Technically, a fire behavior fuel model—Anderson (1982) or Scott and Burgan (2005)—is a set of fuelbed inputs required by fire behavior modeling systems that use the Rothermel (1972) fire spread model. More practically speaking, a fire behavior fuel model represents a range of fuelbed conditions (e.g., load, depth, surface-area-to-volume ratios) in which fire behavior may be expected to respond similarly to changes in fuel moisture, slope, and wind speed (Figure 13). In this sense, a fire behavior fuel model is not so much a model of fuels as it is a model of fire behavior.

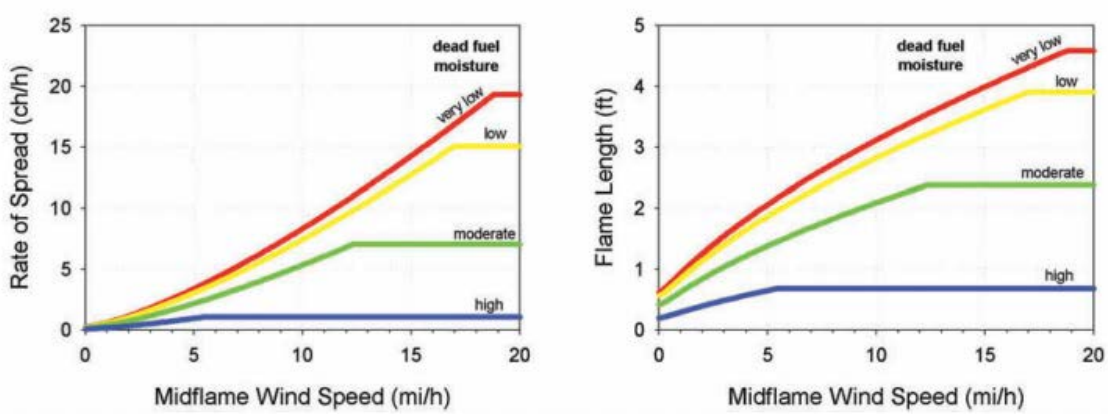

Figure 13. Differences in rate of spread and flame length by dead fuel moisture content and wind speed for fuel model Timber-Understory 1 (Low Load Dry Climate Timber-Grass-Shrub; Scott and Burgan 2005).

Like succession class (Chapter 4), all LANDFIRE surface fuel data products are mapped using an expert-opinion, rule-based approach, where mapping rules are based on unique combinations of: existing vegetation type, cover, and height; biophysical setting; and disturbance (Chapters 3 & 4). Fire behavior fuel model mapping rules were developed by fire and fuel specialists through a series of fuel calibration workshops held across the United States. The purpose of these workshops was to elicit regional expertise about fire behavior characteristics (i.e., how fire burns) in various vegetation types and structures. The calibration workshops were conducted at the extent of a LANDFIRE map zone or multiple adjacent zones. There are 80 LANDFIRE map zones across the continental U.S., Alaska, and Hawaii, ranging in size from 4 to 60 million acres (Figure 2).

The LANDFIRE total fuel change tool (formally known as ToFu Δ) (LFTFCT 2011) is a custom ArcGIS toolbar that links to the national fuel mapping rules through a Microsoft Access database (Figure 14). This tool, originally developed for use in the national calibration workshops, can now be downloaded from the Wildland Fire Management Research, Development and Application website and is highly useful in local LANDFIRE fuel data critiques.

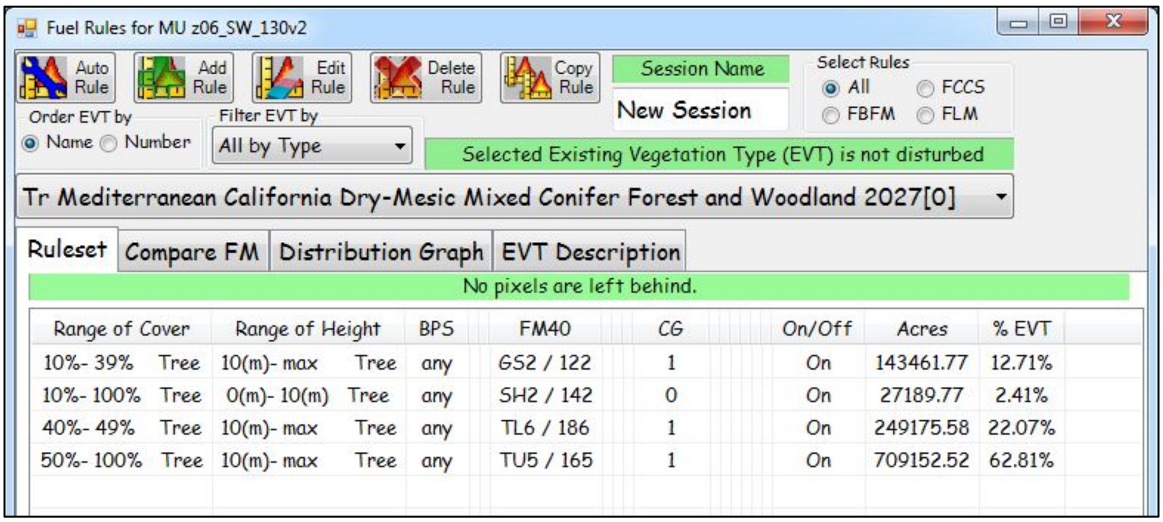

Figure 14. Example LANDFIRE Total Fuel Change Tool (LFTFCT) rule set. The LFTFCT is a custom ArcGIS toolbar that links to the LANDFIRE fuel mapping rules through a Microsoft Access database.

Canopy Fuels

The LANDFIRE canopy fuel data products include canopy base height, canopy bulk density, forest canopy cover, and forest canopy height. Forest canopy cover and canopy height values represent the midpoint of the existing vegetation cover and height data layer classes, respectively. These values are used in some fire behavior modeling systems as variables in predicting dead woody fuel moisture, wind reduction, and crown fire spotting potential. All four variables are required to model crown fire behavior using U.S. fire behavior modeling systems.

Canopy base height is defined as the lowest height above the ground at which there is sufficient available fuel (i.e., ≤ 0.25 inch diameter) to propagate fire vertically through the canopy. It is important to differentiate canopy base height—which is a property of the group of trees represented by the pixel—from *crown* base height, which is a property of an individual tree. Canopy base height is an important variable for fire behavior modeling, as it is used to predict whether crown fire initiation is possible under a given set of environmental conditions (Scott and Reinhardt 2001; Scott 2012). Prior to LANDFIRE 2012, canopy base height was mapped based on plot level averages. Various combinations of existing vegetation type, cover, and height values were crosswalked to an average canopy base height value of associated plots. For the LANDFIRE 2012 canopy base height data layer, a predictive modeling approach was implemented where field referenced plot data were used to develop regression equations based on statistical relationships between canopy base height and existing vegetation type, cover, and height (USGS 2010).

Canopy bulk density is the mass of available canopy fuel per unit canopy volume (Scott and Reinhardt 2001). Like canopy base height, canopy bulk density is a property of a group of trees—*crown* bulk density is a property of an individual tree. In fire behavior modeling, canopy bulk density is used to predict whether an active crown fire is possible under a given set of environmental conditions assuming that a crown fire has initiated (Scott and Reinhardt 2001; Scott 2012). LANDFIRE maps canopy bulk density using a predictive modeling approach based on forest canopy cover, forest canopy height, and membership to a pinyon-juniper existing vegetation type as input to a generalized linear model (Reeves et al. 2009).

In deciduous forest vegetation types—typically not considered prone to crown fire—LANDFIRE assigns canopy base height and canopy bulk density values that prevent fire behavior modeling systems from predicting crown fire. Forest canopy cover and forest canopy height values are still mapped to account for the canopy's effect on fuel moisture and wind reduction.

Fuel Updates

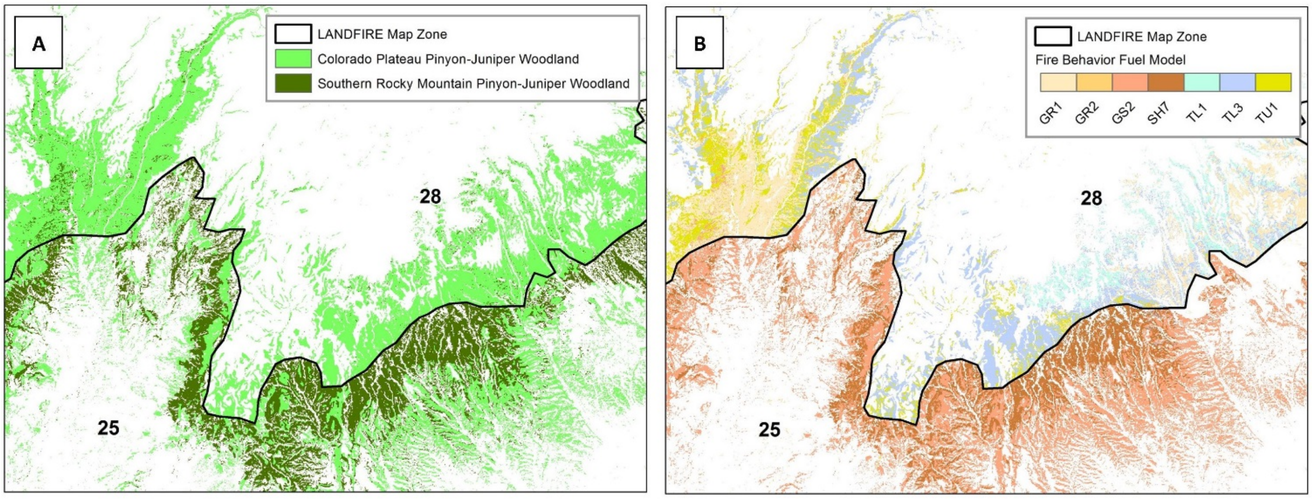
Because surface and canopy fuel mapping rules are tied to existing vegetation type, cover, and height, updates to existing vegetation data due to growth and vegetation succession automatically account for updates to fuels in non-disturbed areas. Whether an update to the fuel data layers occurs or not depends on the magnitude of the change and the threshold values in the mapping rules.

Rules for disturbed areas are independent of rules for non-disturbed areas so that the disturbance type, severity, and time-since-occurrence can be taken into account in combination with the post-disturbance vegetation characteristics, including unique lifeform and species specific disturbance response as discussed in the previous sections. The one-year time-since-disturbance category is used by LANDFIRE to update the immediate post-fire effects to canopy fuels but not used in the assignment of post-disturbance fire behavior fuel model. Fire behavior fuel model is the same for the one-year and two- to five- year time-since-disturbance categories, which are considered to represent the second growing season after the event (C. Martin, personal communication, July 10, 2015).

Considerations

Map Zone Boundaries

As mentioned earlier, fire behavior fuel model mapping rules are developed for individual map zones or groups of adjacent zones based on unique combinations of existing vegetation type, cover, and height; biophysical setting; and, disturbance. It is common to find differences in mapping rules between adjacent map zones that may lead to an "artificial edge" at the zone boundary (Figure 15). In situations where your analysis area overlaps more than one LANDFIRE map zone, a primary consideration is whether there are differences in mapping rules between the zones. If so, determine whether those differences are legitimate or if the rules from one zone more appropriately fit the analysis area as a whole. If working in an area with pinyon-juniper vegetation types, a specific mapping rule issue to watch for is whether or not there are differences between zones in the assignment of canopy fuels. In some cases, the rules for one map zone will consider the canopy fuels in pinyon-juniper vegetation types as part of the surface fuel model, while the rules for an adjacent map zone will not. This may lead to prediction of crown fire on one side of the zone boundary and surface fire on the other. The discrepancies are due to differences in mapping methodology rather than actual fire behavior potential. There may be valid reasons for each case but consistency should be strived for when an analysis area intersects multiple map zones, to ensure consistent interpretation of the results across the entire analysis area.



Existing Vegetation Type	Zone 28				Zone 25			
	Tree Cover (%)	Tree Height	FM	CG	Tree Cover (%)	Tree Height	FM	CG
Colorado Plateau Pinyon-Juniper Woodland	10-29	Any	GR1	1	10-19	Any	GR2	0
	30-39	Any	TU1	1	20-49	Any	GS2	0
	40-59	Any	TL3	1	50-100	Any	TL3	1
	60-100	Any	TL1	1	-	-	-	-
Southern Rocky Mountain Pinyon-Juniper Woodland	10-19	Any	GR2	1	10-29	Any	GS2	0
	20-59	Any	GS2	1	30-49	Any	SH7	0
	60-100	Any	TL3	1	50-100	Any	TL3	1

Figure 15. Example of variation in fire behavior fuel mapping rules by existing vegetation type and map zone. Panel A shows the existing vegetation type at the map zone boundary; panel B shows the fire behavior fuel model. FM refers to the standard Fire Behavior Fuel Model (Scott and Burgan 2005). CG refers to the canopy guide feature in the LANDFIRE Total Fuel Change Tool that controls how canopy fuels are mapped.

Multiple inconsistencies between map zones can be seen in Figure 15. The predominant pinyon-juniper existing vegetation type in map zone 28 is Colorado Plateau pinyon-juniper woodland; in map zone 25 it is southern Rocky Mountain pinyon-juniper woodland (Figure 15A). The fire behavior fuel model mapping rules for these two vegetation types vary both by type and by map zone, resulting in the obvious difference in fuel model seen at the boundary (Figure 15B). Furthermore, in map zone 28, the rules for both vegetation types include the assignment of canopy fuels (i.e., canopy guide of 1); in map zone 25 the rules do not assign canopy fuels to pixels with less than 50% canopy cover, indicating that the trees are part of the surface fuel stratum. This inconsistency forces a different interpretation of fire behavior modeling results for each map zone.

Application Scale and Location

As stated earlier, fire behavior fuel model mapping rules were developed at regional workshops for application to individual, or groups of adjacent, map zones. While these rules may be appropriate at this scale, they may need to be adjusted for application at finer scales. In other words, the “best fit” for an entire map zone may be a compromise between different parts of the zone. For finer-scale applications, fire behavior fuel model mapping rules should be locally critiqued whenever possible. We recommend doing this in a workshop setting, where local specialists with expertise in local fire behavior critique the national mapping rules and make adjustments as needed. Remember, the objective is to choose the fire behavior fuel model that most appropriately simulates the observed or expected fire behavior under a range of fire-environment conditions. It is therefore invaluable to have workshop participants who have seen fire burn under a range of conditions in the local vegetation types.

Another consideration common in more arid locations is whether the fuel models that are appropriate under a typical, or average, yearly weather scenario are appropriate in an atypical scenario. For example, in a typical year, fire behavior in many desert ecosystems may be best represented using a shrub fire behavior fuel model. However, in a year when an unusually wet winter is followed by an influx of annual grasses, the primary carrier of fire will be the herbaceous component and thus fire behavior would be better represented using a grass or grass-shrub fuel model. In this case, two separate versions of fuel data layers could be created to represent the different fuel scenarios.

Similarly, areas with a heavy deciduous tree component may experience very different fire behavior depending on the time of year. In fall, winter, and spring the leaves have fallen from deciduous trees, therefore adding to the load and structure of the surface fuels and associated surface fire behavior. As mentioned above, in deciduous forest vegetation types, LANDFIRE assigns pseudo canopy-fuel values that prohibit the simulation of crown fire in fire behavior modeling systems but retain the actual forest canopy cover and height values for modeling the influence of canopy cover on wind-reduction and fuel moisture. However, in mixed deciduous-conifer existing vegetation types LANDFIRE does not account for the proportion of deciduous-to-conifer cover; canopy bulk density is estimated from the total forest canopy cover. Depending on the proportion of conifer and deciduous trees, canopy bulk density may therefore be overestimated in these stands throughout the year, and wind-reduction and shading may be overestimated during the leaf-off times of the year.

Disturbance

Disturbances may affect both surface and canopy fuels depending on their type and severity. As with undisturbed fuels, the fuel mapping rules for disturbed areas should be critiqued by local fire specialists before application to finer-scale analyses.

In grass and shrub vegetation types the post-disturbance fire behavior fuel model is influenced by the affected species' response to disturbance. For example, wildfire in grass vegetation types is typically high-severity by nature—consuming all of the above-ground biomass. Most grasses, however, return to their pre-fire condition relatively quickly (i.e., one or two growing seasons) and in some cases will respond with increased biomass compared to the pre-fire condition due to an influx of nutrients and more favorable growing conditions. In shrub vegetation types, low-severity fire (less than 25% overstory mortality) may have little effect on the fuel load, fuelbed depth, and other components of a shrub-based fire behavior fuel model, whereas high-severity fire (greater than 75% overstory mortality) may result in immediate resprouting of shrubs or conversion to grass for some period of time, all dependent on the particular species' response to fire.

In tree-dominated vegetation types, low-severity fire will, generally speaking, consume litter (small dead branches and needles on the forest floor) and grass with minimal effect on understory shrubs and small trees. Moderate-severity fire may have a wide range of effects on litter and understory vegetation, but at the pixel level can generally be assumed to have consumed most of the litter and understory vegetation. By LANDFIRE severity definitions, moderate-severity fire in forested vegetation types results in 25% to 75% overstory tree mortality. High-severity fire results in greater than 75% mortality of the overstory trees. The mortality of overstory trees will influence the availability of light, water, and nutrients to understory vegetation, as well as contribute litter (through needle and branch fall) and large woody debris (as dead trees fall) as surface fuels over time.

These same principles apply to non-fire disturbance types. Ask yourself what is the response of the vegetation to the particular disturbance, what influences will this response have on post-disturbance fuel, how fire burns in the disturbed area, and what is the effect of time-since-disturbance.

As discussed in Chapter 3, the generalization of mechanical disturbance types to two categories—mechanical add and mechanical remove—may lead to a misrepresentation of effects. Critique of the LANDFIRE events polygon and individual year disturbance data by local experts can often confirm or provide additional information about the disturbance's effect on fuels.

The effect of time-since-disturbance varies by location and fuel type. Time-since-disturbance is split into three categories, the first of which is "one year". The need for the one year time-since-disturbance category can be evaluated based on your location, how you plan to apply the data, and how frequently you plan, or need, to update it.

Modeling

In-depth discussion of wildfire behavior modeling concepts is beyond the scope of this guidebook. Scott (2012) provides a comprehensive review of the topic in his *Introduction to Wildfire Behavior Modeling* guide. Nevertheless, a few considerations warrant discussion here. Wildfire behavior modeling requires an understanding of how the interaction among vegetation, fuels, and topography—as characterized in LANDFIRE data—influences modeling results. Wildfire analyst support may therefore be desired when critiquing and updating fuel data, depending on local wildfire behavior modeling expertise.

First, there is no direct, repeatable method for measuring canopy base height in the field, and multiple observers will often estimate significantly different values in the same stand. Methods exist to indirectly estimate canopy base height from plot data (Sando and Wick 1972; Cruz et al. 2003; Reinhardt and Crookston 2003; Scott and Reinhardt 2005), but canopy base height is challenging to map at a landscape scale because it is not well-related to characteristics that can be measured by remote sensing techniques. Canopy base height may include ladder fuels such as lichen, dead branches, needle drape, small trees, and shrubs. However, if shrubs and small trees are being considered as part of the fire behavior fuel model, they should not also be included in the canopy base height.

