did not differ between open-scarred and intact trees at one site, but open-scarred trees had 27% fewer fire dates (McClaran 1988). Thus, targeting open-scarred trees thought to be better recorders of fires also leads to omission of fires and the other biases of multi-scarred trees.

Species targeting focuses on particular tree species thought to be better recorders of fire. For example, one might obtain fire scars from ponderosa pine trees on the edge of piñon-juniper woodlands, because the ponderosa are thought to have a better record, from a higher SF (e.g., Miller and Rose 1999). However, fires that burned the ponderosa likely did not penetrate into the woodlands much, if at all (Huffman et al. 2008), thus the apparent difference in SF may reflect real differences in burning rates. To avoid a targeting effect from assuming that the tree species with more scars has a more complete record, data can be acquired from piñon-juniper woodlands and adjusted for their lower scarring fraction. This is what the ATFI method allows, a separate SF for differing trees on the same site (Kou and Baker 2006a).

Individual-tree targeting of older trees for sampling occurs because older trees have a potentially longer record (Farris et al. 2013). This type of targeting may also occur if trees with multiple scars are targeted, since trees generally must get older before they have multiple scars. By definition, individual trees with long fire-scar records have a history of only low-severity fires at that tree, thus a targeted sample of only old trees is certain to indicate a long history of low-severity fire. When fire is moderate- to high-severity, evidence of fire severity on surviving older trees underestimates fire severity in the stand (Hessburg et al. 2007). A targeted sample of old trees in a landscape with trees of other ages thus provides strongly biased evidence about the fire severities that affected the stand.

<u>Targeting sampling areas in landscapes</u>

Targeting particular landscapes or parts of landscapes also leads to bias, generally toward CFI and ITFI estimates that are too short relative to PMFI/FR, since the methods of individual-tree targeting are also used at the landscape scale. Researchers seeking to reconstruct pre-EuroAmerican fire regimes may select parts of landscapes with concentrations of multi-scarred trees, recorders, open-scarred trees or catfaces, and old trees or old-growth forests. In almost 1/3 of the cases where targeting or lack of it was reported, researchers located plots specifically in these areas and in about 10% of cases researchers chose study areas with these concentrations (Table A). These plot locations and study areas may contain long fire records and many fire scars, and are attractive to researchers seeking long fire records (Farris et al. 2013). However, these parts of landscapes also are forests that had a predominance of low-severity fire and little to no mixed- or high-severity fire for hundreds of years, as most trees would otherwise be younger. As explained in the main text, researchers may target areas with abundant fire scars and omit or reduce sampling in areas that lack or have few scars, then also may inappropriately assume that fire history in areas with abundant fire scars also applies to areas with few or no fire scars.

In contrast, probabilistic sampling areas, particularly if appropriately small (e.g., 1 ha) may commonly lack scarred trees or have few. Heyerdahl (1997) sampled using plots located in a grid, thus without targeting sampling areas in landscapes, and found that scarred trees were lacking in more than half the plots at three study sites. These areas could in part have had few scars because of a low scarring fraction, but could also have been areas that really did not burn for a long period. If the latter, then omitting these long intervals, that are real, would bias results toward underestimating fire severity and bias estimated rates of low-severity fire toward shorter intervals. This kind of targeting is not clearly rejected by supporters of targeting (Farris et al. 2013 p. 1030), although they encourage "...clearly defining the inference space, not extrapolating to unrepresentative areas..." This kind of targeting did clearly include extrapolating to unrepresentative areas in past fire histories that are the subject of this paper. I am not singling out particular authors, as most used sampling methods that were common practice at the time, largely aimed at finding and sampling the best evidence (Farris et al. 2013).

However, targeting of old forests, that inherently have a history of low-severity fire, likely explains the unexpected findings of landscape analyses of fire history that did not use targeting. When an objective, large sample (303,156 ha) of historical dry forests was studied in the Pacific Northwest using early aerial photography, middle-aged forests resulting from mixed- and high-severity fires were found to have dominated historical landscapes and old, park-like forests, exclusively with low-severity fire, were found to have been comparatively uncommon (Hessburg et al. 2007 p. 7): "Moreover, old, park-like or similar ponderosa pine stand structures did not dominate the landscapes, and this was particularly perplexing because this was to be the signature outcome of frequent low severity fires." Similarly, spatially extensive reconstruction across landscapes using the early land surveys, found evidence of abundant denser and younger forests from mixed- and high-severity fire across dry forests in northern Arizona, the Colorado Front Range, and the Blue Mountains in Oregon, where previous fire-history studies had found predominantly low-severity fire and open, low-density old forests (Williams and Baker 2012). Finally, stand age data from the Forest Inventory and Analysis Program also showed that young and middle-aged forests, not park-like old forests, were most common historically in ponderosa pine and mixed-conifer forests across relatively undisturbed parts of the western USA (Odion et al. 2014). These studies with probabilistic sampling at the landscape scale show that targeting parts of landscapes containing old forests with abundant fire scars led to very substantial over-estimation of the historical extent of low-density old forests that predominantly had low-severity fire.