Next, understanding the interaction of fire behavior fuel model and canopy base height on modeling results is crucial in critiquing fuel data. The fire behavior fuel model predicts the surface fire intensity under a given set of environmental conditions (e.g., wind speed, slope steepness, fuel moisture). The lower the canopy base height, the milder these conditions can be in order to initiate crown fire. Given the difficulty of measuring and mapping canopy base height, working backwards— that is, adjusting canopy base height based on the conditions expected to initiate crown fire—is an effective way to critique canopy base height in relation to other variables. Tools such as NEXUS (Scott 1999) and BehavePlus (Andrews 2013) can provide information on the torching index—20' wind speed required for crown fire initiation—under various fuel and fire environments. The LFTFC tool also includes an option for calculating the critical canopy base height needed for crown fire initiation for different combinations of fire behavior fuel model, fuel moisture, and wind speed (Figure 16).

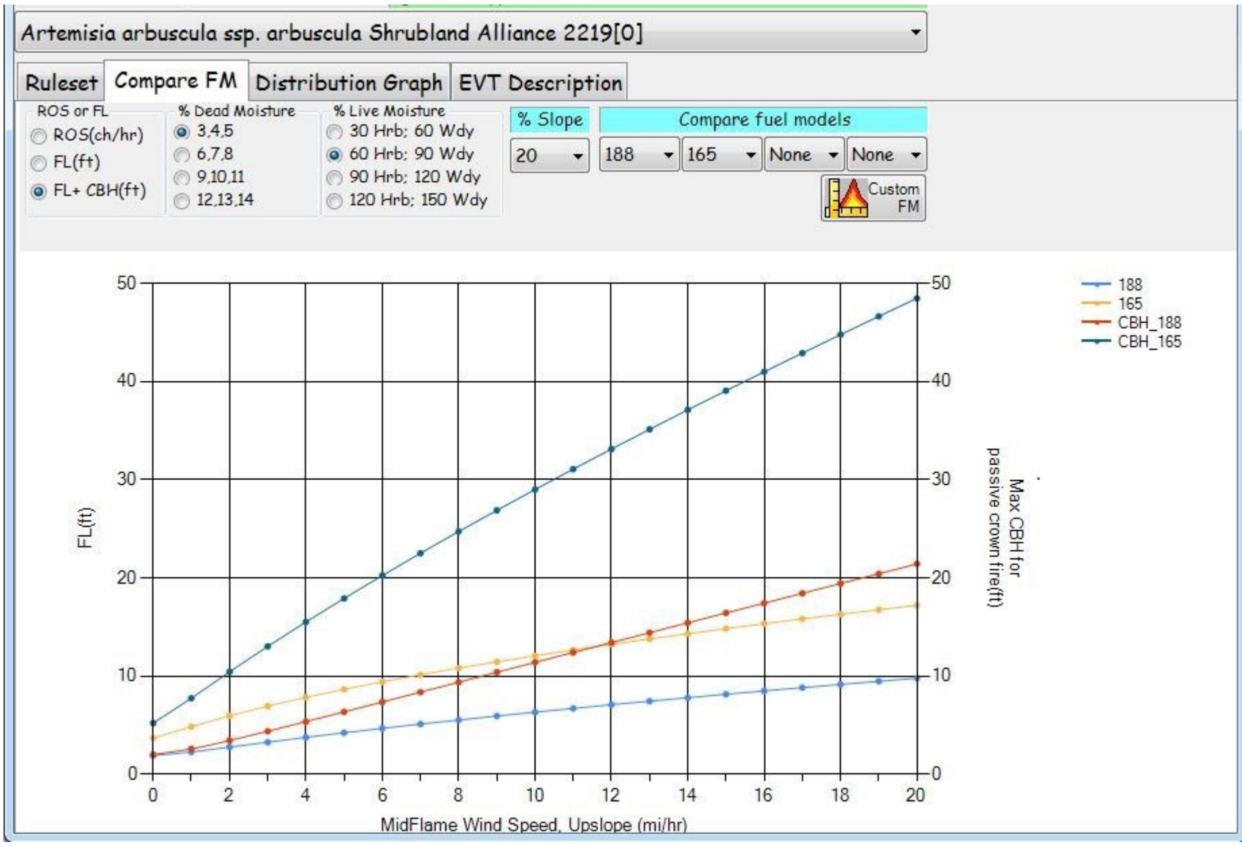


Figure 16. LANDFIRE Total Fuel Change Tool compare fuel model tab. This allows the user to calculate the critical canopy base height needed for crown fire initiation for different combinations of fire behavior fuel model, fuel moisture, and wind speed.

Lastly, in fire behavior modeling, canopy bulk density is a factor in determining whether an active crown fire can be sustained once initiated. Since the existing vegetation height classes used to predict canopy bulk density are rather coarse, they influence the resulting precision of the canopy bulk density values as well. Again, tools such as NEXUS and BehavePlus can be useful in determining if the data will predict the expected fire behavior under various conditions. Analysts are also encouraged to run geospatial fire behavior modeling systems to see if patterns in the results reveal any potential calibration issues that warrant a closer look. This is the *analyze* component of the data critique and modification framework discussed in Chapter 2.

Chapter 6: Fire Regime and Vegetation Departure

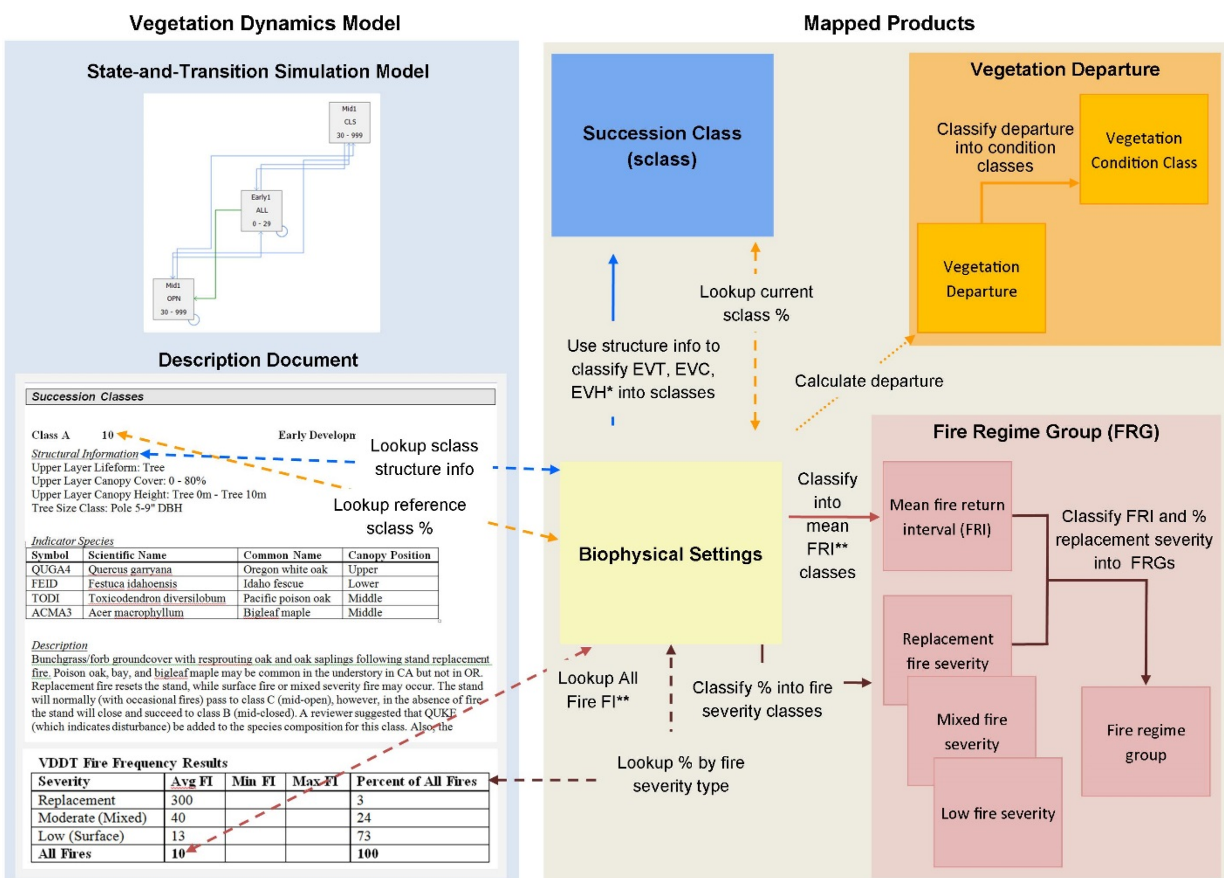
The fire regime and vegetation departure products are useful for understanding historical fire regimes and the current condition of vegetation on the landscape within the context of the historical disturbance regime. The fire regime products include fire regime group, mean fire return interval, percent low-severity fire, percent mixed-severity fire, and percent replacement-severity fire. The vegetation departure products include vegetation departure and vegetation condition class. The departure products were created for the LANDFIRE National, 2001, 2008 and 2012 versions but not for LANDFIRE 2010.

This chapter begins with an overview of the vegetation dynamics models, which form the basis of the fire regime and vegetation departure products, and then describes how those products are mapped by LANDFIRE. The chapter concludes by presenting common considerations for critiquing these data layers and provides examples of common pitfalls.

Fire Regime Mapping Process

Vegetation Dynamics Models

The foundation of the fire regime and vegetation departure products is a set of models that describe the vegetation dynamics and reference conditions of each biophysical setting mapped by LANDFIRE (Figure



*Existing vegetation type (EVT), cover (EVC) and height (EVH)
**Fire Interval (FI) and Fire Return Interval (FRI) refer to the average fire frequency modeled.

17). This section therefore begins with a brief overview of the models and how they relate to the fire regime and vegetation departure products. More information on the vegetation dynamics models can be found on the LANDFIRE program website.

Figure 17. The fire regime and vegetation departure products are created through crosswalks that link each BpS on the BpS data layer to the reference condition values modeled in the corresponding vegetation dynamics model.)

LANDFIRE collaborated with vegetation and fire ecology experts to create a vegetation dynamics model to estimate the reference (i.e., pre-Euro-American settlement) condition for each biophysical setting. The models were created in the Vegetation Dynamics Development Tool (VDDT, ESSA Technologies Ltd. 2007). A model represents a single biophysical setting and consists of five or fewer successional states, or classes, that compose the biophysical setting (Figure 18). Each state is equivalent to a succession class and each succession class is mapped in the succession class data layer (Chapter 4). A state has an age range that indicates how long it typically persists before it transitions to the next state. Disturbance pathways between states are used to represent the impact of important disturbances, and each pathway is defined by a probability that describes how often it occurs. The models were attributed based on scientific literature, available data, and the experience and judgment of the modelers (Rollins 2009).

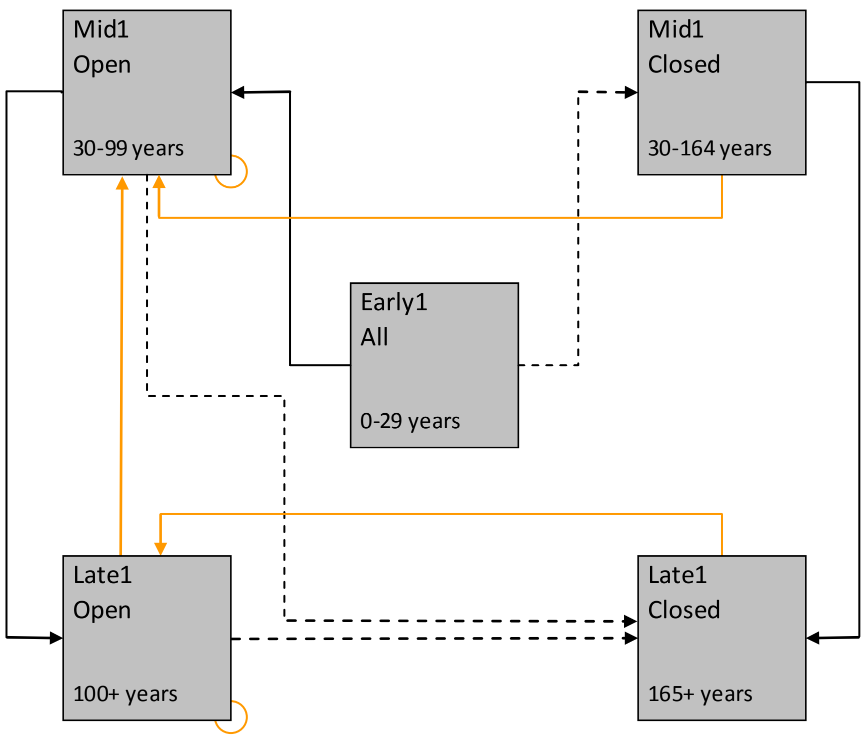


Figure 18. State-and-transition model of the Pacific Northwest Mixed Conifer BpS. This model is comprised of five successional states (boxes). Each state has an age range and is linked to other states through main successional pathways (solid lines), alternative succession pathways (dashed lines) and disturbance pathways (yellow line represent mixed fire transitions).

Once attributed, each model was run for ten 1,000-year simulations, in VDDT, and the results were averaged to estimate the biophysical setting reference conditions. The reference conditions include:

- the fire frequency expressed as a mean fire return interval,

- the fire severity expressed as the relative percent of low-, mixed-, and replacement-severity fire, and
- the relative amount represented by each succession class expressed as a percent.

The reference conditions are published in the LANDFIRE model descriptions along with the VDDT models available from the LANDFIRE website (Figure 19).

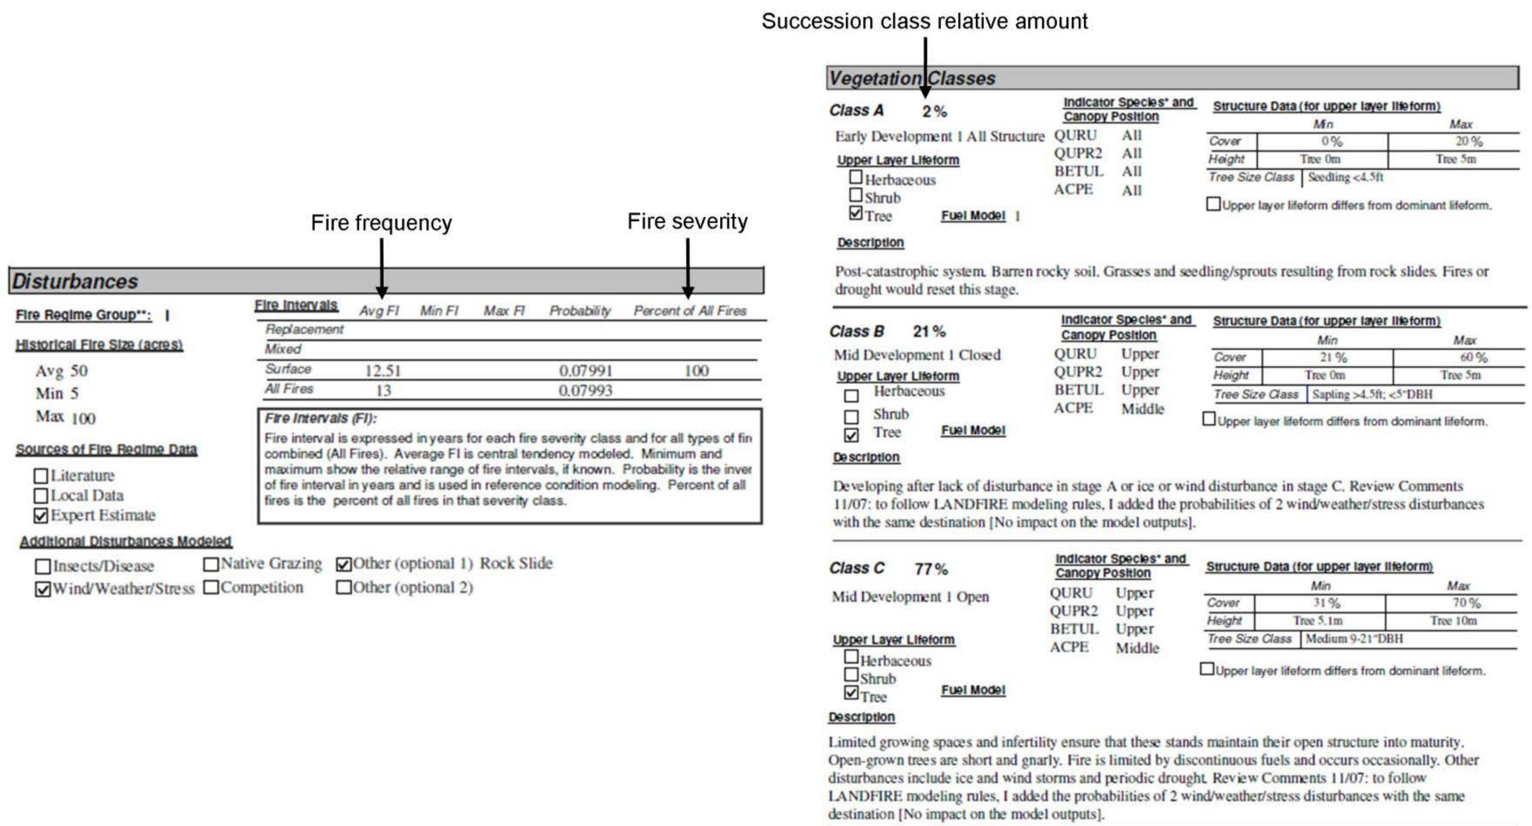

Figure 19. The biophysical setting model descriptions contain the reference conditions. The fire frequency and severity are found in the Disturbances section. The relative amount represented by each succession class is expressed as a percent and is found after the class letter name in the upper left of each vegetation class description.

Vegetation Dynamics Models and Biophysical Setting Map Units

The LANDFIRE biophysical setting data layer contains attributes for two nested map units: biophysical setting and biophysical setting groups. The biophysical setting attribute is the original biophysical setting classification based on NatureServe's Ecological Systems and described in the vegetation dynamics model description documents. LANDFIRE created biophysical setting groups to simplify the mapping of the fire regime products and to reduce the complexity of the vegetation dynamics model set for users. The original units were placed into groups based on similar vegetation and fire regime characteristics. Each biophysical setting group is represented by a single "exemplar" model chosen from the original model set. The fire regime products and the succession class data layer in LANDFIRE 2001 and 2008 are based on the biophysical setting groups and their associated exemplar models. All other LANDFIRE versions, including the most recent versions, use the original biophysical setting attribute. Although the biophysical setting and the biophysical setting groups are related, they can have different succession class definitions and different reference conditions, including different succession class proportions and fire frequency and severity values. Users need to pair the correct biophysical setting attribute in the biophysical setting data layer with the correct model based on the version of LANDFIRE data they are using. The relationship between biophysical setting and biophysical setting groups is described in the "BpS Groups Table" located on the LANDFIRE website (Figure 20).

Original biophysical settings | Biophysical settings group

Table

Figure 20. LANDFIRE biophysical settings were placed into groups based on similar vegetation and fire regime characteristics. Each biophysical setting group is represented by a single "exemplar" model chosen from the original model set. For example, in the table above notice that the seven original Inter-Mountain Basins Big Sagebrush Shrubland biophysical settings models were lumped into two groups: Wyoming Big Sage-Rubber Rabbitbrush-4 and Wyoming Big Sage-Spiny Hopsage-1.

Fire Regime: Frequency, Severity, and Fire Regime Group

The mean fire return interval data layer depicts the presumed historical fire frequency for each biophysical setting. The layer is created by linking the biophysical setting to the VDDT-modeled fire frequency results described in the vegetation dynamics model description document. The mean fire return interval is classified into 22 categories that vary in length to provide greater temporal resolution for frequently burned biophysical settings and less temporal resolution for biophysical settings that burn infrequently.

The fire severity data layers depict the relative percent of low-, mixed-, and replacement-severity fire under the presumed historical fire regime for each biophysical setting. Fire severity is defined as the percent mortality of the overstory vegetation: less than 25% mortality is classified as low-severity, 25-75% mortality is classified as mixed-severity, and greater than 75% mortality is classified as high-severity. The layer is created by linking the biophysical setting to the VDDT-modeled relative amount of each fire severity type as reported in the vegetation dynamics model description document. The results range from 0-100% and they are classified and mapped in 5% increments.

The fire regime group data layer characterizes the presumed historical fire frequency and percent replacement severity fire for each biophysical setting in five classes (Table 8). The fire regime group layer is created by linking the biophysical setting to the fire frequency and severity results described in the vegetation dynamics model description document.

Table 8: Fire regime group mapping rules. The fire regime group layer is created using a rule set that classifies combinations of fire frequency and relative percent replacement severity fire into one of five fire regime groups for each biophysical setting.

Fire Regime Group	All Fire Frequency (years)	Relative Percent Replacement Severity Fire
I	0-35	<66%
II	0-35	>=66%
III	36-100	<80%
	101-200	<66%
IV	36-100	>=80%
	101-200	>=66%
V	>=201	Any fire severity

All of the fire regime products include additional map units for water, snow/ice, barren, and sparsely vegetated systems which are mapped from the existing vegetation type data layer. The value "indeterminate fire regime characteristics" identifies a biophysical setting without fire disturbance in its associated vegetation dynamics model. These are typically biophysical settings that are either too wet or too dry to carry fire (e.g., Alaskan Pacific Maritime Sitka Spruce Forest biophysical setting).

Vegetation Departure

LANDFIRE provides geospatial data that characterize two metrics of vegetation departure: stratum vegetation departure and stratum vegetation condition class. Vegetation departure and vegetation condition class are calculated following the methodology described in the FRCC Guidebook (Barrett et al. 2010) and the FRCC Mapping Tool User's Guide (Jones and Ryan 2012). Both metrics describe the overall departure of the current vegetation conditions from the historical, or reference, vegetation conditions across all succession classes within a particular biophysical setting (i.e., stratum). The historical proportion, or relative amount, of each succession class in a biophysical setting is based on the average proportion modeled in the vegetation dynamics model and reported in the model description document (Figure 17). Current succession class proportions are calculated directly from the succession class data layer.

Stratum vegetation departure is calculated by determining the succession class "similarity" (the smaller of the reference, or the current proportion, for each succession class), summing the similarities, and then subtracting from 100. This provides the percent departure for a biophysical setting and that value is mapped in the vegetation departure data layer. To create the vegetation condition class data layer, the percent departure is classified into three classes: 0-33% departure in condition class 1, 34-66% departure in condition class 2, and 67-100% departure in condition class 3 (see sidebar).

Calculating Vegetation Departure

Stratum vegetation departure is calculated by comparing the reference distribution of succession classes (i.e., the proportion that each contributes to the whole expressed as a percent) to the current distribution of succession class for individual biophysical settings. In the table below, departure is calculated for a biophysical setting with three reference succession classes (A, B, and C), which are defined in its vegetation dynamics model. The Uncharacteristic succession class only includes a current value because by definition it does not occur under the reference condition. The uncharacteristic class proportion is the sum of the uncharacteristic native and uncharacteristic exotic proportions.

The first step in calculating stratum vegetation departure is to determine the succession class similarity (i.e., the lower of the reference or current percent) of each succession class. Next, stratum similarity is calculated by summing the succession class similarity values. Then, the current stratum vegetation departure is calculated by subtracting the stratum similarity value from 100. This is the value mapped in the LANDFIRE vegetation departure grid. Finally, the vegetation condition class is calculated by classifying the current stratum vegetation departure value into the three condition classes (1 = ≤ 33%, 2 = > 33% to ≤ 66%, 3 = > 66%). This is the value mapped in the LANDFIRE Vegetation Condition Class grid:

Succession Class (S-Class)	Reference Percent	Current Percent	S-Class Similarity
A-Early	15	3	3
B-Mid	40	25	25
C-Late	45	31	31
Uncharacteristic	0		
Stratum Similarity	**59**		
Current Departure	**41**		
Vegetation Condition Class	**2**		

Departure is calculated for a specific geographic area referred to as the landscape summary unit. For LANDFIRE National, departure was calculated for ecological subsections (Cleland et al. 2005) within a LANDFIRE map zone. In LANDFIRE 2001 and 2008 departure was calculated within nested hydrologic unit codes (HUCs; Seaber et al. 1987). Departure for biophysical settings in fire regime groups I and II was calculated at the sub-watershed level (HUC 12); biophysical settings in fire regime group III were calculated at the watershed level (HUC 10); and biophysical settings in fire regime groups IV and V were calculated at the sub-basin level (HUC 8). In LANDFIRE 2012 the landscape summary unit was defined as a biophysical setting with identical reference condition values regardless of map zone. To understand this, imagine that a biophysical setting is mapped in map zones 1, 2, and 3 and that zones 1 and 2 have identical reference conditions in their associated vegetation dynamics models but that zone 3 has a unique set of reference conditions. In this case, the departure would be calculated using the biophysical setting's extent in zones 1 and 2 as one summary unit and zone 3 as another summary unit.

Considerations

Understanding the Source Data

All of the fire regime and vegetation departure products are derived from other LANDFIRE products. Any assumptions, limitations, and issues associated with the source data are inherited by the fire regime and vegetation departure products. To understand and critique these products, the user must therefore understand the source data. The fire frequency, fire severity, and fire regime group values come from the vegetation dynamics models. Vegetation departure and vegetation condition class results are derived from the modeled reference conditions, the biophysical setting data layer, the succession class data layer, (which is itself derived from the biophysical setting, existing vegetation type, existing vegetation cover, and existing vegetation height data layers; see Chapter 4), and the landscape summary unit. The information from other chapters in this guide will help the user critique these geospatial data inputs. For more information on critiquing the vegetation dynamics models, refer to the *Reviewing and Modifying LANDFIRE Vegetation Dynamics Models* (The Nature Conservancy 2011a) user's guide.

Knowledge Uncertainty

The quality of the fire regime and vegetation departure products depends to a great extent on the quality and quantity of the information used to create the vegetation dynamics models. In general, there are more data to attribute models for economically valuable and heavily studied biophysical settings, such as forested ecosystems, than there are for biophysical settings with little economic value and those that are rare (Blankenship et al.2012). The quantity and quality of fire regime information also varies considerably based on the characteristics of the vegetation comprising the biophysical setting. Fire history from recent centuries tends to be most reliably documented in systems where the evidence of low- and moderate-severity fires is recorded and persists within the annual rings of long-lived tree species (Swetnam et al. 1999) such as longleaf pine and ponderosa pine, and/or where the time since the last stand-replacing fire can be determined from the stand age. In non-forested systems, little direct evidence persists for inferring the characteristics of historical fire regimes (Swetnam et al. 1999) although historical records, charcoal and pollen records, and dependence or sensitivity of long-persisting species provide clues to the fire frequency and severity. The vegetation dynamics model description documents often provide information about the sources and the quality of the information on which they are based and can provide users with valuable information for evaluating the fire regime products derived from them.

Map Zone Boundaries

The vegetation dynamics models were developed to apply at the level of a LANDFIRE map zone (Figure 2). Sometimes the same biophysical setting may have different succession class mapping rules, succession class reference proportions, and fire frequency and severity information in different map zones. This can lead to abrupt changes in the fire regime and vegetation departure products at map zone boundaries, even for the same biophysical setting. Users performing an independent departure analysis can address this issue (see Vegetation Departure Analysis below).

Changes in Departure Methods

The methods LANDFIRE used to create the departure products have changed between versions (Table 9). Users should be cautious when comparing the departure products (vegetation departure and vegetation condition class) between different LANDFIRE versions because changes in the biophysical setting map units and the landscape summary unit discussed above, as well as the source of the reference conditions, can change the departure score. Theoretically the LANDFIRE 2001 and 2008 departure data layers are comparable because they were calculated using the same method, but it may be too short a time period to see substantial change across broad areas. LANDFIRE 2001, 2008 and 2012 departure data layers are not comparable to LANDFIRE National because of the changes in the methods (USFS [n.d.] Fire Regime Data…).

Table 9: Comparison of the methods and input data used to create the LANDFIRE departure data products by data version.

Version	Departure Products Mapped	Departure BpS Unit[a]	Summary Unit	Reference Condition Source[b]
National	Yes	BpS	Ecological Subsections within Mapzones	VDDT & LANDSUM
2001	Yes	BpS Group	Nested Hydrologic Unit Codes	VDDT
2008	Yes	BpS Group	Nested Hydrologic Unit Codes	VDDT
2012	No	BpS	Unique Combination of BpS Code and BpS Model	VDDT

[a]Vegetation departure products were calculated for the biophysical setting (BpS) or the BpS groups depending on the version. In versions where departure products were not mapped, the Departure BpS Unit refers to the units used to map the fire regime and succession class layers.
[b]The reference conditions were derived from the Vegetation Dynamics Development Tool (VDDT) and the Landscape Succession Model (LANDSUM). For LANDFIRE versions 2001 and greater the reference condition source is as described in this guide. The reference conditions source for the National version is described in the document "Developing the LANDFIRE Fire Regime Data Products" on the LANDFIRE Program website.

Vegetation Departure Analysis

Rather than use the LANDFIRE vegetation departure products as-is, many users prefer to complete their own, local, departure analysis. Performing an independent departure analysis allows users to address the issues discussed above, critique and refine the succession class mapping rules, and integrate ancillary data (e.g., locally mapped invasive species distribution). The Fire Regime Condition Class Mapping Tool also allows for the calculation of additional vegetation departure metrics beyond stratum vegetation departure and stratum vegetation condition class, as well as fire *regime* departure analysis. In addition to the considerations listed above, there are some considerations specific to an independent departure analysis using LANDFIRE data.

Biophysical Setting Thematic Resolution

Users performing an independent departure analysis may want to consider the thematic resolution (Chapter 1) of the biophysical setting data layer in relation to their analysis objectives (Chapter 2), especially if there are concerns about the source data or knowledge uncertainty as discussed above. Using the biophysical setting group attribute is one way to "coarsen" the biophysical setting data layer to a more appropriate thematic resolution, but careful critique of the "exemplar" vegetation dynamics model associated with the biophysical setting group is critical. In some cases, the user may want to choose a different "exemplar" model that better represents the biophysical setting group for their analysis location.

Biophysical setting classes may also be grouped using local, ancillary information. For example, in a vegetation condition analysis of Southern Sierra National Forests, analysts grouped models based on similarity of vegetation characteristics and fire regimes following a crosswalk between LANDFIRE biophysical setting and presettlement fire regime groups presented in Van De Water and Safford (2011), thus reducing the number of biophysical settings from 25 to 15.

If biophysical settings are grouped to coarsen the thematic resolution of the biophysical setting data layer, the user will usually be required to manually map succession class due to differences in succession class definitions between the original and chosen vegetation dynamics models. The guide *How to Map Successional Stages Using LANDFIRE Products* (The Nature Conservancy 2013) provides step-by-step instructions on how to do this.

Biophysical Settings that Cross Map Zone Boundaries

In situations where the analysis area overlaps more than one LANDFIRE map zone, a primary consideration is whether there are differences in the vegetation dynamics models between zones, and if such differences reflect reality. If the map zone boundary reflects an ecological transition, then differences between models for the same biophysical setting may be acceptable and necessary. However, if the map zone boundary creates an artificial demarcation in the analysis area, users will want to choose the model that best fits the analysis area and make the appropriate modifications to the related geospatial data. If a new biophysical setting model is chosen, the succession class data layer will need to be adjusted so that it reflects the succession class mapping definitions of the new model (the guide *How to Map Successional Stages Using LANDFIRE Products* provides instructions for re-mapping succession classes) (The Nature Conservancy 2013).

Succession Class Mapping Rules

It is particularly important to critique the succession class mapping rules because the vegetation departure calculation is very sensitive to the amount of area mapped to each succession class. The LANDFIRE succession class data layer is created by applying rule sets to combinations of biophysical setting, existing vegetation cover, existing vegetation height, and to a lesser extent existing vegetation type (Chapter 4). Any problems in the input data layers will carry through to the succession class data layer. Three general concerns with the succession class mapping rules that can impact departure assessments are: 1) the mappability of the classes; 2) the completeness of the succession class rule set; and, 3) the classification of uncharacteristic types.

> *Mappability of Succession Classes*. Succession class is a concept that can be difficult to translate into mappable criteria. Height and cover, the primary variables LANDFIRE uses to map succession class, may not always be the best surrogate for vegetative development and can be difficult to map (Chapter 4). In particular, the height classes for shrub and herbaceous lifeforms are difficult to discern using LANDFIRE's two dimensional satellite imagery. For example, it may be difficult to distinguish 0.5m tall grass from 1.0m tall grass using Landsat data, but some succession classes are mapped based on this distinction. In forests, the height classes tend to be mapped more accurately (see Chapter 4 - Existing Vegetation), but they may be too coarse to adequately differentiate succession classes (e.g., 10 to 25m and 25 to 50m).
>
> *Completeness of the Rule Set.* Ideally, the succession class rule sets would cover all possible mapped combinations of existing vegetation type, existing vegetation cover, and existing vegetation height for every biophysical setting without gaps or overlaps. In other words, the rules should be mutually exclusive and exhaustive, but this is not the case for all LANDFIRE succession class rules.

Take, for example, a hypothetical shrub biophysical setting with two succession classes defined as follows:

A - shrubs 10-100% cover and height < 1m

B – shrubs 50-100% cover and height > 0.5m

In this case shrubs .5-1m tall with >50% cover could be classified in either succession class A or B; the rule set is not mutually exclusive.

Take another hypothetical example of a tree-dominated biophysical setting:

A – trees 0-100% cover and < 5m height; or herbs or shrubs 0-100% cover and “any” height

B – trees 0-100% cover and 5-10m height

C – trees 0-100% cover and 10-25m height

In this example, if trees are not established or trees are less than 5m in height, the pixel is mapped as succession class A. Trees that are 5-10m in height are mapped as succession class B and trees 10-25m in height are mapped to succession class C. What about trees greater than 25m in height? Did the model developers intend for this condition to be mapped as uncharacteristic? In many cases this is not the intent; rather, the rule was developed before the geospatial data were mapped and the modelers chose the most reasonable height class without knowledge of the possible mapped height range. When the rules are not exhaustive and/or mutually exclusive, pixels can be mapped into an inappropriate class.

Users also should watch for rules that overlap in structure (cover and height) but differ by species composition. Some vegetation dynamics model descriptions use existing vegetation type as criteria for distinguishing between succession classes, but it was not a primary variable used in mapping—although this varies by biophysical setting and data version. In these cases the succession class assigned by LANDFIRE may not be in agreement with the vegetation dynamics model description. For example, in LANDFIRE map zone 21, the Rocky Mountain Aspen Forest and Woodland vegetation dynamics model differentiates between succession classes C and E by species composition (Figure 12). Both classes have the same structural criteria but succession class C represents a “relatively pure aspen stand,” whereas succession class E represents “aspen replaced by other vegetation types or a mixed aspen-conifer overstory that is changing to a conifer dominated forest.” These classes should be differentiated by existing vegetation type, but as recent as LANDFIRE 2010 no pixels were mapped to succession class E because existing vegetation type was not used in the succession class mapping process.

If manually mapping succession class, the existing vegetation type data layer can be used to mitigate this issue. For instance, where the structural criteria are met, succession class C would be assigned to pixels classified as the Rocky Mountain Aspen Forest and Woodland existing vegetation type; succession class E would be assigned to pixels classified as an aspen-mixed conifer or a pure conifer existing vegetation type.

Classification of Uncharacteristic Types. LANDFIRE classifies uncharacteristic vegetation as either uncharacteristic native or uncharacteristic exotic (Chapter 4). The uncharacteristic native class indicates that the existing characteristics (i.e., cover, height, and composition) of native vegetation are outside the reference condition range. When conducting a local vegetation departure analysis users may want to critique the mapping rule thresholds for local relevance. For example, if the maximum canopy cover in the vegetation dynamics model is 40%, any cover greater than 40% will be mapped as uncharacteristic native. Does local research of reference conditions corroborate the 40% threshold? Another instance in which the succession class might be mapped as uncharacteristic native is when a *native* riparian existing vegetation type is mapped to a non-riparian biophysical setting. As discussed in Chapter 4 this situation may be due to differences in the mapping methodologies for biophysical setting and existing vegetation type (see Chapter 4 - Potential vs. Existing Vegetation Type Rectification). Users may wish to further critique the data in such situations.

The uncharacteristic exotic class indicates that an exotic species has become established in an area. Succession class is mapped as uncharacteristic exotic wherever an "introduced" existing vegetation type is mapped (e.g., introduced upland vegetation-perennial grassland and forbland). A consideration related to the presence of exotic species is that LANDFIRE classifies less than 10% vegetation cover as "sparsely vegetated." For some analysis objectives, it may be important to identify sparse cover of exotics, such as cheatgrass (*Bromus tectorum)*, and this may require ancillary data sources (Provencher et al. 2009).

Landscape Summary Unit

Independent vegetation departure analyses are not tied to the landscape summary units used by LANDFIRE. The key criterion for landscape delineation is that the summary unit needs to be large enough to encompass the full range of succession classes expected under the historical disturbance regime (Barrett et al. 2010). Careful consideration should be given to the choice of the landscape summary unit using the guidance in the Fire Regime Condition Class Guidebook and Fire Regime Condition Class Mapping Tool User's Guide, keeping in mind that departure scores may vary with changes in the summary unit. If the landscape summary unit is so small that it would not contain the full range of succession classes under the historical disturbance regime, misleading departure scores can result, and lead to errors in the subsequent planning process (Barrett et al. 2010). In contrast, summary units that are too large may make it difficult to discern changes in departure due to planned (e.g., restoration treatments) and unplanned disturbances (Barrett et al. 2010). This may be the case for some biophysical settings under the LANDFIRE 2012 methodology for mapping departure, in which the full extent of the biophysical setting in one or multiple map zones is used as the summary unit to calculate departure. However, it is the intent of the off-the-shelf LANDFIRE products to assess departure at a much broader scale than that of a typical local analysis.

Chapter 7: Interpreted Examples

In this chapter, we (the authors) illustrate the data critique and modification process in two example applications. The first example critiques LANDFIRE data for use in fire behavior analysis of the Rogue Basin located in southwest Oregon (Figure 21). The second example focuses on the critique of LANDFIRE data for use in vegetation departure analysis in the southern Sierra Nevada Mountains of California (Figure 21).

Figure 21. Project area boundaries for interpreted examples.

There are multiple approaches and tools available for critiquing and modifying geospatial data. In these examples we demonstrate the use of common approaches and tools that are available to most natural resource professionals. The following examples summarize the concepts and considerations for modifying LANDFIRE data discussed in previous chapters and therefore should be beneficial to all readers regardless of expertise in working with geospatial data. Details on geospatial analysis and data manipulation tasks, however, are beyond the scope of this document and are only outlined here.

Example 1: Critiquing LANDFIRE data for local fire behavior analysis

Define objectives

For this example we turned to the 3.3 million-acre Rogue Basin in southwest Oregon, where the Southern Oregon Forest Restoration Collaborative and its partners are undertaking the development and implementation of a cohesive forest restoration strategy. A key component in the development of this strategy was an understanding of the current wildfire hazard and associated risk to the Basin's natural resources and assets. Our objective was to conduct a wildfire hazard analysis using LANDFIRE data and geospatial wildfire behavior modeling software.