Unstudied fire severity in dry forests also inflates low-severity fire rates

Estimates from CFIs, ITFIs, and FRs likely often included all fire severities, not just low severity, and the low-severity rates alone are thus likely longer. Fire severity has been relatively infrequently studied in dry forests. Baker and Ehle (2003) found that only about 25% of fire-scar studies also collected the age-structure data needed to determine whether higher-severity fires occurred historically. Of the 335 cases in the merged dataset with data, 254 (74.3%) did not study fire severity, 80 (23.4%) did study fire severity, and 8 (2.3%) did not explain whether they studied fire severity. Most studies that did analyze fire severity did not distinguish fire severities when they reported fire rates (e.g., Taylor and Skinner 1998). Where fire severity was studied, some mixed- or high-severity fires were nearly always found, but few studies estimated PMFI or FR for the higher-severity fires. Thus, most fire-history studies provide estimates of rates for all fires combined, including low, moderate- and high-severity fires.

The potential effect of combined fire severities on estimated rates for low-severity fire can be illustrated by subtracting, using partitioning (Baker 2009), reported rates of moderate- to high-severity fire from rates of low-severity fire. Odion et al. (2014) reported historical rates of combined moderate- to high-severity fire ranged from 115-128 years in the eastern Cascades of Oregon to 319 years on the Mogollon Plateau. I used the full range of 115-319 years to remove the moderate- to high-severity component, and found that 10-year combined PMFI/FRs would have a 10.3-11.0 low-severity component, but 50-year combined PMFI/FRs would have a 59.3-88.5-year low-severity PMFI/FR after removing the moderate- to high-severity component (Table B). I did not apply an adjustment, for this fire-severity issue, to estimated PMFI/FRs because the adjustments are imprecise and have a large range, and because sites where fire severity was unstudied did not necessarily have higher-severity fires. Nonetheless, this finding illustrates the limitation of unstudied fire severity, and shows that many estimates of low-severity PMFI/FR are likely low estimates.

Table B. Partitioning combined fire rotations (FR) into components for low- versus moderate and high-severity fire for three example levels of combined fire rotations.

	10-year combined-severity PMFI/FR	25-year combined-severity PMFI/FR	50-year combined-severity PMFI/FR
a. Combined annual probability of fire (1/FR)	0.10000	0.04000	0.02000
UPPER LIMIT OF LOW-SEVERITY RANGE			
b. Annual probability of fire for moderate-high component of 115 years†	0.00870	0.00870	0.00870
c. Annual probability of fire for low-severity component, from a - b.	0.09130	0.03130	0.01130
d. Net fire rotation for low-severity component, from 1 / c.	10.95 years	31.95 years	88.50 years
LOWER LIMIT OF LOW-SEVERITY RANGE			

e. Annual probability of fire for moderate-high component of 319 years†	0.00313	0.00313	0.00313
f. Annual probability of fire for low-severity component, from a - e.	0.09687	0.03687	0.01687
g. Net fire rotation for low-severity component, from 1 / g.	10.32 years	27.12 years	59.28 years
NET ESTIMATED LOW-SEVERITY RANGE	10.32-10.95 years	27.12-31.95 years	59.28-88.50 years

Notes

† The 115-319 year range for moderate- to high-severity fire rotation in dry forests is from Odion et al. (2014)

Human-started wildfires expand the fire niche across the United States

Edited by Gregory P. Asner, Carnegie Institution for Science, Stanford, CA, and approved January 6, 2017 (received for review October 20, 2016)

The economic and ecological costs of wildfire in the United States have risen substantially in recent decades. Although climate change has likely enabled a portion of the increase in wildfire activity, the direct role of people in increasing wildfire activity has been largely overlooked. We evaluate over 1.5 million government records of wildfires that had to be extinguished or managed by state or federal agencies from 1992 to 2012, and examined geographic and seasonal extents of human-ignited wildfires relative to lightning-ignited wildfires. Humans have vastly expanded the spatial and seasonal "fire niche" in the coterminous United States, accounting for 84% of all wildfires and 44% of total area burned. During the 21-y time period, the human-caused fire season was three times longer than the lightning-caused fire season and added an average of 40,000 wildfires per year across the United States. Human-started wildfires disproportionally occurred where fuel moisture was higher than lightning-started fires, thereby helping expand the geographic and seasonal niche of wildfire. Human-started wildfires were dominant (>80% of ignitions) in over 5.1 million km^2, the vast majority of the United States, whereas lightning-started fires were dominant in only 0.7 million km^2, primarily in sparsely populated areas of the mountainous western United States. Ignitions caused by human activities are a substantial driver of overall fire risk to ecosystems and economies. Actions to raise awareness and increase management in regions prone to human-started wildfires should be a focus of United States policy to reduce fire risk and associated hazards.

anthropogenic wildfires | fire starts | ignitions | modern fire regimes | wildfire causes