Identify data requirements

Eight geospatial data layers are required inputs for simulating the full range of wildfire behavior—surface through active crown—in the geospatial fire modeling systems used in this analysis. These layers characterize surface fuels (fire behavior fuel model), canopy fuels (canopy base height and canopy bulk density), forest canopy structure (canopy cover and canopy height), and topography (elevation, aspect, and slope). Each geospatial data layer is available from LANDFIRE.

Given our objective to geospatially analyze wildfire hazard, it was important that the geospatial data represent the fuels and wildfire potential as appropriately as possible for the scale of the analysis. To evaluate the LANDFIRE fuels data we would use the LANDFIRE Total Fuel Change Tool (LFTFCT 2011), which allows for the critique, modification, and analysis of fuel mapping rules and their effect on simulated fire behavior within the tool itself. Because LANDFIRE fuel data (Chapter 5) are derived from existing vegetation type, cover, and height (Chapter 4), biophysical setting (Chapter 4), and disturbance (Chapter 3), the tool requires these geospatial data layers as input, thus increasing our data requirements. We downloaded the additional data layers using the LANDFIRE Data Access Tool (Figure 22, LFDAT 2012).

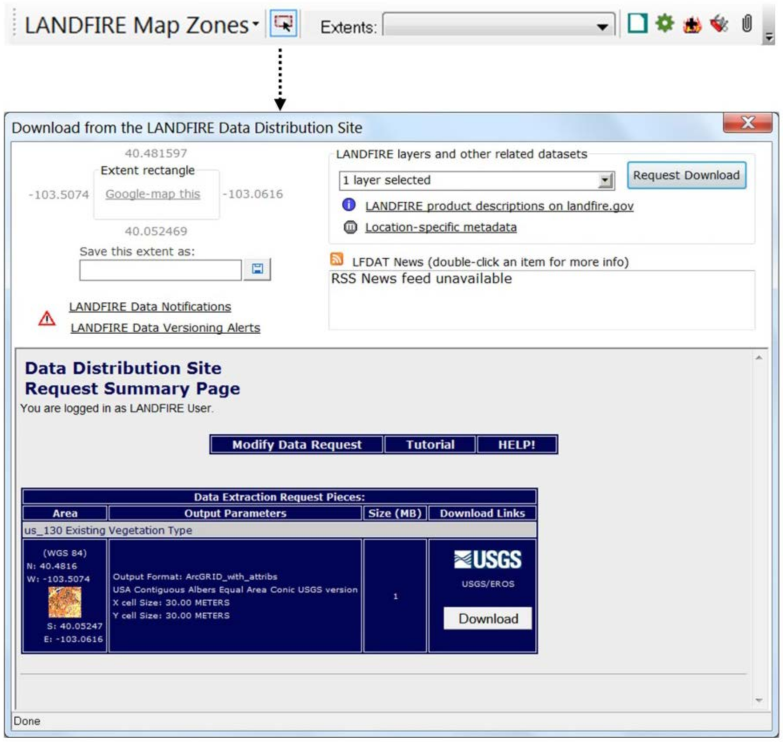

Figure 22. The LANDFIRE Data Access Tool (LFDAT). The LFDAT is a custom ArcGIS toolbar that links to the LANDFIRE Data Distribution Site.

Critique

The fundamental question of our critique was whether LANDFIRE data would be appropriate for simulating wildfire behavior at the analysis location and scale. The LANDFIRE Total Fuel Change Tool would be used to assess the fuel mapping rules in addressing this question; however, *data currency* and *map unit accuracy* (Chapter 1) are also important to accurately simulate the current wildfire hazard so we began our critique there.

The wildfire analysis component of this project began in January 2015, just after LANDFIRE version 1.3.0 (LANDFIRE 2012) data were released for the region. This meant the data were two years out-of-date at the time of acquisition. A critical first task was therefore to determine how much the landscape had changed in the preceding two years.

Approximately 200,000 acres of wildfire and 11,500 acres of mechanical disturbance had occurred over 2013 and 2014 within the wildfire simulation landscape. Given this information, it was clear that currency updates to the LANDFIRE vegetation and disturbance data inputs would be required prior to critiquing the fuel mapping rules with the LANDFIRE Total Fuel Change Tool.

The input data were also critiqued for map unit accuracy. Upon field review, local resource managers felt that oak woodland ecological systems were underrepresented in the LANDFIRE existing vegetation type data layer and that ancillary data would be required to address this issue. In critiquing the LANDFIRE disturbance data, local resource specialists also determined that certain disturbance type assignments were not correct for the local area. For example, the assignment of mechanical remove to all silvicultural treatments (i.e., clearcut, harvest, thinning) was not appropriate for the Rogue Basin because not all local harvesting methods are accompanied by activity-fuel treatments such as hand-pile burning or biomass extraction. Similarly, there were activities assigned to the "other mechanical" event type (a mechanical-add disturbance) that participants felt should be assigned to mechanical-remove. In addition, participants felt that although mastication event types add fuel to the surface fuelbed, they should be differentiated from the other mechanical add disturbances due to the effect of the structure and compactness of masticated fuel on fire behavior.

Finally, as discussed in Chapter 3, LANDFIRE does not currently use a cumulative effect approach to assign disturbance attributes in the composite fuel disturbance data layer. Rather, if multiple treatments occurred in the same location within the update period, the attributes of the most recent treatment are assigned (except where fire has occurred; see Chapter 3). This was also a potential cause of inaccurate map unit assignment.

To summarize, the following information was gathered from the data critique and used to modify the geospatial data inputs to the LANDFIRE Total Fuel Change Tool.

- Data is not current through 2014.
- Oak woodland ecological systems are underrepresented.
- Some disturbance type map unit assignments are inaccurate due to generalization of treatment types at the national scale and/or incorrect accounting of cumulative treatment effects.
- Grouping of mastication treatments with other mechanical add disturbances does not represent the unique fire behavior of masticated fuel.

Modify LANDFIRE Total Fuel Change Tool inputs

As discussed above, the LANDFIRE Total Fuel Change Tool requires geospatial data layers of: existing vegetation type, cover, and height; biophysical setting; and disturbance as inputs. The amount of updating required for these layers varies depending on analysis objectives. The following sections describe the modifications that were made, or why modification was determined to be unnecessary, for each of the required geospatial data layers based on our data critique.

Disturbance

Data Currency

Because the LANDFIRE 2012 composite fuel disturbance data layer only represents conditions through 2012, two data currency updates were required to create an up-to-date 2014 disturbance layer: 1) the time-since-disturbance attribute needed to be updated to reflect the two additional years that had passed, and 2) new disturbances—those that occurred in 2013 and 2014—would need to be added. The following methods were used to create the updated disturbance layer.

First, we determined the years for which the time-since-disturbance attribute would need to be updated (Table 6). Disturbances that occurred from 2005-2007 would remain in the 6-10 year time-since-disturbance class. Likewise, disturbances that occurred in 2010 and 2011 would remain in the 2-5 year time-since-disturbance class. However, disturbances that occurred in 2008 and 2009 would need to be updated to the 6-10 year class and disturbances that occurred in 2012 would need to be updated to the 2-5 year class.

The 2003 and 2004 disturbances would now be greater than ten years old. LANDFIRE removes disturbances greater than ten years old from the composite vegetation and fuel disturbance data layers (Chapter 3) and may also update existing vegetation layer map units to reflect a vegetation transition based on the ecology of the region. For example, a forested, existing vegetation type that experienced a high-severity wildfire, and was subsequently reassigned as an herbaceous or shrub existing vegetation type, may be reassigned to a forest vegetation type after ten years if reestablishment of trees is expected. More information on LANDFIRE vegetation transition rules is available on the program's website. Based on our analysis objectives we determined that we could leave the 2003 and 2004 disturbances in the 6-10 year time-since-disturbance class since we were only concerned with the fuel data layers required for wildfire hazard analysis and therefore not required to update existing vegetation layers.

Next, we downloaded the individual-year disturbance data layers for the years 2008-2012 using the LANDFIRE Data Access Tool. These layers were used to create two "geospatial masks" using the ArcGIS Spatial Analyst extension—one representing the 2008-2009 disturbances and one representing the 2010-2012 disturbances (Figure 23). Masks are used in geospatial analysis to constrain operations to certain pixels within a raster dataset. In our case, we used the masks to identify and update the time-since-disturbance of pixels where a disturbance had occurred in 2008 or 2009 without subsequent disturbances in 2010-2012. As in the LANDFIRE mapping process, if a fire disturbance occurred prior to 2008 we retained the time-since-disturbance of the fire (Chapter 3).

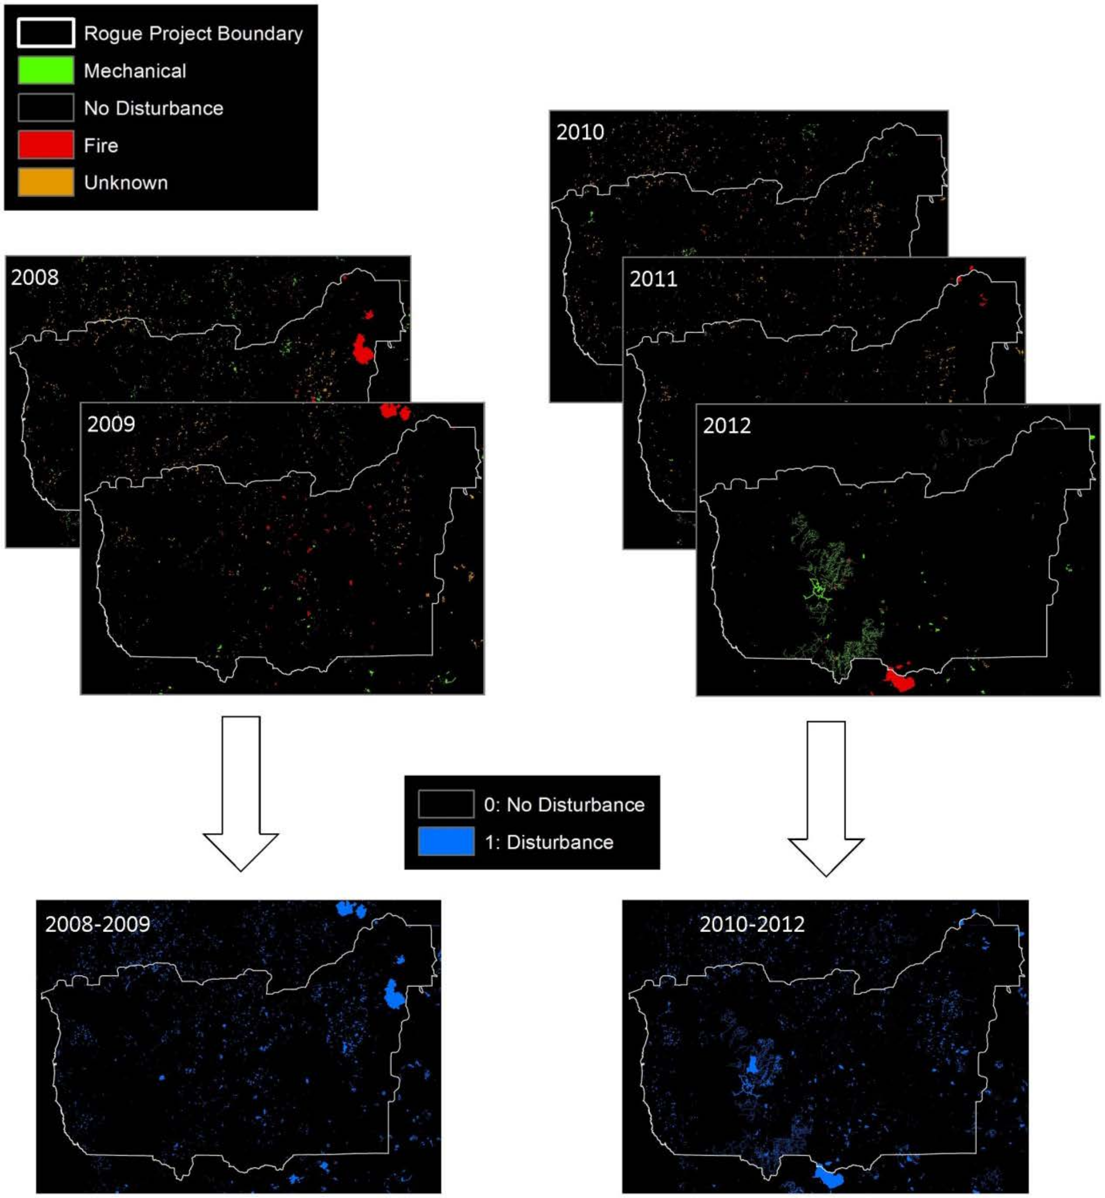

Figure 23. Updating time-since-disturbance. Two geospatial masks were created from the LANDFIRE individual year disturbance layers: one representing disturbances from 2008-2009 and the other representing disturbances from 2010-2012. Time-since-disturbance was updated from the 2-5 year class to the 5-10 year class only where disturbances occurred in 2008-2009 without subsequent disturbance in 2010-2012

With the time-since-disturbance updates complete, we next needed to incorporate 2013 and 2014 disturbances into our updated composite fuel disturbance layer. To reflect large wildfires (> 1,000 acres), we acquired wildfire severity data from the Forest Service Rapid Assessment of Vegetation Condition after Wildfire (RAVG) program website. Recall from Chapter 3 that the LANDFIRE disturbance severity classes represent the effect of disturbances on the vegetation cover of the dominant lifeform. The RAVG program produces a raster data layer representing canopy cover reduction, as a result of fire, through a process that correlates percent change in canopy cover to a remote sensing change detection protocol (Miller and Thode 2007, Miller et al. 2009). We used this data layer to further update the composite fuel disturbance layer based on the percent canopy cover reduction using the ArcGIS Spatial Analyst Extension *Reclassify* tool (Figure 24).

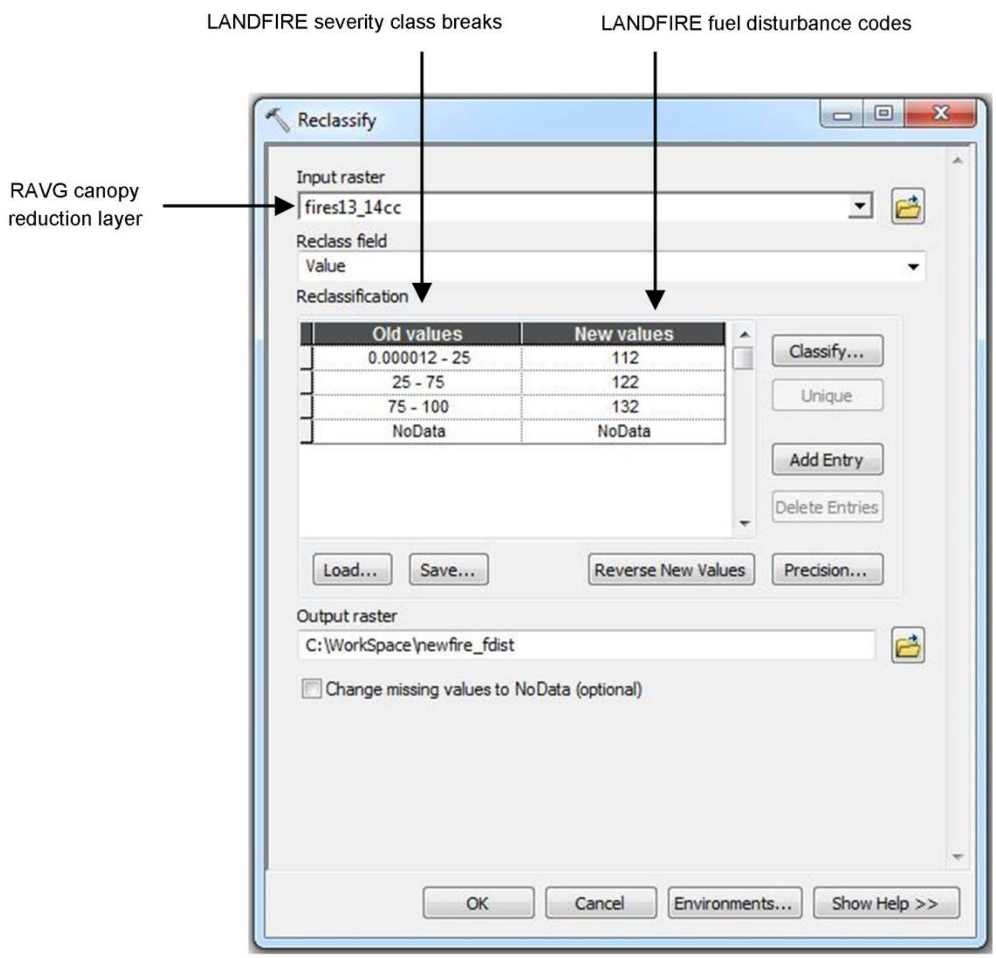

Figure 24. Reclassification of canopy cover reduction estimates from the Rapid Assessment of Vegetation of Condition after Fire (RAVG) program data to LANDFIRE fuel disturbance codes.

We followed a similar process for non-wildfire disturbances. First we acquired 2013 and 2014 Forest Service activities data from the agency's Forest Activities Tracking System (FACTS) and Bureau of Land Management activities from the National Fire Plan Operations and Reporting System (NFPORS). Forest Service and Bureau of Land Management personnel assigned the LANDFIRE disturbance type (mechanical add, mechanical remove, or prescribed fire), severity, and time-since-disturbance codes to each of the activity polygons. If subsequent activities occurred in the two-year time frame, the cumulative effect of those activities was used to determine the most appropriate disturbance attributes. We converted the polygon data to raster format and used ArcGIS Spatial Analyst Extension tools to further update the composite fuel disturbance layer.

Map Unit Accuracy

As mentioned above, our data critique identified two map unit accuracy issues in the disturbance data layer: 1) disturbance type map unit assignments were inaccurate due to generalization of treatment types at the national scale and/or incorrect accounting of cumulative treatment effects, and 2) the grouping of mastication treatments with other mechanical add disturbances does not represent the unique fire behavior of masticated fuel.

We used the ArcGIS Spatial Analyst *combine* function to combine the composite fuel disturbance layer with the individual disturbance layers from 2003-2012. The combine function creates a new raster where each unique combination of values from the input layers represents a single row in the attribute table. Using this table we were able to identify four unique situations and make adjustments based on local resource specialist input (Table 10).

Table 10: Adjustments made to mechanical disturbance type based on local input.

Criteria	Acres	Adjustment
Silvicultural treatments only	200,039	Disturbance type was changed from mechanical remove to mechanical add.
Mastication treatments only	9,188	Created a mask of mastication only pixels and changed the final fuel model values to a "post-mastication" fuel model within the mask during post-processing.
'Other mechanical' treatments only	75,936	Modified disturbance type only if local resource specialists felt the cumulative effect of the treatments was incorrectly assigned.
Combination of mechanical treatment types	289,248	Typically a combination of "other mechanical" and silvicultural treatment. Modified disturbance type only if local resource specialists felt the cumulative effect of the treatments was incorrectly assigned.

Biophysical Setting

Since the biophysical setting data layer represents potential vegetation based on the biophysical characteristics and historical disturbance regime of the site (Chapter 4), disturbances by definition do not have an effect on this layer[2]. Furthermore, because biophysical setting criteria are infrequently used in the LANDFIRE fuel mapping rules for the Northwest Geographic Area, we did not critique this layer for content accuracy.

Existing Vegetation Type

As mentioned above, our data critique identified that oak woodland ecological systems were underrepresented in the existing vegetation type layer. We therefore acquired ancillary geospatial vegetation data developed by the Landscape Ecology, Modeling, Mapping, and Analysis team (LEMMA). We extracted the oak woodland vegetation cover types from this data and augmented the LANDFIRE existing vegetation type data layer using ArcGIS Spatial Analyst tools.

Disturbances may result in a change to the existing vegetation type. For example, tree- or shrub-dominated vegetation may transition to herbaceous-dominated vegetation as a result of high-severity fire. If the existing vegetation type layer was to be used for purposes beyond the critique and development of fuel data, a separate data layer would need to be created to account for any post-disturbance effects to the existing vegetation type. However, since we were only concerned with post-disturbance effects on fuels, we were able to omit this step and rely on our updates to canopy structure and the *canopy guide* feature of the LANDFIRE Total Fuels Change Tool (see below) to correctly assign post-disturbance fuel attributes.

Existing Vegetation Cover

Two updates to the existing vegetation cover layer were required based on our data critique. First, because we used the LEMMA cover type data to augment our existing vegetation type data layer for oak woodland, we also updated the existing vegetation cover layer with LEMMA canopy cover values to ensure consistency across layers. That is, wherever existing vegetation type was updated with LEMMA data, we also updated existing vegetation cover with LEMMA data. Second, we needed to update existing vegetation cover to reflect the 2013 and 2014 disturbances added to the composite fuel disturbance layer.

The structural characteristics of existing vegetation are what the fire behavior fuel model mapping rules are keyed to (Figure 14). We were therefore required to adjust the existing vegetation cover for the new (i.e., 2013 and 2014) disturbances we added to the composite fuel disturbance layer. The post-disturbance canopy cover of forested vegetation types is also required for calculating post-disturbance canopy base height and canopy bulk density.

For the 2013 and 2014 large wildfire disturbances we used the RAVG canopy cover reduction data layer directly to adjust existing vegetation cover. For the non-wildfire disturbances we first assigned a canopy cover reduction value to each severity class midpoint (low severity: 12.5%, moderate severity: 50%, high severity: 87.5%). We did not allow values to be reduced below the lowest canopy cover class (10%-20%) because with few exceptions (e.g., clearcuts), even high-severity disturbances leave some cover. In the case of forested vegetation, leaving 15% forest canopy cover allows for simulating a slight effect of shading and wind reduction to surface fuel from the standing dead trees.

Existing Vegetation Height

[2] Although there are exceptions that could lead to a biophysical setting type conversion, such as those influenced by climate change, uncharacteristic disturbances, and/or exotic species, these occurrences are rare and even if present would have little effect on the assignment of fuel model in this analysis area—that is, biophysical setting criteria are infrequently used in the LANDFIRE fuel model mapping rules in the western states.

As with existing vegetation cover we first updated the existing vegetation height with the LEMMA data in the oak woodland vegetation type.

LANDFIRE existing vegetation height represents the basal-area weighted average of the dominant and co-dominant trees (Chapter 4). In forested vegetation types it is therefore typically not necessary to reduce forest canopy height due to disturbance, as most disturbances would not change the average height significantly enough to reduce existing vegetation height to a lower height class (Table 7). Certain silvicultural methods that target dominant trees, such as clearcuts or thinning from above, are exceptions. For high-severity wildfire, we retained the pre-disturbance canopy height. In combination with the low canopy cover value we assigned, retaining a canopy height value would allow us to simulate a slight effect of the standing dead trees on shading and wind reduction to surface fuel. We were able to prohibit crown fire from being predicted in the post high-severity fire pixels through use of the LANDFIRE Total Fuel Change Tool "canopy guide" function (see below).

Integration of steps with the LANDFIRE Total Fuel Change Tool

With the preliminary critique and updates to the required vegetation and disturbance data layers complete, we then critiqued the LANDFIRE fuel mapping rules using the LANDFIRE Total Fuel Change Tool. A user's guide, tutorial, and information on training for this tool are available on the Wildland Fire Management Research Development and Application – Fuels and Fire Ecology Program website. In this section we will highlight key features of the tool that were used to critique and update fuels for the Rogue Basin analysis.

The LANDFIRE Total Fuel Change Tool provides users the ability to critique and modify the LANDFIRE fire behavior fuel model mapping rules. Additionally, the tool will create canopy fuel data layers (canopy base height and canopy bulk density) using LANDFIRE's methodology, or allow users to "hardcode" base height and bulk density values to unique combinations of vegetation and disturbance attributes. This allows the user to "fine-tune" the interaction of fuel model, canopy base height, and canopy bulk density that is so critical to accurately simulating wildfire behavior.

Critique and Modification of Fire Behavior Fuel Model

The fuel critique was done in a workshop setting where local fire and vegetation specialists from the Forest Service, Bureau of Land Management, and The Nature Conservancy participated. This collaborative approach not only provides a wide range of local knowledge and expertise but also facilitates a sense of ownership and confidence in the end product.

We critiqued the fire behavior fuel model mapping rules for each of the major existing vegetation types in the analysis area. For each existing vegetation type, we first reviewed its description and where it was mapped. If photos were available they would be displayed to provide further context. Next, we discussed which factors—canopy cover; canopy height (a surrogate for stand age); biophysical setting; and disturbance type, severity, and time-since-occurrence—influenced the surface fuels and reviewed how the mapping rules used different combinations of these variables.

Adjustments to the fuel model mapping rules can be made in one of two ways, either to the fuel model assignment itself or to the combination of variables that define a rule (Figure 25). Adjustments to the fuel model assignment were made if workshop participants felt the specified fuel model didn't represent the expected surface fire behavior for the vegetation type and structure identified (that is, if the flame length was too high/low or the rate of spread was too fast/slow). The LFTFC tool provides an interface for comparing the flame length and rate of spread of different fuel models under varying combinations of fuel moisture, slope, and wind speed (Figure 26) as an aid to making modification decisions. Adjustments to the canopy cover and height thresholds, or addition of biophysical setting criteria will influence the spatial distribution and proportion of area assigned to each fuel model. We modified these criteria if participants felt the location or distribution of fuel models did not reflect on-the-ground conditions.

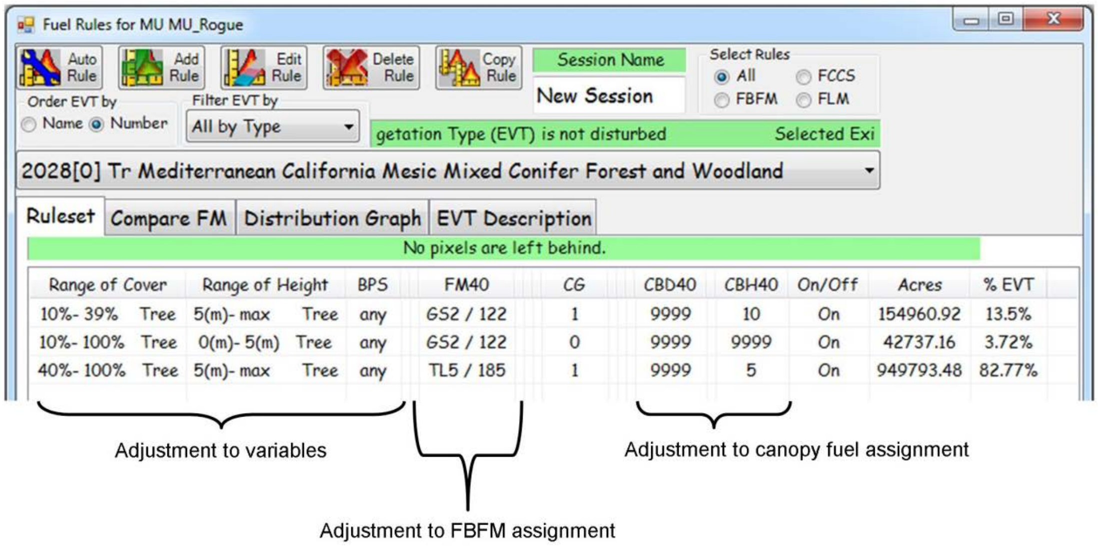

Figure 25. LANDFIRE Total Fuel Change Tool rulesets. Adjustments can be made to the range of variables, fire behavior fuel model (FBFM), and canopy fuel.

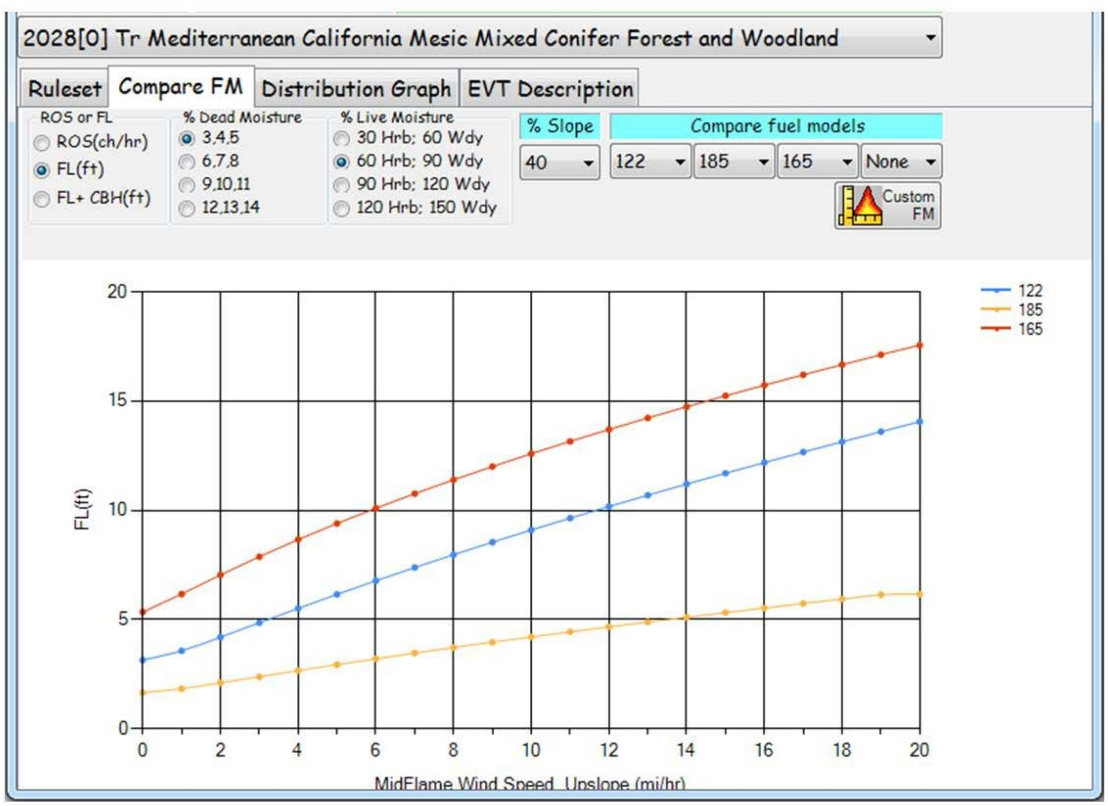

Figure 26. Comparing fuel models. The LANDFIRE Total Fuel Change Tool has built-in functionality to compare fire behavior between fuel models under a variety of fuel moisture and slope conditions.

Finally, for areas where a mastication treatment occurred we assigned the fire behavior fuel model outside of the LANDFIRE Total Fuel Change Tool using ArcGIS Spatial Analyst tools.

Critique and Modification of Canopy Fuels

There are two ways a user has control over how canopy fuels are mapped with the LANDFIRE Total Fuel Change Tool. The first is to use the tool's canopy guide feature; the second is to "hardcode" canopy fuel values. The canopy guide options are as follows:

- 0: No forest canopy structure characteristics (i.e., cover and height) or fuels are assigned. In forested existing vegetation types this may be used to represent a disturbance that removes the forested canopy (e.g., clearcut) or when the "forested" canopy is already considered in the fire behavior fuel model assignment (e.g., short trees).
- 1: The standard LANDFIRE methodologies (Chapter 5) are used to calculate canopy structure and canopy fuel values.
- 2: The canopy base height and canopy bulk density are artificially set to a point where crown fire—passive, active, or conditional (Scott and Reinhardt 2001)—will not be simulated (canopy base height of 10m and canopy bulk density of 0.012 kg/m-3). This value may be used in cases where canopy height and canopy cover values are still desired due to their influence on reducing wind speed and dead fuel moisture content through shading (Chapter 5) but where crown fire is unlikely (e.g., broadleaf forests).

We set the canopy guide value to 2 for all high-severity fire disturbances. As discussed previously, this technique allows for the standing dead trees to still have some, albeit minimal, influence on dead fuel moisture content and wind reduction, but eliminates crown fire and spotting from being modeled in fire behavior modeling systems. The use of a canopy guide value of 2 also served as an alternative to modifying the existing vegetation type due to high-severity fire. That is, by "turning off" crown fire and assigning the appropriate fire behavior fuel model for the expected change in the dominant vegetative lifeform, we accomplished the same goal.

For non-disturbed, and low- and moderate-severity fire disturbances, we assessed the effect of fire behavior fuel model and the LANDFIRE default canopy base height values on crown-fire initiation using the NEXUS (Scott 1999) fire modeling system (Figure 27). Canopy base height values were "hardcoded" (Figure 25) in the fuel rules if workshop participants felt that simulated crown-fire initiation didn't accurately represent expected crown-fire initiation. There are many factors to consider when assigning a canopy base height value. Knowledge of local wind patterns and/or analysis of the wind data that will be used in your analysis are paramount. We accepted the LANDFIRE default canopy base height assignments for all mechanical disturbances.

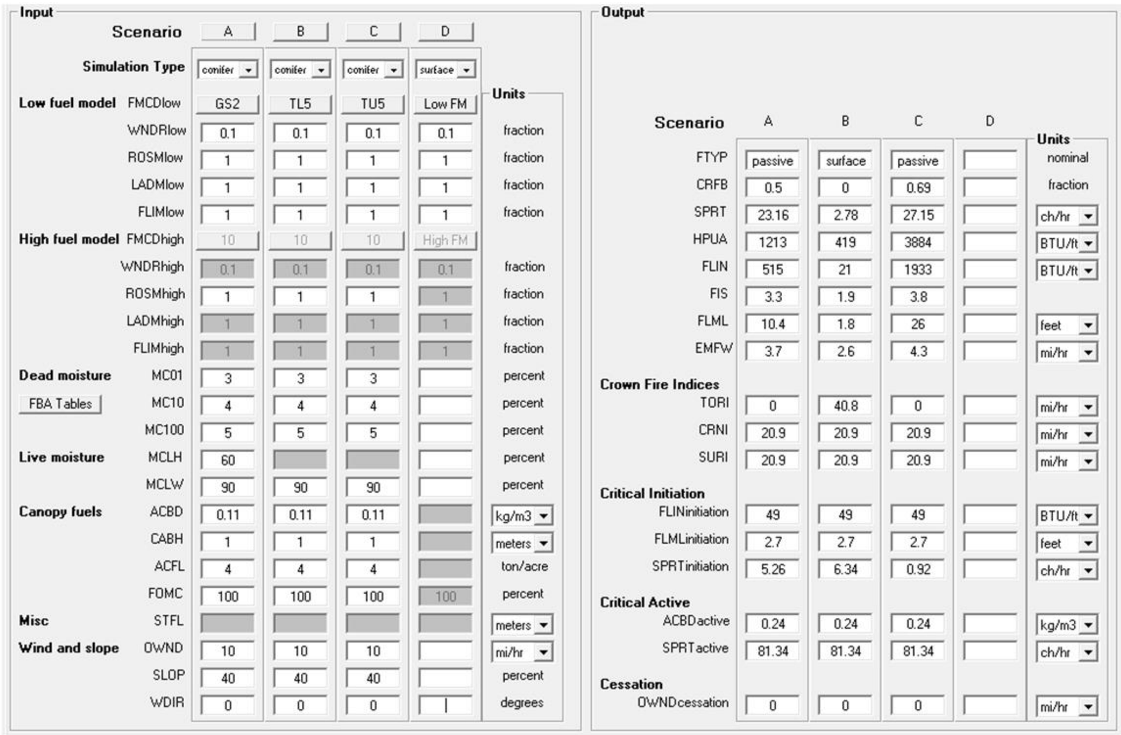

Figure 27. NEXUS fire modeling system. NEXUS facilitates in depth fire behavior critique and is particularly useful in assessing the environment conditions required to transition surface fire to crown fire based on fire behavior fuel model and canopy base height values.

Analysis

We created a new fire behavior modeling landscape (i.e., LCP file) based on our updated disturbance data layers and fuel model mapping rules. We then used this LCP to run basic fire behavior simulations as an additional critique. This final analysis step was used to highlight issues that were possibly overlooked or might have been hard to detect during the fuel calibration, thus necessitating further data modifications. After completion of this final step, the modified fuel data layers were used to analyze wildfire hazard in the Rogue Basin.

Example 2: Using LANDFIRE for local vegetation departure analysis

In this example we illustrate the data critique and update tasks conducted as part of an analysis of vegetation departure in the southern Sierra Nevada Mountains. The 12.5 million-acre planning area includes the Inyo, Sequoia, and Sierra National Forests; Sequoia and Kings Canyon National Parks; and portions of Yosemite and Death Valley National Parks (Figure 21). Because LANDFIRE provides wall-to-wall geospatial vegetation data, it was an obvious choice for vegetation departure analysis at such a broad spatial extent.

Define objectives

The objective of this project was to conduct a vegetation departure analysis using the FRCC Mapping Tool (Hutter et al. 2012) and LANDFIRE data. The results of this analysis would be further integrated into a wildfire hazard and risk assessment. The analysis was conducted in the fall of 2013.

Identify data requirements

Vegetation departure analysis requires data that characterize both the historical and current vegetation condition. LANDFIRE vegetation dynamics models (Chapter 6) would be used to describe the baseline historical conditions for each biophysical setting mapped to the analysis extent. LANDFIRE vegetation data would be used to characterize the current vegetation composition and structure. LANDFIRE 2008 vegetation data layers were acquired and updated for disturbance through 2012 by USDA Forest Service regional office geospatial analysts.

Critique and modification

We began our critique by listing biophysical settings by analysis area acreage from largest to smallest. A team of regional ecologists, vegetation specialists, and GIS and remote sensing specialists reviewed the data list to determine which biophysical settings to assess for departure. Biophysical setting classes comprising insignificant acreage, those that were difficult to accurately map (Chapter 6), and those determined not important to the analysis objectives were dropped. The review team further determined that the thematic resolution (Chapter 1) of the biophysical setting data layer was too fine, given local knowledge of historical vegetation dynamics and disturbance regimes (Chapter 6). Biophysical setting classes were therefore grouped (Table 11) based on recently developed presettlement fire regime groups that summarize presettlement fire frequency estimates for California ecosystems dominated by woody plants (Van de Water and Safford 2011).

Because the analysis area intersects multiple LANDFIRE map zones, we next reviewed the vegetation dynamics models for each of the biophysical settings for consistency across zones. It is common for the vegetation dynamics model to differ across zones for the same biophysical setting. If the map zone boundary reflects an ecological transition, then the differences between models may be appropriate (Chapter 6). However, if the map zone boundary creates an artificial demarcation in the analysis area, users will want to choose a single model that best fits the analysis area. The review team chose the most representative vegetation dynamics model for each biophysical setting or group of biophysical settings to be assessed. The LANDFIRE 2008 biophysical setting data layer was reclassified using the *reclassify* tool in the ArcGIS Spatial Analyst extension to the final 15 classes represented in Table 11.