The United States has experienced some of the largest wildfire years this decade, with over 36,000 km^2 burned in 2006, 2007, 2012, and 2015 (1). There is national and global concern over how fire regimes have changed in the past few decades and how they will change in the future (2–4). In the western United States, there is strong evidence that regional warming and drying, including that directly attributed to anthropogenic climate change, are linked to increased fire frequency and size and longer fire seasons (5–9). However, the role that humans play in starting these fires and the direct role of human-ignitions on recent increases in wildfire activity have been overlooked in public and scientific discourse because of the difficulty in ascribing a cause, either human- or lightning-started (10). Humans primarily alter fire regimes in three ways: changing the distribution and density of ignitions, shifting the seasonality of burning, or altering available fuels (2, 3). Geographic variability in regional and continental-scale fire activity in the United States is strongly tied to proxies for these human-caused changes, including population and road density, and different land-use and development patterns (10–15). Although changing climate and fuels also influence fire regimes across the United States (10, 16, 17), there can be no fire without an ignition source. Here, we explore the role that human-started wildfires play in modern United States fire regimes.

Ignitions are often presumed to be saturated (18, 19), and therefore have limited ability to predict fire activity. However, several studies suggest that humans play an important role in redistributing ignitions (20–22), particularly where lightning rarely occurs or where lightning is not concurrent with dry conditions (23). The human–fire connection in the modern era appears strongest at intermediate levels of development, as fires become less likely in the landscape beyond a certain population density, level of urbanization, or dependence on fossil fuels (11, 13, 24). Overall, humans expand the spatial and temporal "fire niche" by introducing ignitions into landscapes when fuels are sufficiently dry enough to ignite and carry fire, but when lightning is rare. Human ignitions are therefore a critical force acting to expand how the fire niche is realized across United States ecoregions.

National-scale analysis of human alteration of the fire niche is critical given that the annual expense of fighting wildfires has exceeded $2 billion in recent years, and the accrued direct and indirect impacts of wildfire on infrastructure and communities could be 30 times that amount (25). Policies that govern wildfire management and response are also directed at the national level, demanding analysis at a national scale (10, 22, 26). Although recent human influence on fire regimes has been studied at local (13) to regional scales (14), human influence nationally remains poorly understood (10). National policies can strongly influence fire regimes (27) and, with sufficient information on human ignitions, policy directives could target human behavior in ways that remediate increasing trends in wildfire risk.

Here, we ask how human ignitions have altered the spatial extents, seasonality, and temporal trends in wildfire across the coterminous United States. We analyze over 1.5 million records of both human- and lightning-started fires in the United States from

Significance

Fighting wildfires in the United States costs billions of dollars annually. Public dialog and ongoing research have focused on increasing wildfire risk because of climate warming, overlooking the direct role that people play in igniting wildfires and increasing fire activity. Our analysis of two decades of government agency wildfire records highlights the fundamental role of human ignitions. Human-started wildfires accounted for 84% of all wildfires, tripled the length of the fire season, dominated an area seven times greater than that affected by lightning fires, and were responsible for nearly half of all area burned. National and regional policy efforts to mitigate wildfire-related hazards would benefit from focusing on reducing the human expansion of the fire niche.

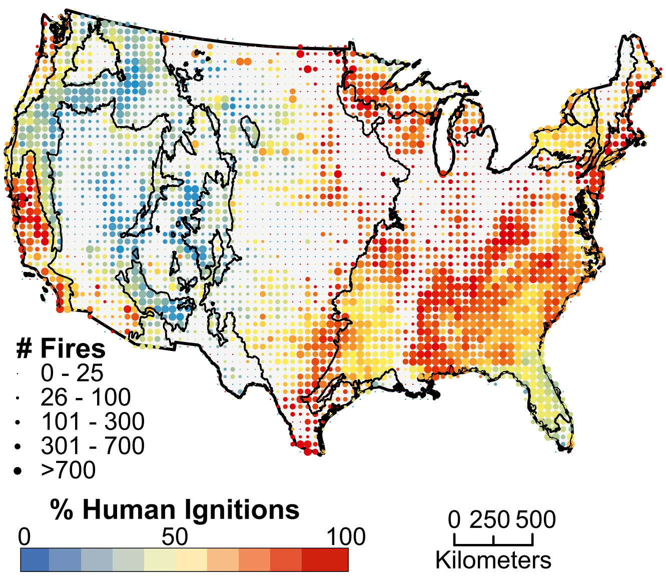

Fig. 1. The total number of wildfires (dot size) and the proportion started by humans (dot color: red indicating greater number of human started fires) within each 50 km × 50-km grid cell across the coterminous United States from 1992 to 2012. Black lines are ecoregion boundaries, as defined in the text.

1992 to 2012 (28). All of these wildfires necessitated an agency response to manage or suppress them, and therefore posed a threat to ecosystems or infrastructure; this record does not include intentionally set prescribed burns or managed agricultural fires. To our knowledge, this is the most comprehensive assessment of the role of human-started wildfires across the United States over the past two decades. We compare: (*i*) the spatial extents of human- vs. lightning-started wildfires, (*ii*) the seasonality of human vs. lightning wildfires, (*iii*) the climate niche for human- vs. lightning-started wildfires, and (*iv*) 21-y trends in large human vs. lightning wildfires. Our analysis documents the pronounced expansion of wildfire extent, seasonality of wildfires, and increasing numbers of large wildfires through time as a result of human-related ignitions across the United States.