Table 11: LANDFIRE biophysical setting (BpS) model groupings for the Southern Sierra vegetation departure analysis.

[a] Van de Water and Safford (2011) pre-settlement fire regime vegetation types shown for reference.
[b] Vegetation Condition Assessment.
[c] Based on local knowledge and ancillary vegetation data, workshop participants felt that areas mapped as a Mediterranean California Mixed Oak Woodland biophysical setting were incorrectly classified and should be classified as Central and Southern California Mixed Evergreen Woodland (BpS model 410140).

Next, the succession class mapping rules for each of the final vegetation dynamics models were assessed. Adjustments were made to ensure rules were *exhaustive* and *mutually exclusive*, and that uncharacteristic native conditions were appropriately represented for the local area (Chapter 6). Succession class was then remapped, accounting for the adjustments, using ArcGIS software (Figure 28). First, the existing vegetation type layer was reclassified to create an exotic vegetation mask, where exotic vegetation types were assigned a value of 1 and native vegetation types were assigned a value of 0. Next, the biophysical setting, existing vegetation cover, existing vegetation height, and exotic vegetation mask data layers were combined using the ArcGIS Spatial Analyst extension *combine* tool. A new field was then added to the output combine layer and populated with the new succession class values by first selecting combinations of the data layer attributes as defined in the mapping rules and using the *field calculator* function. Finally, after all combinations had been assigned a new succession class value, the ArcGIS Spatial Analyst extension *lookup* tool was used to create a new succession class data layer.

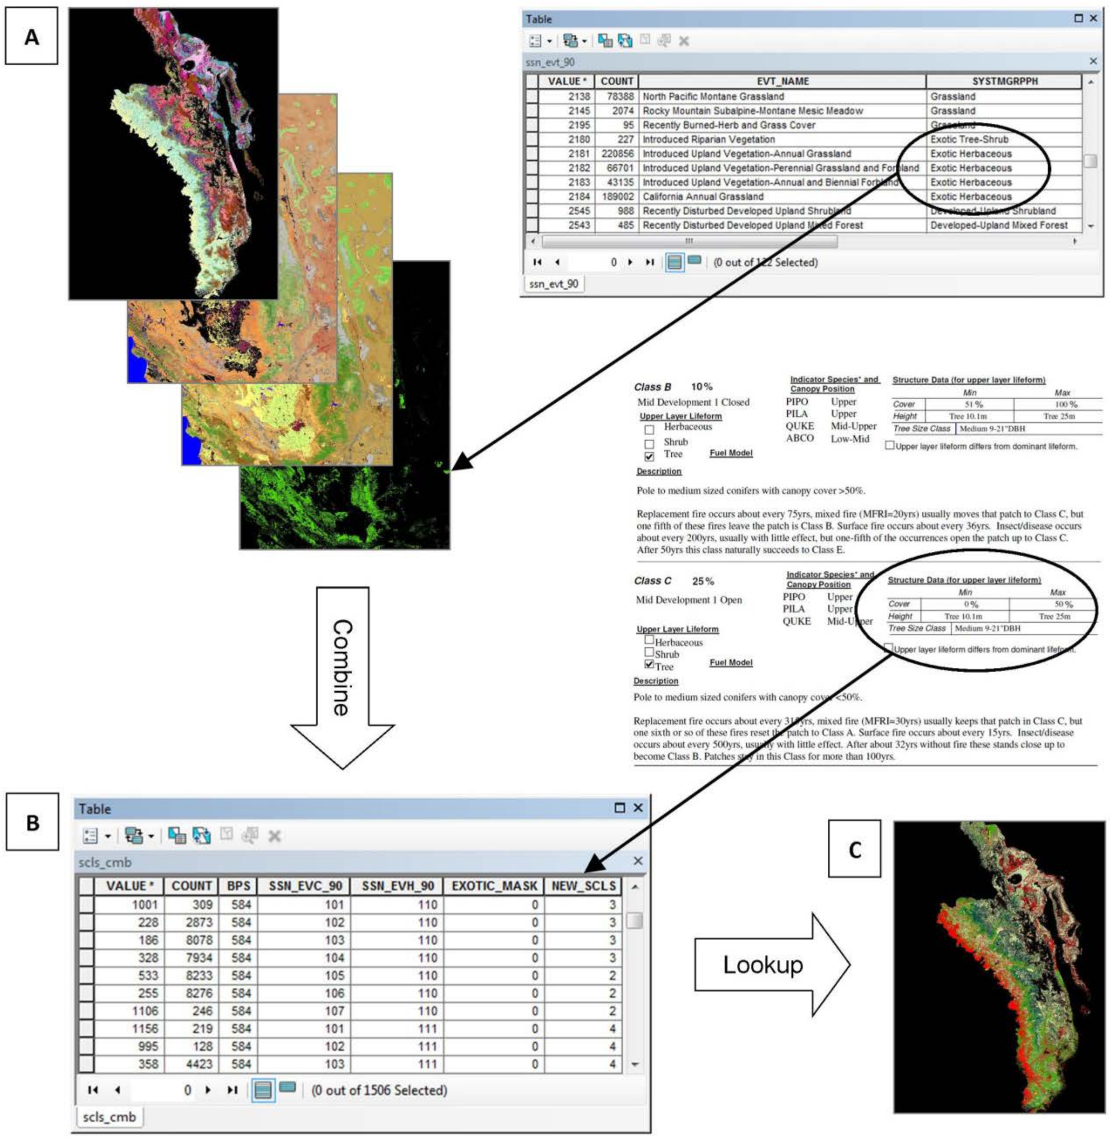

Figure 28. Succession class remapping process. (A) Biophysical setting, existing vegetation cover and height, and exotic vegetation data layers were combined using ArcGIS Spatial Analyst. (B) New succession class values were then assigned based on vegetation dynamics models and adjustments defined by local specialists. (C) Finally, the ArcGIS Spatial Analyst *lookup* tool was used to create a new succession class spatial data layer.

Analysis

We created a spatial landscape assessment unit data layer for conducting the vegetation departure analysis. Each biophysical setting was assigned to an assessment unit based on fire regime characteristics, including historical fire-size distribution (Barrett et al. 2010). Finally, we ran the Fire Regime Condition Class Mapping Tool and reviewed the results.

No issues were identified and the results informed managers where on the landscape specific vegetation development classes (i.e., succession class) were in either surplus or deficit in relation to their presettlement condition. As noted in Example 1 of this chapter, sometimes an analysis may highlight issues that were overlooked or hard to detect earlier in the data critique process that necessitate further data modifications. Analysis should be viewed as an iterative process.

ACKNOWLEDGMENTS

Funding for the production of this guide was provided by the Wildland Fire Management Research, Development, and Application program and the LANDFIRE Program through Cooperative Agreement 14-CA-11132543043. We thank the following people for their helpful review comments: Greg Dillon, Wendel Hann, Don Long, Charley Martin, James Napoli, Kurtis Nelson, Brianna Schueller, Tobin Smail, Jim Smith, Jenna Volpe, and Erin Noonan-Wright. We also thank Kim Ernstrom and Eva Strand for their project support and give a special thanks to our editor Joan Jones.

Abstract

Uncertainties about the consequences of natural resource management mean that managers are required to make difficult judgments. However, research in behavioral economics, psychology, and behavioral decision theory has shown that people, including managers, are subject to a range of biases in their perceptions and judgments. Based on an interpretative survey of these literatures, we identify particular biases that are likely to impinge on the operation and success of natural resource management. We discuss these in the particular context of adaptive management, an approach that emphasizes learning from practical experience to reduce uncertainties. The biases discussed include action bias, the planning fallacy, reliance on limited information, limited reliance on systematic learning, framing effects, and reference-point bias. Agencies should be aware of the influence of biases when adaptive management decisions are undertaken. We propose several ways to reduce these biases.

Introduction

Natural resource management is often a complex and uncertain process. The underlying environmental and physical processes are sometimes not well understood. Even when they are understood, there are likely to be uncertainties about the quantitative outcomes of management. The current actual status of the resource may be difficult to determine. Managers cannot always fully control which on-ground actions are undertaken due to lack of resources, legal powers, or capacities (Williams & Brown 2014).

These complexities and uncertainties mean that managers are required to make judgments. However, it has been shown that, in making judgments of these types, decision makers do not always undertake decisions "rationally." Simple rational decision-making models assume that agents always take decisions to maximize the achievement of their objectives, based on accurate knowledge of the outcomes, costs, and constraints. In reality, however, people have limited information, limited time, and limited cognitive capacity. As a consequence, they are restricted in formulating and solving complex problems, and they are susceptible to different types of biases (Arnott 2006; Tasic 2011)—beliefs that are inconsistent with reality (Chira *et al.* 2011) or behaviors that compromise the achievement of objectives. For example, Guthrie *et al.* (2000) found that some of the biases listed in Box 1 affect judges when they are making judicial decisions. Similarly, Hirshleifer (2008) found that financial regulators are subject to a different set of biases that influence their decisions, plans, and polices. The impacts of such biases can be substantial. For example, Kahneman (2012) reports on a 2005 study of rail projects worldwide undertaken between 1969 and 1998. Passenger usage of the rail system was overpredicted in 90% of cases. On average, planners overestimated passenger usage of new train lines by over 100%, reflecting a common bias known as the "planning fallacy."

Box 1: Selected behavioral biases with potential impact on adaptive management

- Action bias: Tendency to take actions even when it is better to delay action
- Framing effect: Tendency to respond differently to alternatively worded but objectively equivalent descriptions of the same item
- Reference-point bias: Tendency to overemphasize a predetermined benchmark for a variable when estimating the level of that variable
- Availability heuristic: Tendency to give more weights to events that can be recalled more easily
- Planning fallacy: Making judgments about a planned activity that are systematically over-optimistic, including underestimating project completion time, underestimating costs, or over-estimating benefits
- "Satisficing rule": Tendency to stop searching for a better decision once a decision that seems sufficiently good is identified
- Loss aversion: Tendency to value losses more highly than similar gains
- Reliance on limited information: Tendency to use a subset of information even when full set of information is available
- Limited reliance on systematic learning: Tendency to use information from past successful efforts rather than using information from both successful and failed efforts

For a general list of behavioral biases, see Arnott (2006) and Gino & Pisano (2008).

Managers of natural resources and the environment are likely to be just as susceptible to these biases as are other professionals who must make complex judgments, such as judges and financial regulators (Carlsson & Johansson-Stenman 2012). However, these issues have received little attention in the conservation literature. Our aim in this article is to draw from psychology, behavioral economics, and behavioral decision theory research literatures to identify key insights about biases that are relevant to conservation, and to understand their implications for managers responsible for management of environmental projects or programs.

In doing so, we focus to some extent on Adaptive Management (AM), since this is a process that has been promoted or used to manage complex and uncertain natural resource issues. AM is a process of "learning by doing" (Walters & Holling 1990) where learning from experience is combined with the need for immediate action (Westgate *et al.* 2013). Under AM, management policies are formulated as experiments that investigate ecosystems' responses to changes in people's behavior or management actions (Lee 1999). Conceptually, a set of potential models representing relationships between human actions and ecological outcomes are developed and tested. Viewing the learning process through a Bayesian lens, each model is assigned a probability of being the true model. In each time step, a management decision is made based on the current model probabilities, the current system state, and predicted future states. Model probabilities are updated after each time step based on each model's success in predicting outcomes (Conroy & Peterson 2012), and management may subsequently be modified.

Traditionally, AM has focused on learning from experimental trials or pilots of management approaches for biological and ecological systems (Wilhere 2002; McCarthy & Possingham 2007). It has been assumed that the decision makers will interpret the information collected and make their choices or decisions rationally and without bias. We will explore the extent to which research on human behavior and decision making casts doubt on this assumption. Broader implications for management of natural resources and the environment will also be discussed.

AM: Definition and Stages of Learning

AM has been defined by Williams *et al.* (2009) as "a systematic approach for improving resource management by learning from management outcomes" (p. 1). In active AM, the learning process is supported by purposefully collected information (Walters & Holling 1990), rather from observation of management actions chosen without regard to their ability to provide useful information for future decisions. In active AM, learning is often represented through single- and double-loop processes (Figure 1). Under a single-loop learning cycle, the key steps involved are: (1) define management goals with stakeholders involvement (step 1); (2) develop alternative management options, including an option to maintain the "status quo" (step 2); (3) develop models or statistical processes to trace system responses to management actions (step 2); and (4) implement management options (step 3; Westgate *et al.* 2013). Steps 4 and 5 involve monitoring and assessment of the outcomes, respectively. In a single-loop learning cycle, it is often assumed that project objectives, societal needs, and policy structures are fixed (Allen & Gunderson 2011).

In double-loop learning, on the other hand, it is assumed that policy objectives and structure could change. For example, in long-term projects, societal values and

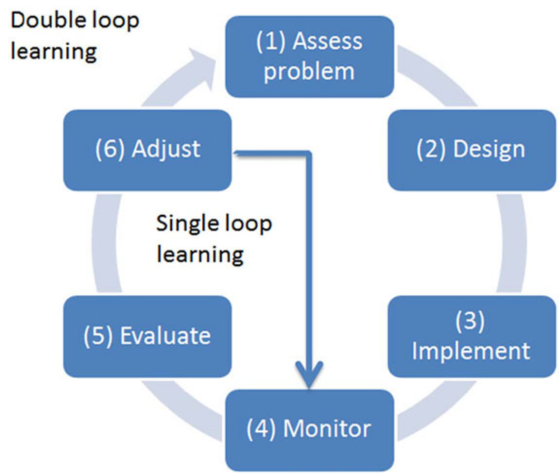

Figure 1 Different steps in active AM cycle with single- and double-loop learning (based on Williams & Brown 2014).

needs could change as time progresses and new management actions are introduced. The resource or the system under experimentation could also change to make the original project objectives unsuitable or unattainable. Therefore, the objectives, management options, or institutional arrangements might need to be changed. Under double-loop learning, original project objectives and management options are revisited after certain steps (step 6). New information from experimentation and model predictions are taken into account as well as changed policy and societal landscapes (Williams & Brown 2014).

In an AM regime, decision makers are responsible for defining management goals, identifying alternative management options, developing models, and implementing programs (Westgate *et al.* 2013). It is common to assume that in each step the resource managers would make "rational" decisions based on the information obtained from biological, physical, and social experiments. However, numerous studies inform us that people have cognitive limitation and bounded rationality, and are influenced by different types of biases. We expand on these issues in the following section.

Key Behavioral Biases

Both psychology and economics have rich literatures on the influences of different types of bias on behavior. Experimental economics serves three main purposes: testing theories, building new theories from observing experimental outcomes, and testing policy and management options. Behavioral economics also integrates insights from psychology to explain economic decision making. It studies the effect of psychological factors such as emotional, social, and cognitive factors on many decisions and economic processes (Camerer 1999). A related field is behavioral decision theory, which studies how people make decisions as well as how they should make decisions (Moore & Flynn 2008). The key biases identified in these research efforts that are relevant to AM are outlined below.

Action bias

"Action bias" occurs when the decision makers choose to take actions even when a "rational" decision maker would prefer to delay actions to allow further information collection, or to take no action. Possible reasons for action bias include that decision makers give higher weight to things that are readily observable and attributable (i.e., the management actions themselves), rather than to things that are delayed, indirect, or unobservable (i.e., potentially the outcomes from those actions; Patt & Zeckhauser 2000). For example, a study of elite soccer goalkeepers showed that they tend to jump to try to save goals even when the optimal strategy is to stay in place (Bar-Eli *et al.* 2007). In this case, taking action is valued in its own right, in addition to the value attributed to the outcome achieved. Similarly, environmental managers may feel that they will earn credit from their superiors, the general public, and the media if they take action even when it is not justified or should be of relatively low priority (Tasic 2011).

Action bias could be increased by uncertainty (Tan *et al.* 2012). In most environmental projects, knowledge of the effectiveness of interventions that will be taken on the ground is rather weak (Ferraro & Pattanayak 2006). As a result, taking action may be evaluated more positively than collecting additional information, partly because of a lack of evidence that actions would be ineffective.

The implication of "action bias" for AM is that it may be difficult to convince managers that an investment in information collection (i.e., AM) is worthwhile. They will tend to prefer to allocate the resources to additional on-ground management actions. Proponents of AM may enhance their persuasiveness by arguing that AM does not require actions to be delayed, and allows more effective or less costly actions to be taken in future. If AM is implemented, it should help to reduce action bias over time by providing additional information about whether the actions being undertaken are effective.

The planning fallacy

The "planning fallacy" is the tendency of project planners to be excessively optimistic about the performance of a project that they are developing (Kahneman & Tversky 1977; Kahneman & Lovallo 1993). For example, many investments in abatement of dryland salinity under Australia's National Action Plan for Salinity and Water Quality program were too small to make a notable difference to salinity outcomes (Auditor General 2008; Pannell & Roberts 2010). Apparently, managers choosing these investments greatly overestimated the effectiveness of the actions being funded, despite ample scientific evidence being available (Prosser *et al.* 2001; Dawes *et al.* 2002). The extent of bias due to the planning fallacy can be substantial. According to Griffin & Buehler (1999), only 1% of the U.S. military high-technology equipment purchases were delivered on time and on budget.

There are various factors that contribute to the planning fallacy. Buehler *et al.* (1994) observed that people estimate a project's expected completion time by constructing mental scenarios of how the project may develop. However, due to cognitive limitations, they generate a smaller range of scenarios than is realistically possible, overlooking many barriers and risks. The scenarios generated tend to reflect their hopes and preferences (Newby-Clark *et al.* 2000) and to neglect their own previous negative experiences with similar projects (Koole & van't Spijker 2000). To some extent, overoptimism is likely to reflect strategic biases adopted to increase the competitiveness of projects when funding is being allocated (Flyvbjerg 2007), but overoptimism is often present even when planners are attempting to be realistic (Kahneman 2012).

A strategy to reduce the planning fallacy is to ask managers to forecast the completion time, cost, or benefits for a range of comparable projects rather than a single project. This strategy, known as Reference Class Forecasting (Kahneman & Tversky 1977), has been effective in reducing time and cost overruns of large infrastructure projects (Buehler *et al.* 2010).

Where the planning fallacy is in evidence, AM may help to reduce its adverse consequences. AM, involving information collection and refinement of project design, helps in correcting decisions that were initially made on an excessively confident or optimistic basis. If necessary, targets can be modified or the project can be terminated following the collection of improved information (Dvir & Lechler 2004).

Reliance on limited information

Decision makers sometimes use only a subset of information even when the full-set information is available. In a series of experiments with common-pool resources, Apesteguia (2006) studied the impact of additional information on individual behavior and payoffs. The individual payoff depended on player's own investment as well as investments made by others. In one treatment, participants had complete information about the expected payoffs from their choices, while in another they had no relevant information. The experimenter observed that the aggregate outcomes (in terms of investment decisions and actual payoffs from the decisions made) were not significantly different between these two treatments (Apesteguia 2006). More-or-less similar observations have been made in other studies (Mookherjee & Sopher 1994; Oechssler & Schipper 2003; Van Huyck *et al.* 2007). One hypothesis to explain this phenomenon is that decision makers follow a "satisficing rule" to limit the cognitive costs of decision making (Hertwig & Pleskac 2010). Under such a rule, the decision maker stops searching for a better decision once he or she identifies a decision that seems sufficiently good.

Another version of this bias is "availability bias" in which people give more weights to certain types of events that can be recalled more easily (Tversky & Kahneman 1974). For example, a manager may assess the risk of bushfire higher than the risk of plant disease spread if bushfires have been more common or more salient in recent times. Underutilization of information is often observed in environmental planning. For example, it has been observed that many existing environmental planning systems fail to account for project costs (Mazor *et al.* 2013), for the effectiveness of management actions (Maron *et al.* 2013), or for behavior change (Pannell & Roberts 2010).

AM potentially provides a mechanism to counter this tendency of decision makers to ignore relevant information. It has been shown in many studies that use of systematic learning through use of data and models could outperform heuristic decision making and predictions by experts (Camerer 1981). It has also been shown that decision makers may employ information more comprehensively if they are asked to make a decision several times sequentially (with time delays) and to explain their decisions to third parties (Vul & Pashler 2008; Herzog & Hertwig 2014). By emphasizing the importance of using accurate information and encouraging use of a structured approach for doing so, AM may prompt a general strengthening of the evidence base for environmental decision making. There can also be a social aspect to AM, with different people contributing to decisions about how management should be adapted in response to new information. This socialization of the process may reduce the tendency of any individual to ignore information.

Limited reliance on systematic learning

Active AM involves systematic experimentation and learning from the outcomes. However, experimental studies on learning reveal that humans are not good at systematic learning. Instead, learning is often messy, noisy, and based on trial-and-error (Hertwig & Pleskac 2010). In practice, people hardly use systematic learning models where they compute and compare expected outcomes from every option before making a decision. Rather, they use heuristics and repeat their past successful choices without fully considering other potentially superior alternatives (Erev & Haruvy 2009).

One implication of limited reliance on systematic learning is that managers will try to learn only from their past “successful” project rather than learning from both “successful” and “failed” projects. In doing so, risk-averse managers are more likely to repeat their past successful choices instead of trying new management interventions (Denrell & March 2001). They are less likely (relative to risk-neutral managers) to invest resources to collect more information about the past unsuccessful strategy (Erev & Haruvy 2009). By contrast, a systematic AM approach would seek to learn from previous mistakes to avoid repeating them, and to enhance the resilience of the management system. AM encourages a systematic approach to learning, and to the use of new information for decision making. It makes explicit the importance of obtaining and using new information, at least partially countering tendencies not to do so.

An institutional barrier to systematic learning is staff turnover, which can be high in the environmental sector, sometimes due to the short duration of funding programs (Grafton 2005). Unless new staff commence before the departures of experienced staff, they must rely on written or verbal communication to learn about the existing or past project (Shogren & Taylor 2008). If the logic behind past decisions is not well-documented, new staff cannot integrate the successes or failures of past decision-making processes into their decision making. There are also differences in the way a new and an experienced manager would approach a problem. A new manager would use facts in a context-free manner whereas, for an experienced manager, problem recognition and action selection would be more intuitive (Hayes 2013).

One potential way to promote systematic learning is through the use of decision support systems (DSSs) that enable the storing of such information. There can be synergies between the use of DSSs and AM. Depending on the type of DSS, it may increase the transparency and evidence base of the initial decision to support a project. This transparent information can be updated as the AM process proceeds, allowing the DSS to inform decisions about modifications to the project (Dicks *et al.* 2014).

Framing effect and reference-point bias

The “framing effect” refers to a situation when people respond differently to statements that are worded differently but are objectively equivalent. Among the many ways of framing an environmental management issue, we mention three that are commonly discussed in the literature: (1) risky choice framing, where the expected outcomes of a risky option are described in different ways; (2) attribute framing, where some characteristics of an object or event are highlighted or focused on; and (3) goal framing, where different potential objectives of the program or activity are emphasized (Levin *et al.* 1998). In a risky choice, framing the outcomes from a lottery could be presented as a loss (say 50% chance of losing) or as a gain (50% chance of winning). In attribute framing, we might focus on only one or a few features of a project (say number of days required to complete a project) rather than all relevant features. For example, we could say that the project is successful if it is completed within a certain number of days (and ignore other features such as the achievement or nonachievement of environmental outcomes). In goal framing, we could focus on gain from undertaking a project (such as “Native animal population will increase if fox control bait is used”) or loss from not undertaking the project (such as “Native animal population will continue to decline if fox control bait is not used”; Krishnamurthy *et al.* 2001).

Reference-point bias may cause managers to respond differently to a program or activity depending on the level of a predetermined reference point or benchmark. For example, the same level of environmental improvement could be seen as a success if it is well above a benchmark level of improvement or a failure if it is less than a benchmark, even if the benchmark is arbitrary (Kühberger 1998). It has been shown that people are more sensitive to losses relative to a benchmark than to gains (Camerer 1998). This may mean that managers are strongly motivated to prevent their program from being perceived to be a failure relative to the reference point, but less strongly motivated to seek to make a program perform above the reference point, even if a stronger performance would be feasible and worthwhile.

By regular monitoring and evaluation of project outcomes, AM may help to enhance flexibility in the setting of project goals and to reduce dependence on a fixed reference point. AM, in conjunction with a DSS could help in reducing the impacts of framing effect and reference-point bias by helping managers to assess potential strategies more comprehensively and objectively. Reasons why DSSs are not more commonly used by environmental managers include: lack of adequate training, no clear policy guideline to use the best possible information or DSS, and pressure to spend money within a deadline that is too short to allow time for using the DSS (Shtienberg 2013). To address the last of these issues, in particular, agencies should ideally plan and prepare for potential programs or the next phase of an existing program well before the existing program has concluded.

Discussion

Although many natural resource managers claim to use AM, rigorous and systematic applications are rare (McFadden *et al.* 2011; Westgate *et al.* 2013; Williams & Brown 2014). This is surprising given the theoretical attractiveness of AM in the face of risk and uncertainty (Stankey *et al.* 2005). There has been little research about the impact of psychological biases on decision making by managers of environmental or natural-resource programs (Westgate *et al.* 2013). Based on a survey of the economics and psychology literature, we have identified a set of biases that have implications for AM in particular and NRM in general. As a result of this review, there are grounds to expect that: (1) the managers are likely to take on-ground actions even when these are not worthwhile (Patt & Zeckhauser 2000); (2) they could suffer from the cognitive illusion of being more in control of the system than they actually are (Koole & van't Spijker 2000); (3) they could be overconfident about the expected outcome of their decisions (Flyvbjerg 2007); (4) they may be overly optimistic in terms of expected completion time of the project (Kahneman 2012); (5) they might rely on a partial set of information for decision making even when fuller information is available (Hertwig & Pleskac 2010); (6) they might rely on trial-and-error learning and repeat their past successful choices instead of collecting and comparing information about the full set of decision options (Erev & Haruvy 2009); and (7) managers could try to achieve predefined goals rather than the best possible outcomes from a project (Kühberger 1998; Table 1).

Different biases could influence various steps of the AM cycle differently. For example, action bias could influence the design phase of the AM cycle and lead the planners and managers to design projects with more emphasis on on-ground actions and less on the expected outcomes. Similarly, overconfidence and reliance on limited information would mean the managers would fail to consider all relevant information during the design and monitoring phases. Limited use of systematic learning process would mean failure to learn from previous mistakes during the evaluation phase. Lack of systematic learning would also make mangers susceptible to framing effect and reference-point bias (Klayman & Brown 1993). Agencies should be cautious about the impact of these biases and take remedial measures (Fischhoff 1982).

First, the agencies need to promote a culture of learning (e.g., García-Morales *et al.* 2012). It needs to be recognized that both successful and failed projects generate valuable information about the future state and expected impacts of the management interventions. This could be done by providing appropriate incentives (tangible and intangible) for the managers and decision makers to consider the full range of options before making any decision (Arnott 2006), requiring them to repeat the same decision several times before finalizing it (Vul & Pashler 2008; Herzog & Hertwig 2014), or asking mangers to justify their decisions to external parties (Gollwitzer & Sheeran 2006).

Second, adoption of a DSS could facilitate retention and storing of relevant information (e.g., Behrens & Ernst 2014). It may also make learning from past projects easier and help in systematic evidence-based decision making. Relevant staff should be adequately trained and properly incentivized to use DSSs (Dicks *et al.* 2014).

Third, conducting benefit-cost analyses of planned options would help to refine and prioritize the options during the design phase of the AM cycle (e.g., Pannell *et al.* 2012, 2013). Benefit-cost analysis provides a systematic and objective framework to include all relevant costs and benefits (both market and nonmarket goods and services) related to a project. In the process of identifying benefits and costs, it also helps in identifying if there is complementarity among them (to avoid double counting) and the time lag and uncertainty attached to realization of each benefits and costs. Thus, benefit-cost analysis could be used as a tool to comprehensively assess the expected benefit of a project (Sunstein 2000; Atkinson & Mourato 2008).

Fourth, involvement of external third-party reviewers may also help in designing more realistic and feasible projects (Chen & Volden 2013; Behrens & Ernst 2014). Finally, scenario analysis should be conducted as part of the assessment and design phase of AM cycle to anticipate the expected outcomes of different options (Lautenbach *et al.* 2009). The likely impact of different types of biases, their impact and the effectiveness of potential remedial measures should be systematically analyzed and studied before making any final recommendation for use in decision making for natural resources.

Table 1 Potential psychological biases, their impacts on different steps of the AM cycle, and potential remedial measures to overcome the impact of the biases

Biases	Potential impact on behavior	Potential impact on different steps of AM cycle	Potential remedial measures
Action bias	• Tendency to rely more on actions rather than on results	• During design phase (step 2) projects with visible actions will be prioritized which may lead to wastage of valuable resources (money and time)	• Emphasize the value of information and learning from the AM cycles during the evaluation (step 5), adjustment (step 6), and assessment (step 1) phases rather than on the actions undertaken on ground • Conduct a benefit-cost analysis during the design phase (step 2) of the cycle
Planning fallacy	• Overoptimistic or wrong judgments on the expected benefits, completion time, and costs of the project	• Failure to implement the project (step 3) in due time • During the monitoring phase (step 4), all relevant indicators may not be included, which lead to inadequate assessment during the evaluation phase (step 5)	• Conduct feasibility study as part of the assessment of the problem (step 1) and design of the options (step 2) • Involve external third parties during design phase (step 2) to review proposed actions and their underlying assumptions.
Reliance on limited information	• Make quick judgment • Lack of clearly specified project goals	• During assessment of the problem (step 1), full set of information will not be considered, which will lead to faulty prioritization of projects	• Develop DSSs which will automate incorporation of available information and facilitate consideration of full range of available information during assessment (step 1) and design (step 2) phases
Limited reliance on systematic learning	• Failure to consider the full range of the options • Repetition of the "safe" options • Failure to learn from previous mistakes	• Failure to consider learning from "failed" projects during the evaluation phase (step 5) may lead to missed opportunities to learn and realize the full potential of the situation	• During the evaluation (step 5) and adjustment (step 6) phases, consider learning from all projects (complete/incomplete, successful/failed, etc.) • Always conduct a scenario analysis with a range of options and expected future states during assessment (step 1) and design (step 2) phases
Framing effect and reference-point bias	• Failure to understand the real implications of an option • Success as well as failure is measured relative to a reference point • Follow a satisficing rule rather than a maximization rule while making decisions	• Use wrong measures to evaluate a project (step 5) • Managers may not give their full efforts if they think that they have performed better than others (or with respect to a predefined goal) already (step 3)	• Use DSSs and train managers on how best to use it • A scenario analysis could demonstrate the best possible outcomes from a given situation

Global fire emissions buffered by the production of pyrogenic carbon

Matthew W. Jones[1,4*], Cristina Santín[1,2], Guido R. van der Werf[3] and Stefan H. Doerr[1]

Landscape fires burn 3–5 million km^2 of the Earth's surface annually. They emit 2.2 Pg of carbon per year to the atmosphere, but also convert a significant fraction of the burned vegetation biomass into pyrogenic carbon. Pyrogenic carbon can be stored in terrestrial and marine pools for centuries to millennia and therefore its production can be considered a mechanism for long-term carbon sequestration. Pyrogenic carbon stocks and dynamics are not considered in global carbon cycle models, which leads to systematic errors in carbon accounting. Here we present a comprehensive dataset of pyrogenic carbon production factors from field and experimental fires and merge this with the Global Fire Emissions Database to quantify the global pyrogenic carbon production flux. We found that 256 (uncertainty range: 196–340) Tg of biomass carbon was converted annually into pyrogenic carbon between 1997 and 2016. Our central estimate equates to 12% of the annual carbon emitted globally by landscape fires, which indicates that their emissions are buffered by pyrogenic carbon production. We further estimate that cumulative pyrogenic carbon production is 60 Pg since 1750, or 33–40% of the global biomass carbon lost through land use change in this period. Our results demonstrate that pyrogenic carbon production by landscape fires could be a significant, but overlooked, sink for atmospheric CO_2.

Globally, landscape fires, which include wildfires, deforestation fires and agricultural burns, emit approximately 2.2 Pg C yr^{-1} to the atmosphere (1997–2016)[1]. The majority of this total emission flux is contributed by non-deforestation and non-peatland fire emissions, which are approximately balanced by vegetation regrowth and thus have no net influence on atmospheric stocks of carbon on decadal timescales[2,3]; however, around ~0.4 Pg C yr^{-1} are emitted during tropical deforestation and peatland fires, which contribute to the net global emissions of carbon due to land use change (~1.1–1.5 Pg C yr^{-1} (Fig. 1))[4–6]. These global carbon budget (GCB) estimates are generated by models that represent the temporally distinct processes of immediate carbon emission from burned areas and decadal-scale sequestration through vegetation (re)growth in a spatially explicit manner[1,7,8]. However, such models routinely overlook the coincident flux of biomass carbon to recalcitrant by-products of fire, which can be stored in terrestrial and marine pools for centuries to millennia, and thus provide a long-term buffer against fire emissions (Fig. 1)[9,10–13]. Consequently, the legacy effects of fire that operate on the longest timescales are systematically excluded from models of the carbon cycle and from GCBs[12,14].

These legacy effects are due to the incomplete combustion of vegetation during landscape fires, which transforms part of the remaining organic carbon in the biomass to a continuum of thermally altered products that are collectively termed pyrogenic carbon (PyC)[10,12,15]. The majority of the PyC produced during landscape fires remains initially on the ground in charcoal particles of varying size and is subsequently transferred to its major global stores in soils[16–18], sediments[19,20] and water bodies[21,22]. A smaller fraction of fire-affected vegetation carbon is emitted as PyC in smoke[23,24]. PyC includes labile products of depolymerization reactions as well as aromatic molecules that result from condensation reactions, the latter of which are depleted in functional groups and thus chemically and biologically recalcitrant[25–27]. The enhanced resistance of PyC to biotic and abiotic decomposition leads to its preferential storage in environmental pools[15,20] and a residence time that is typically 1–3 orders of magnitude greater than that of its unburnt precursors[12]. This makes PyC one of the largest groups of chemically discernible compounds in the soil with a contribution to the soil organic carbon stocks of 14% globally[16]. A fraction of the PyC is also conserved across the land-to-ocean aquatic continuum and thus accounts for approximately 10% of riverine dissolved organic carbon[28], 16% of riverine particulate organic carbon[29] and 10–30% of the organic carbon in ocean sediments[13,19,30,31].

A series of reviews and data syntheses have recognized the potential of PyC production to invoke a drawdown (sink) of photosynthetically sequestered CO_2 to pools that are stable on timescales relevant to anthropogenic climate change and its mitigation[9,10,12,13,32–37]. Owing to the relative recalcitrance of PyC, the conversion of biomass carbon to PyC represents an extraction of carbon from a pool cycling on decadal timescales to a pool cycling on centennial or millennial timescales[13,19,20,25,38]. This storage potential contrasts with that of dead vegetation, which degrades on timescales of months to decades or enters soil pools with a shorter residence time than that of PyC[7,11,25,39,40]. Consequently, postfire PyC pools emit carbon to the atmosphere over a significantly longer time period than would be the case in the absence of PyC production and also provide a buffer that moderates atmospheric CO_2 stocks (Fig. 1)[9,12,13]. At present, the fire-enabled vegetation models that are used to make GCB calculations account for short-term fire emissions but routinely exclude fluxes of carbon from biomass to PyC or the delayed emission of carbon from legacy PyC stocks to the atmosphere (Fig. 1)[7,8,14,41,42]. This introduces systematic errors to GCBs through misrepresentation of the effects of modern and historical fires on the exchange of carbon between the atmosphere and terrestrial–marine pools[12–14].

Although PyC has been recognized as a major component of the postfire ecosystem carbon stocks for a number of decades[10,35],

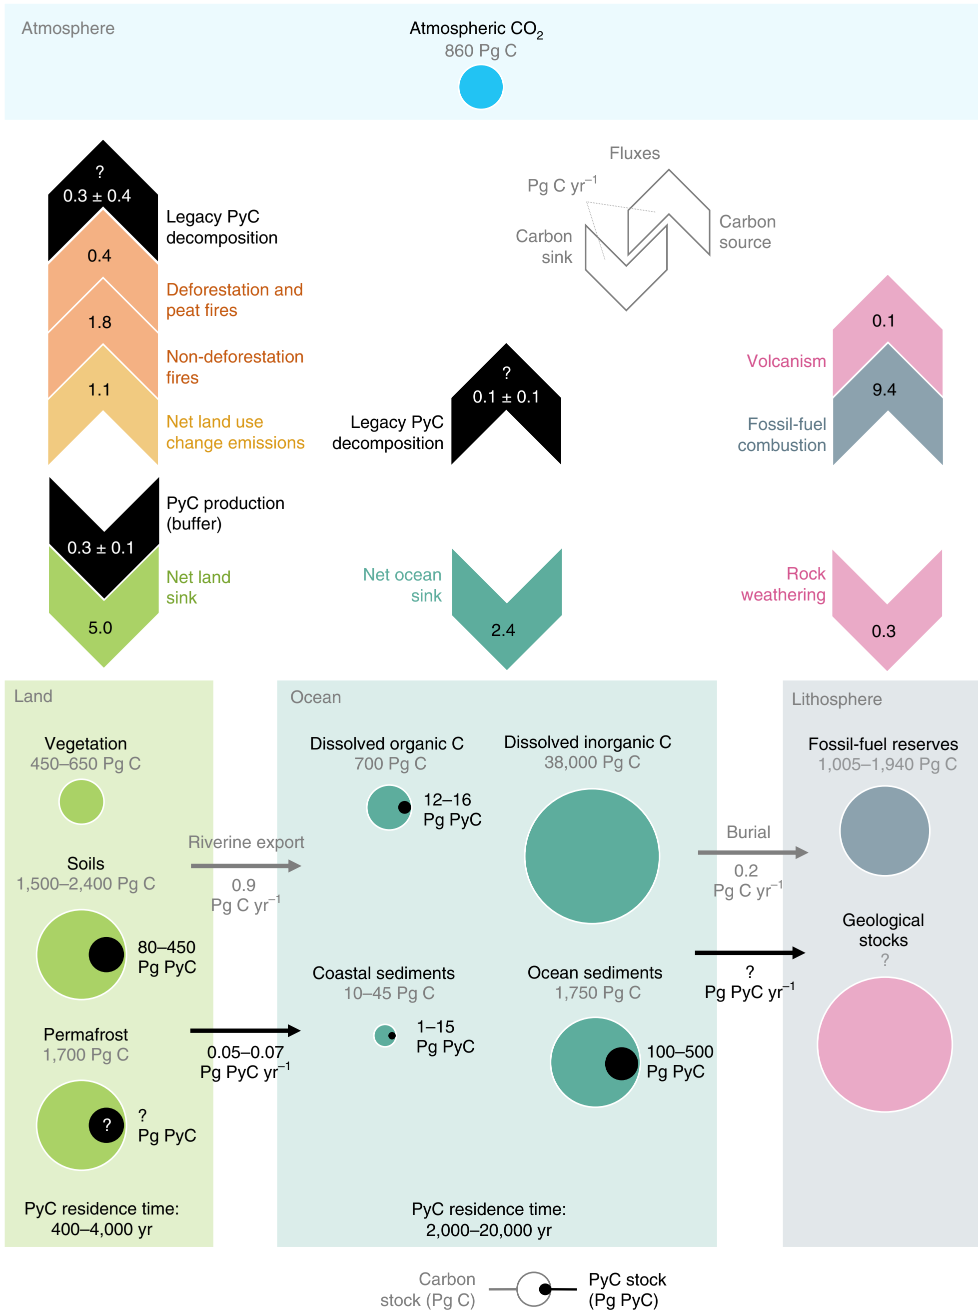

Fig. 1 | Schematic of the global carbon cycle including the buffer and legacy roles of PyC. Stocks (Pg C (1 Pg C = 1×10^{15} g of carbon)) and fluxes (Pg C yr^{-1}) of the global carbon cycle are represented by values from the GCB assessment of the decade 2008–2017[4] and the Intergovernmental Panel on Climate Change fifth assessment report of the decade 2000–2009[6]. Fluxes of carbon due to the net land sink are modified from the GCB to exclude non-deforestation fire emissions, whereas net land use change emissions are modified to exclude deforestation fire emissions. Carbon emissions from deforestation and peat fires and from non-deforestation fires were derived from GFED4s (ref. [1]) and relate to the period 1997–2016. PyC production fluxes due to deforestation and non-deforestation fires are based on estimates from GFED4s+PyC (this study). PyC stocks in soils, ocean dissolved organic carbon and ocean sediments are based on representative PyC/organic carbon ratios in the literature[13,16,68] applied to the estimates of organic carbon stocks and fluxes. PyC fluxes through rivers are the sum of global dissolved and particulate PyC export fluxes[28,29]. Residence times shown for soils derive from a meta-analysis of PyC decomposition in space-for-time substitution studies[69] and incubation experiment estimates extrapolated to field conditions[25]. Residence times for oceanic PyC pools are derived from the literature[19,70]. First-order estimates for legacy PyC decomposition fluxes and their uncertainties are calculated in quadrature for land and ocean pools as the product of the PyC stocks and the reciprocal of the residence times for PyC in these pools, assuming that the low- and high-end estimates for each term represent a consistent portion of normally distributed uncertainty.