Human-Related Ignitions Vastly Expanded the Extent of Wildfire

Human-started wildfires represented 84% of the 1.5 million wildfires included in this analysis (n = 245,446 lightning-started fires; n = 1,272,076 human-started wildfires). The eastern United States and western coastal areas were dominated by human-started wildfires, whereas lightning-started fires dominated the mountainous regions of the western United States (Fig. 1, Table 1 and Table S1). Here we define a fire regime as dominated by either human or lighting ignitions when one cause accounts for more than 80% of the number of fires in a given 50 × 50-km grid cell. Based on this definition, 5.1 million km^2, or 60% of the total land area of the coterminous United States, was dominated by human-started wildfires, whereas only 0.7 million km^2, or 8% of the area, was dominated by lightning-started fires. In addition to expanding the numbers of fires, humans also expanded the total area burned. Human-started wildfires burned a total of 160,274 km^2, or ~44% of the total area burned from 1992 to 2012 (Table 1).

Human-Related Ignitions More Than Tripled the Length of the Wildfire Season

Human ignitions dramatically expanded the wildfire season in the United States, particularly during spring. The length of the human-started wildfire season [defined as the interquartile range (IQR) of human-ignited fires] was 154 d, more than triple that of the lightning wildfire season (IQR = 46 d) (Fig. 2 and Table 1). This national-scale expansion is driven by earlier (spring) human-started fires in eastern ecoregions coupled with later (late summer or fall) human-started fires in western ecoregions (Table S2). The median discovery date for human-started fires was over 2-mo (May 20th) earlier than lightning-started fires (July 25th). Summed across the 21-y record, the most common day for human-started fires by far was July 4th, US Independence Day, with 7,762 fires starting that day over the course of the record (Fig. 2), whereas, the most common day for lightning-started fires was July 22nd. Of all lightning-ignited fires, 78% occurred in the summer (June–August), 9% in the spring (March–May), and 12% in the fall (September–November). In contrast, human-ignited wildfires were more evenly distributed throughout the year, with 24% in summer, 38% in spring, 19% in fall, and 19% in winter. This pronounced expansion of the wildfire season was also evident spatially (Fig. 3), with human-ignited wildfires occurring predominantly in spring in the eastern United States and in the fall and winter in Texas and the Gulf states. See Table S1 for state-level analysis. When lightning-started fires were rare (<5% and >95% quantile; i.e., before May 13th or after September 16th), humans ignited 842,289 wildfires, effectively increasing the number of wildfires 35-fold compared with the 24,081 lightning-ignited wildfires during these spring, fall, and winter seasons.

Table 1. The number of wildfires, total burned area (ha), and fire season length (IQR, in days), by ecoregion (ordered by percent human-caused fires) and within the coterminous United States from 1992 to 2012

SUSTAINABILITY SCIENCE

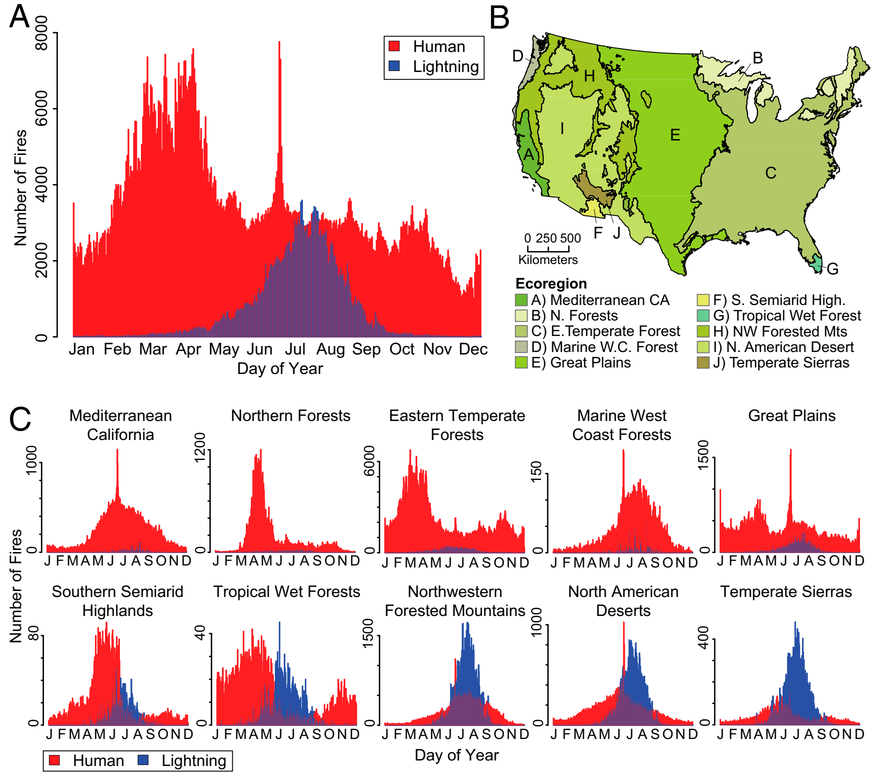

Fig. 2. Frequency distributions of human and lightning-caused wildfires by Julian day of year. (*A*) Frequency distribution of wildfires across the coterminous United States from 1992 to 2012 (n = 1.5 million); (*B*) map of United States ecoregions; (*C*) frequency distributions of wildfires by ecoregions, ordered by decreasing human dominance.

Human-Driven Expansion of the Fire Niche

Humans greatly expanded the natural fire niche (Fig. 4), which we calculated as the co-occurrence of the average monthly lightning density and 1,000-h dead fuel moisture. Regions and seasons of moderate to high lightning-started fire density (>0.4 fires per 1,000 km^2 per month) had a median lightning-strike density of 0.19 (IQR: 0.065–0.57) strikes per square kilometer per month and a median 1,000-h fuel moisture of 11.9% (IQR: 9.25–15.6%) (Fig. 4*A*). In contrast, regions and seasons of moderate to high human-started fire density (>0.4 fires per 1,000 km^2 per month) had a median lightning-strike density of only 0.11 (IQR: 0.025–0.39) strikes per square kilometer per month and a median 1,000-h fuel moisture of 17.8% (IQR: 15.95–19.25%) (Fig. 4*B*). The median fuel moisture and lightning conditions when human-started wildfires occurred were significantly different from those values for lightning-started fires (P < 0.0001). Areas and months of moderate to high human-caused fire density had approximately 40% fewer lightning strikes, and nearly 50% higher fuel moisture levels (based on median values) than for moderate to high lightning-caused fire density. Additional exploration of the fire niche for human-started and lightning-started fires relative to lightning density, fuel moisture, and net primary production (NPP), a proxy for fuels, is provided in Figs. S1 and S2.

Increasing Trends in Large Human-Started Wildfires

During the 21-y time period, there were significant increasing trends in large wildfires ignited by both lightning (n = 4,312; Theil-Sen estimated slope = 12.2; P = 0.001) and humans (n = 4,143; Theil-Sen estimated slope = 3.6; P = 0.004) (Fig. S3). There was a strong dichotomy in human vs. lightning trends seasonally (Fig. 5). Overall trends in lightning-caused fires were primarily driven by increasing numbers of large summer fires (Fig. 5*B*), whereas overall trends in human-caused fires were primarily driven by increasing numbers of large spring fires (Fig. 5*D*). Spatially, lightning-caused fires increased the most in the Northwest Forested Mountains ecoregion (Fig. S4*A*), whereas human-caused wildfires increased the most in the Great Plains ecoregion (Fig. S4*B*).

Discussion

Humans, the keystone fire species (29), play a primary role in spatially and temporally redistributing ignitions and resulting wildfires. We document that over 84% of the government-recorded

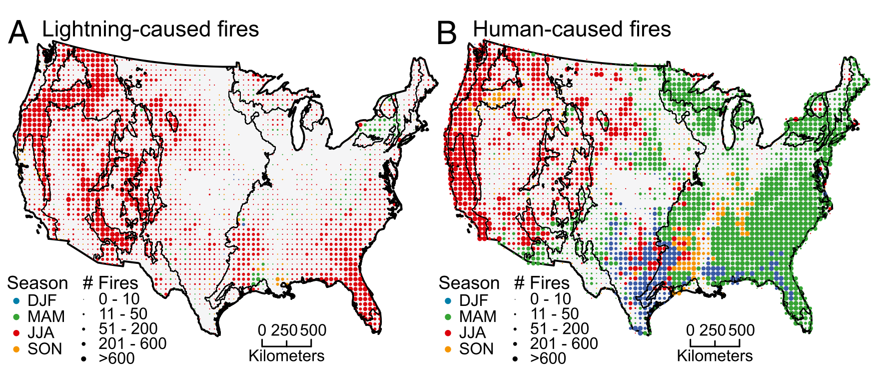

Fig. 3. Comparison of seasonality for (*A*) lightning- vs. (*B*) human-ignited wildfires. Human ignitions expand the seasonal fire niche considerably into spring and fall months. Colors show the season with the maximum ignitions caused by lightning and human within each 50 km × 50-km grid cell. Size of dot indicates the number of unique lightning and human fires between 1992 and 2012. Ecoregion boundaries are overlaid for visualization.

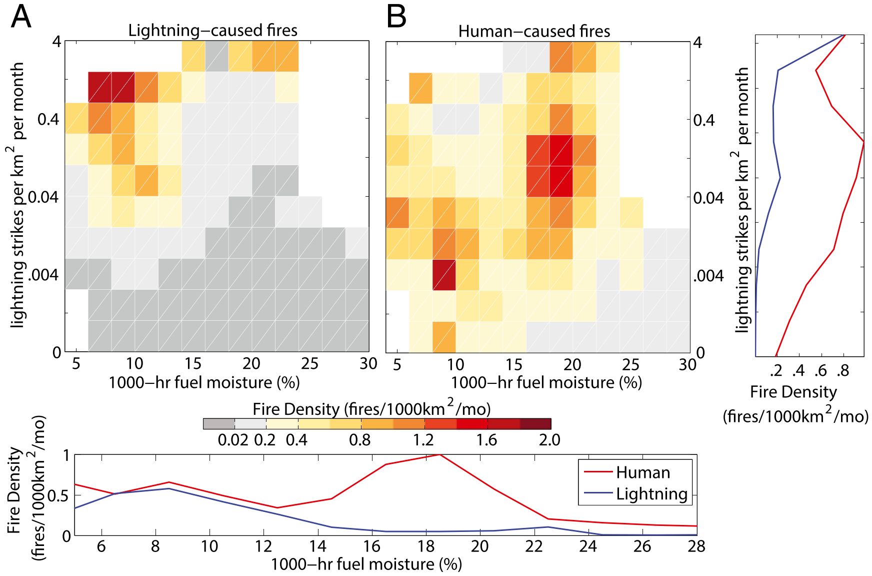

Fig. 4. Human vs. lightning fire niche relative to fuel moisture and lightning density, with greatest resulting wildfire density represented by dark red. (*A*) Lightning-started fires occur in areas with high lightning-strike density and dry fuels. (*B*) Human-started wildfires expand the fire niche to include areas with low lightning-strike density as well as areas with higher fuel moisture. Graphs on the bottom and far right show histograms of 1,000-h dead fuel moisture and lightning strikes, respectively, for human- and lightning-started fires.

wildfires were started by people from 1992 to 2012. Sixty percent of the total land area of the coterminous United States was dominated by human-started wildfires, whereas only 8% of the area was dominated by lightning fires. Humans tripled the length of the wildfire season, extending burning into the spring, fall, and winter months. During the spring, fall, and winter, people added more than 840,000 wildfires, a 35-fold increase over the number of lightning-started fires in those seasons. This expansion of the fire-niche was caused by human-related ignitions under higher fuel moisture conditions, compared with lightning-started fires. Moreover, during this 21-y record, large human-started wildfires increased significantly.

There was a strong national east–west dichotomy in the spatial distribution of human-started wildfires. Although human-started wildfires were pervasive across the United States (Fig. 1), the expansion of human-started wildfires relative to lightning-started fires was most dramatic in the eastern United States and central and southern California (Figs. 1 and 2*C*). Recent work for California confirms the important role of humans, with anthropogenic variables explaining half of the variability in fire probability over the past four decades (30). In contrast, lightning-started fires were found primarily in the intermountain west and Florida and occurred predominantly in the summer, reflecting national lightning strike patterns (31) (Fig. 2*C*). This finding supports other studies of human vs. lightning ignition sources that have found an important distinction between eastern and western United States fire patterns (10, 21) and drivers (32). Some explanations for this distinction include higher population and housing densities, lower proportions of public land, and more extensive land use and development in the eastern United States (33, 34), all of which could lead to more sources of anthropogenic ignitions. Synchrony between lightning activity and the seasonal nadir of fuel moisture in the western United States also likely contributes to these geographic differences. However, even with a projected increase in the number of lightning strikes as a result of anthropogenic climate change (50% by 2100) (35), humans would still remain the dominant ignition source across the majority of the United States land area. The majority of the wildfires requiring agency suppression in the east can be attributed to escaped fires from debris burning occurring in the spring months (or winter in Texas and the Gulf Coast) (Fig. 3). Between 1992 and 2012, wildfires caused by debris burning tended to be small (median

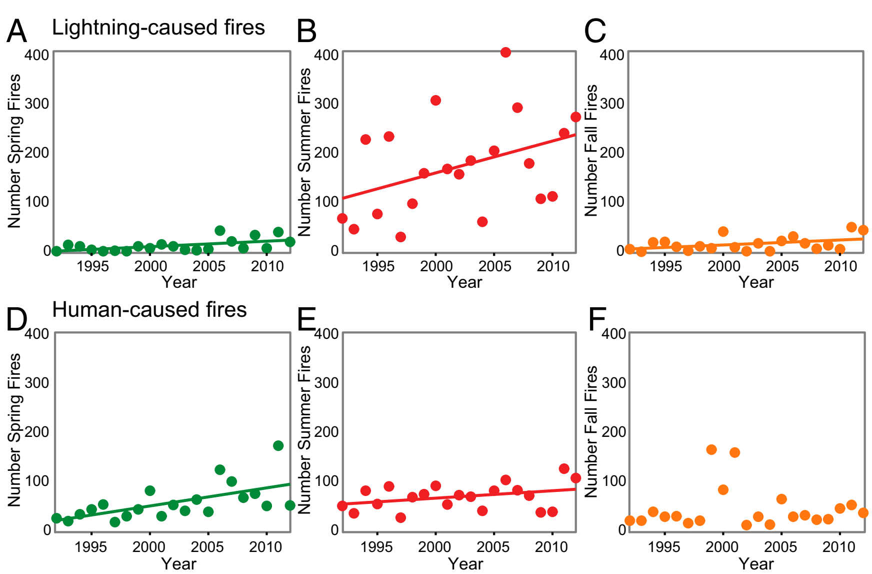

Fig. 5. Trends in the number of large wildfires verified by MTBS records from 1992 to 2012 for lightning-started fires (*A*–*C*) vs. human-started fires (*D*–*F*) in the spring (green: *A* and *D*), summer (red: *B* and *E*), and fall (orange: *C* and *F*). Where trend lines are shown, Theil-Sen estimated slopes are significantly different from zero ($P < 0.05$).

fire size 0.4 ha, IQR: 0.14–1.62 ha), but still an important source of risk to surrounding ecosystems. At finer scales, there are also notable patterns in human- vs. lightning-started wildfires (Fig. S5). Increased wildfires can follow road networks (36), the wildland–urban interface (13), and boundaries between agricultural and forested areas (37), highlighting just a few examples of how human activities and cultural drivers provide ignitions that substantially change the distribution of fire across the United States (38).

Our findings reinforce the strong imprint of people on fire regimes through changes in wildfire seasonality, which has been documented globally (39). In the past few decades, early onset of warmer and drier conditions has promoted greater fire activity across the western United States (6, 7, 40). However, our study highlights the equally important role of human ignitions in changing modern fire regimes by increasing the fire season length to encompass the entire year. The vast majority (78%) of lightning-started fires occurred during the summer months, whereas 76% of human-started fires occurred during the spring, fall, and winter months. Moreover, this trend varies substantially by ecoregion, reflecting again the principle dichotomy between the eastern and western United States (Fig. 3). Human-started fires extend the fire season earlier in the east, and later in the west (Fig. 3 and Table S2). Observations suggest that climate change has extended the duration of the fire weather season across most of the globe, including parts of the United States by a couple of weeks over the past three decades (5, 9), whereas we show that human ignitions in the United States increased the length of the fire season by more than three mo. There was also a notable mark of American culture on the distribution of wildfires, with the peak day of wildfires occurring on July 4th, concurrent with Independence Day fireworks displays (Fig. 2). Indeed, Americans start over twice as many wildfires on July 4th as any other summer day. A similar cultural mark has also been demonstrated globally with a marked decline in wildfires on Sunday compared with other weekdays (41).

Thus, at the national scale, human ignitions dramatically expand the spatial and seasonal niche of fire. The key components that define the fire niche are ignition sources, fuel mass, and desiccation. By exploring the fire niche along these axes, our results show that lightning fires are primarily constrained to areas with a lightning-strike density of greater than 100 strikes per grid cell per month (0.04 strikes/km^2 per month) and are concurrent with drier fuels (< 15% fuel moisture) (Fig. 4). Human ignitions expand fires into regions with higher fuel moisture (Fig. 4) and higher NPP (Figs. S1 and S2), suggesting that humans create sufficient ignition pressure for wetter fuels to burn. As a consequence, human ignitions have expanded the fire niche into areas with historically low lightning-strike density, such as Mediterranean California, or low concurrence of lightning and dry conditions, such as Eastern Temperate Forests (Fig. 1).

Over the past two decades, there was a significant increase across the United States for both human- and lightning-caused large fires (Fig. S3). The significant increase in large lightning fires is driven primarily by fires in summer months (Fig. 5) in the Northwest Forested Mountains ecoregion of the western United States (Fig. S4). This finding is consistent with other studies that have demonstrated an increase in large fires across the western United States (6, 7, 40), likely as a consequence of changes in climate and fuels rather than ignitions. In contrast, the significant trend in human-caused fires is primarily driven by an increase in large fires during spring months (Fig. 5) in the Great Plains ecoregion of the United States (Fig. S4). This increasing trend suggests that earlier springs as a result of climate change (42, 43) may be interacting with human ignition sources to increase the risk of large fires in the central United States.

The strong year-to-year variability in human ignitions (Fig. S3 and S4) may reflect the degree to which human choices can affect fire regimes. However, interannual climate variability also influences fuel moisture, NPP, and short-term weather conditions that enable the spread of human-ignited wildfires (44). There was a significant temporal correlation between large human- and lightning-started fires (R = 0.75). This pattern has been observed previously in the western United States (23) and suggests that large-scale climate drivers affect the frequency of both human- and lightning-caused fires. It is unknown how human actions will be affected by hotter and drier conditions, potentially increasing or decreasing ignitions from land use, recreation, and other sources. Increased public awareness and focused policy and management, particularly in years with elevated fire risk associated with climatic anomalies, are needed to reduce the number of human-caused ignitions.

In conclusion, we demonstrate the remarkable influence that humans have on modern United States wildfire regimes through changes in the spatial and seasonal distribution of ignitions. Although considerable fire research in the United States has rightly focused on increased fire activity (e.g., larger fires and more area burned) because of climate change, we demonstrate that the expanded fire niche as a result of human-related ignitions is equally profound. Moreover, the convergence of warming trends and expanded ignition pressure from people is increasing the number of large human-caused wildfires (Fig. 5). Currently, humans are extending the fire niche into conditions that are less conducive to fire activity, including regions and seasons with wetter fuels and higher biomass (Figs. 3 and 4). Land-use practices, such as clearing and logging, may also be creating an abundance of drier fuels, potentially leading to larger fires even under historically wetter conditions. Additionally, projected climate warming is expected to lower fuel moisture and create more frequent weather conditions conducive to fire ignition and spread (45), and earlier springs attributed to climate change are leading to accelerated phenology (42). Although plant physiological responses to rising CO_2 may reduce some drought stress (46), climate change will likely lead to faster desiccation of fuels and increased risk in areas where human ignitions are prevalent.

Uncertainty remains regarding how anthropogenic climate change will alter wildfire activity geographically and seasonally (47, 48), particularly in areas where human-caused fires dominate. Moreover, the current wildland–urban interface, where houses intermingle with natural areas, constitutes 9% of the United States total land area (33) but is projected to double by 2030, predominantly in the intermountain West (49). This expected development expansion will increase not only ignition pressure, but also the vulnerability of new infrastructure. Human-driven expansion of the spatial and temporal distribution of ignitions makes national- and regional-scale policy interventions and increased public awareness critical for reducing national wildfire risk.

Materials and Methods

For this analysis, we used the publically available US Forest Service Fire Program Analysis-Fire Occurrence Database (FPA-FOD) (28). This comprehensive dataset includes United States federal, state, and local records of wildfires (both on public and private lands) that were suppressed from 1992 to 2012, a total of ~1.6 million records. Previous studies have focused on the western United States (20), federal lands (22), or records from just one agency (21). Each entry includes at minimum the location, discovery date, and cause of the wildfire. We excluded 114,191 wildfires with an unknown cause and analyzed the spatial, seasonal, and temporal patterns of human- vs. lightning-started wildfires. In total, 1,517,522 wildfires were included in the analysis. Human-started wildfires were caused by a variety of sources, including the US Forest Service-designated categories of equipment use, smoking, campfire, railroad, arson, debris burning, children, fireworks, power line, structure, and miscellaneous fires (28). Spatially, we calculated the proportion of human- vs. lightning-caused wildfires within equal-area 50 × 50-km grid cells across the coterminous United States. This grid size corresponds roughly to the size of an average United States county. For each grid cell, we calculated the season (winter, spring, summer, or fall) when the majority of human-caused and lightning-caused wildfires were started. All spatial analyses were conducted in the Albers-Conical equal-area projection. To determine the seasonal distribution of wildfires, we plotted the distribution of human- and lightning-started fires by the day of year for the coterminous United States and for individual ecoregions. We used the level 1 ecological regions of North America, developed by the Commission for Environmental Cooperation (50). We calculated the length of the human- and lightning-caused fire seasons as the IQR of the Julian day of recorded fire ignition: that is, the difference between the first and third quartiles.

We determined how humans expanded the fire niche by comparing the lightning-strike density (i.e., natural ignition pressure) and fuel-moisture conditions under which actual human- and lightning-started fire events occurred. We obtained daily 1,000-h dead fuel moisture data from the surface meteorological data (51) on a 4-km grid from 1992 to 2012, and computed monthly averages across the 21-y study period. We obtained 4-km gridded monthly lightning-strike data from the Vaisala National Lightning Detection Network (https://www.ncdc.noaa.gov/data-access/severe-weather/lightning-products-and-services) and averaged the data over the 21-y study period. To account for fuel limitations, we also explored the fire niche as a function of fuel amount (approximated by NPP). We used MODIS mean annual NPP data (1-km resolution, from 2002 to 2015) (52) for this purpose. These three datasets were aggregated to the common 50×50-km grid cell. We calculated the number of human- and lightning-started fires by grid cell using the FPA-FOD dataset (28). We excluded any grid cells from subsequent analyses that did not report at least one lightning-caused or human-caused wildfire over the period of record. We tested whether fire niche expansion (as determined by fuel moisture and lightning-strike density) caused by human ignitions was significant based on Mann–Whitney tests between human- vs. lightning-started fires.

To assess trends in human- vs. lightning-caused wildfires through time, we used only large fires that were independently verified by the Monitoring Trends in Burn Severity (MTBS) project (53). We specifically focused on these large fires (>400 ha in the west, >200 ha in the east; n = 8,455) for comparability with previous research, which has examined temporal trends in the western United States and the link to climate warming (6, 7, 40), but has not investigated the relative contribution of human-started fires at a national scale. In addition to overall temporal trends, we tested for significant trends by ignition source versus season (spring, summer, fall) and versus ecoregion based on the level I ecological regions of North America (50). We explored a similar analysis using all available FPA-FOD data, but changes in reporting frequency through time for some states precluded a robust temporal analysis. We tested for trends in wildfire numbers through time using the nonparametric Theil-Sen estimator (54) and tested for trend significance using nonparametric Mann–Kendall tests (55).