quantification of its production rate at the global scale has been problematic and estimates vary by roughly an order of magnitude (50–379 Tg C yr^{-1}) (refs. [12,13,34,36]). A cause of the large range of production estimates is that calculations previously relied on incomplete information regarding the spatial distribution and type of fires, the allocation of carbon among the biomass fuel

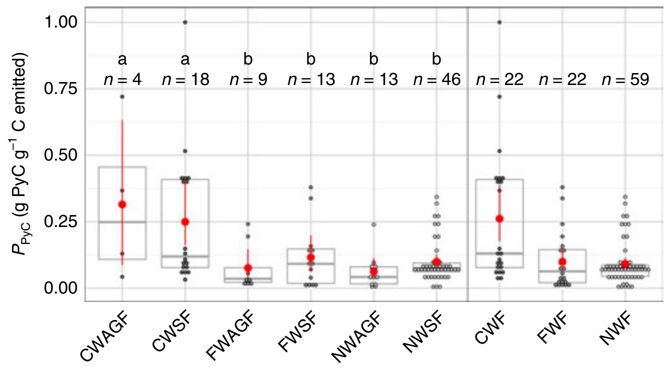

Fig. 2 | The box plots show the distributions of P_{PyC} values for each of the biomass component classes in the production factor dataset. Dots mark the distribution of P_{PyC} values across 1% intervals on the *y* axis. Red dots show the mean P_{PyC} values and red lines show the bootstrapped 95% confidence interval (Methods). Boxes illustrate the median and interquartile range of values. Letters a and b indicate biomass components with statistically similar P_{PyC} distributions at the 95% confidence level according to Tukey honest significant difference tests. The number of data entries (*n*) is also shown. CWF includes both CWSF and CWAGF. CWAGF, coarse woody aboveground fuels; CWSF, coarse woody surface fuels; FWAGF, fine woody aboveground fuels; FWSF, fine woody surface fuels; NWAGF, non-woody aboveground fuels; NWSF, non-woody surface fuels; FWF, fine woody fuels (includes both FWAGF and FWSF); NWF, non-woody fuels (includes both NWAGF and NWSF).

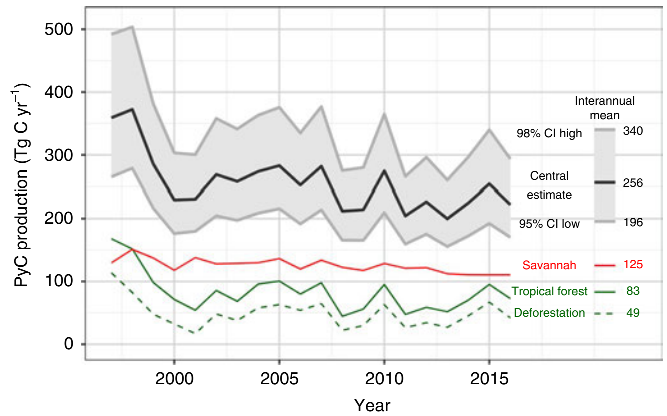

Fig. 3 | Annual global PyC production estimates from GFED4s+PyC for the period 1997–2016. The black line plots the modelled rate of production based on central P_{PyC} ratios (g PyC g^{-1} C emitted) from the global dataset. The shaded area indicates the uncertainty range of the modelled values based on the 95% confidence intervals (CIs) of P_{PyC} values (Fig. 2). The contributions of savannah burning (red line) and tropical forest burning (green solid line) to global PyC production totals are shown, the latter of which includes tropical deforestation fires (green dashed line).

components in burned areas and the specific PyC production factors for these distinct biomass fuel components. To alleviate these issues, we enhanced the Global Fire Emissions Database version 4 with small fires (GFED4s)[1], which is one of the principal process-based models used to make estimates of carbon emission from landscape fires[41,43,44]. Specifically, PyC production was incorporated by following a three-step approach that consisted of: (1) the assembly of the most comprehensive global database of PyC production factors (P_{PyC} (g PyC g^{-1} C emitted)) compiled to date, (2) the assignment of production factors for individual fuel classes stratified as coarse or fine and as woody or non-woody (Fig. 2) and (3) the application of P_{PyC} values to fuel-stratified carbon emissions (grams of C emitted) modelled by the native fuel consumption model in GFED4s. The output is the first global gridded dataset for monthly PyC production at a resolution of 0.25 × 0.25°, covering the years 1997–2016.

Global PyC production

Our central estimate for global PyC production in the period 1997–2016 was 256 Tg C yr^{-1} (Fig. 3), with an uncertainty range of 196–340 Tg C yr^{-1}, which includes variability in the measured P_{PyC} and interannual variability in global production, but excludes uncertainty in GFED4s emissions estimates (Methods). Interannual variability in global PyC production, expressed as the s.d. around the mean, was 47 Tg C yr^{-1} and was most strongly associated with variability in woody fuel combustion, which includes standing wood and coarse woody debris (CWD) (Supplementary Section 1 and Supplementary Fig. 1). Coarse woody fuels (CWF) produce PyC at a greater rate than finer fuels (Fig. 2) and consequently forest fires have disproportionate potential to influence global rates of PyC production (Supplementary Fig. 2).

The El Niño–Southern Oscillation (ENSO) is the primary driver of interannual variability in the burned area in the tropics[45] and previous analyses conducted with GFED showed that carbon emissions from tropical forest ecosystems more than doubled on average during the positive (El Niño) phases relative to the negative (La Niña) ENSO phases[46]. Correspondingly, we calculated that global rates of PyC production in tropical forests were 111% greater during the main fire season of the El Niño phases than during the La Niña phases (Supplementary Table 1). As rates of PyC production by non-forest fires were not sensitive to ENSO (Supplementary Table 1), the major driver of interannual variability in the total PyC production was variability in the tropical forest burned area (Fig. 3). The production of PyC was anomalously high in 1997–1998 (366 Tg C yr^{-1}), which aligns with a particularly strong positive El Niño phase that promoted extensive burning of (tropical) forests in South and Central America and in Southeast and Equatorial Asia[1,46].

Major production regions

The PyC production rates modelled by GFED4s+PyC conformed to a latitudinal pattern (Fig. 4) in which the tropical latitudes clearly dominated production at the global scale. Of the global production, 91% occurred in the tropics and subtropics (0–30° N and 0–30° S), whereas temperate (30–60° N and 30–60° S) and high-latitude (60–90° N) regions provided small contributions to the global total (8% and 1%, respectively).

The global distribution of PyC production also shows intricate regional patterns driven by variation in both the frequency at which fuel stocks were exposed to fire and the magnitude of the fuel stocks that were combusted during the fires that occurred (Supplementary Figs. 3 and 4). Fire frequency was ultimately the key determinant of PyC production rate, which explains why the tropics and subtropics were the dominant source regions. Although savannah fires affect low fuel stocks (Supplementary Section 2), these fires occur frequently and were spatially extensive (Supplementary Fig. 5 and Supplementary Table 2). They thus made the largest contribution to the global PyC production flux (125 Tg C yr^{-1}). Although tropical deforestation fires affected approximately 1% of the area of savannah fires, they affected large stocks of fuel (Supplementary Table 2) and were thus the second largest driver of global PyC production, at 49 Tg C yr^{-1}. The area affected by non-deforestation tropical forest fires was more than a factor of four larger than that of deforestation fires, but fuel consumption was relatively low (Supplementary Table 2). These fires provided the third major component of the global PyC production flux (34 Tg C yr^{-1}). Overall, 81% of the total global PyC production in the period 1997–2016 occurred in savannahs (49%) and tropical forests (32%).

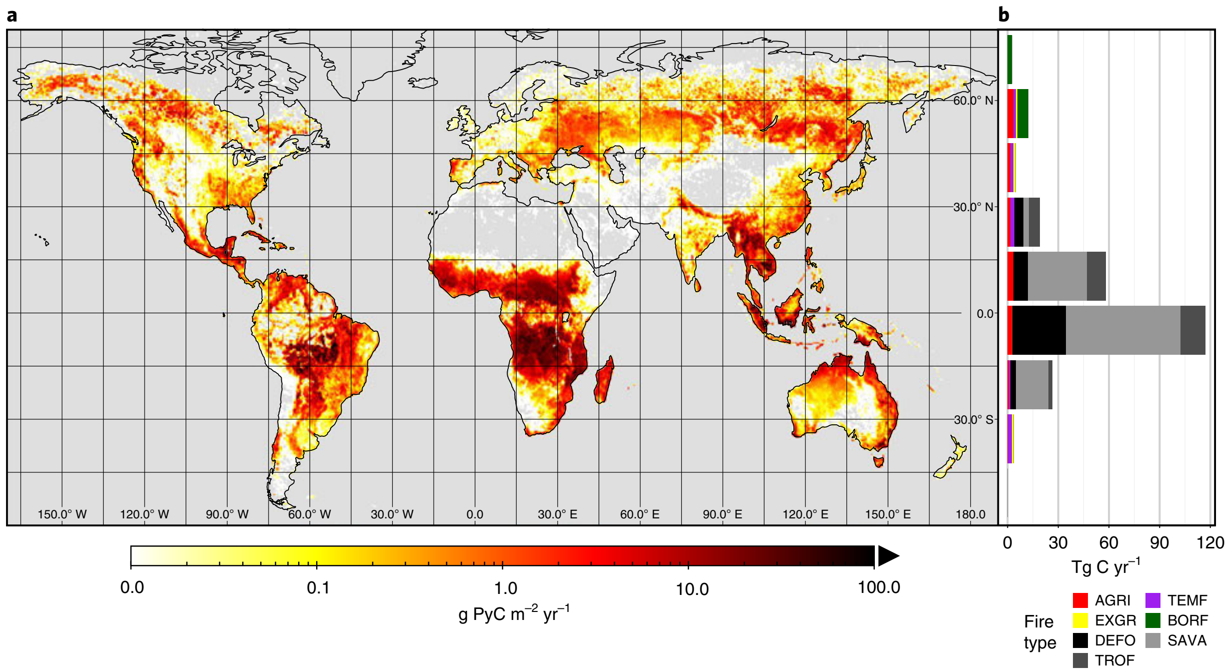

Fig. 4 | Annual average PyC production rates for the period 1997–2016 from GFED4s+PyC, based on central production factors (Fig. 2). a, The average global distribution of PyC production (g C m^{-2} yr^{-1}; note the log scale). **b**, The total production of PyC (Tg C yr^{-1}) in 15° latitudinal bands segregated according to the fire type, which includes savannah fires (SAVA), non-deforestation tropical forest fires (TROF), tropical deforestation fires (DEFO), agricultural fires (AGRI), temperate forest fires (TEMF), extratropical grassland fires (EXGR) and boreal forest fires (BORF).

Global carbon budget implications

Here we have quantified the global gross sink of atmospheric carbon caused by the transfer of photosynthetically sequestered biomass carbon to stocks of PyC during vegetation fires. Our central global PyC production flux estimate (256 Tg C yr^{-1}) is non-trivial within the context of the global carbon cycle (Fig. 1), as it equates to 12% of the global carbon emissions flux due to biomass burning and ~8% of the land sink for atmospheric CO_2 (~3.0–3.2 Pg C yr^{-1}) (refs. [4,6]). The global PyC production flux also equates to 75% of the carbon emitted from tropical deforestation and peat fires, which are the main categories of fire that cause a net loss of carbon to the atmosphere[1,9,47]. The PyC flux modelled here occurs in addition to the smaller global flux of 2 Tg C yr^{-1} caused by the emission of PyC in smoke from vegetation fires (according to equivalent estimates made using GFED4s in the years 1997–2016)[1].

The magnitude of our global estimate for PyC production indicates that the production of PyC during vegetation fires has the potential to significantly influence the atmospheric stock of carbon. A net sink of atmospheric carbon to stocks of PyC can be expected to develop if the flux associated with its production is unmatched by remineralization fluxes from legacy PyC stocks in terrestrial–marine pools (Fig. 1). Earth system models (ESMs) are the most sophisticated tools available to quantify the exchange of carbon between the atmosphere and these pools in time periods for which robust empirical data are sparse or unavailable. Despite previous attempts to highlight the importance of PyC production for carbon storage over timescales relevant to anthropogenic climate change and its mitigation[34,35,48], the absence of the PyC cycle from ESMs has restricted the scope to quantify its role in the carbon cycle[14]. The method introduced here allows for the routine integration of PyC production into fire-enabled vegetation models in a manner that systematically considers the spatial distribution of fire, the composition of the fuel stocks affected and the specific PyC production factors that apply to individual fuel components. This procedure is simple to implement in other fire-enabled vegetation models, which means that the major outstanding challenge to quantifying the net exchange of carbon between the atmosphere and PyC stocks with ESMs is to improve constraints over its storage and residence time in terrestrial and marine pools (Fig. 1)[13,14].

We also show that the PyC cycle must be integrated into ESMs if they are to represent accurately the role of fire in Earth's carbon cycle. The production flux of PyC represents the quantity of carbon that models would otherwise treat either as emitted or as unburned biomass with a residence time in terrestrial pools on the order of months to decades[7,11,25,39,40,49]. At present, the fate of 11% of the global biomass carbon stocks affected annually by fire is misrepresented in global models. As PyC dynamics are not represented in the ESMs used to make GCB calculations[4], this pool may represent a quantitatively significant missing sink or source of carbon to the atmosphere[14,50]. Recent estimates suggest that total carbon emissions from biomass burning in the period 1750–2015 amounted to ~500 Pg C (averaging 1.9 Pg C yr^{-1}) (ref. [41]). Under the assumption that the modern global PyC production flux maintained a constant ratio with the carbon emissions flux throughout this period, we estimate that since the beginning of the industrial revolution ~60 Pg C was transferred to the PyC stocks. This value is equivalent to 33–40% of the carbon lost from biomass pools due to land use change in the same time period (145–180 Pg C) (refs. [6,51]).

Our estimates for the modern and historical PyC production incorporate the best current understanding of PyC production through the combustion of vegetation biomass; however, the limitations of these estimates are worthy of mention. Notably, we do not include the production of PyC through the combustion of organic matter in soils, which may be an important process that drives the accumulation of PyC stocks in environments with deep organic layers, particularly peatlands[52]. We also do not account for the recombustion of PyC in locations that experience secondary burns, which can drive losses of the PyC that remains exposed at the surface[53]. PyC mass losses through recombustion have been reported as <8% in savannahs[54] and 17–84% in boreal forests[53,55]; however, the long fire return intervals in the latter biome typically allow sufficient time for PyC to be protected from recombustion through its burial in soils[17]. Our exclusion of recombustion is deliberate as we consider the process to be a component of the legacy PyC decomposition flux, which we do not quantify here (Fig. 1). Finally, our dataset of PyC production factors provides values for P_{PyC} that are modulated by fuel class (Fig. 2), but does not take into account fire characteristics (for example, temperature and duration) that are relevant to the formation of PyC[36,56,57]. The continued study of PyC production, with a particular focus on regions with high or rising fire incidence[58–60] and a range of fire intensities[61], will facilitate the application of more specific production factors in spatially explicit global models and thus result in reduced uncertainties in the global PyC production.

The production of PyC may become an increasingly important process for global carbon cycling in future centuries. Although the global burned area has declined in at least the past two decades, due predominantly to the conversion of savannah and grassland to agriculture[62,63], recent fire modelling studies generally agree that this decline is unlikely to continue past the year 2050[58–60]. It is also likely that a higher fraction of global burned area will be distributed in forests in which significant stocks of vegetation carbon are held[58,64,65]. As woody fuels generate more PyC per unit of biomass carbon than other fuels (Fig. 2), the spread of fire into forests can be expected to disproportionately enhance the global PyC production (Supplementary Fig. 2). Although it is less clear how fire prevalence will change in tropical and temperate forests owing to a stronger human control over burning in these regions[58,62], recent increases in fire extent caused by an increasing drought frequency in Amazonia already counteract reductions in the extent of deforestation fires[66]. Notwithstanding the significant uncertainty that exists in model predictions of future fire regimes, there are strong indications that PyC production rates will increase in some of the Earth's most carbon-dense regions in response to a changing climate[7,9,67]. This implies that the buffer for atmospheric CO_2 emissions that results from PyC production will grow in future centuries.

Jenkins for their assistance during the collation of the global dataset of PyC production factors. We also thank B. de Groot for his part in securing funding of the Leverhulme Trust Grant.

Author contributions

M.W.J., C.S. and S.H.D. designed the study. S.H.D. led the Leverhulme Trust Research Project grant that funded the main body of the work. M.W.J. collated the PyC production factor dataset with support from C.S. C.S. and S.H.D. provided unpublished PyC production data. G.R.vdW. provided access to the GFED4s code. M.W.J. adapted the GFED4s code to include PyC production with the support of G.R.vdW. M.W.J. conducted the formal analysis of the production factor dataset and model outputs. All the authors contributed to the interpretation of the results. M.W.J. wrote the manuscript and produced all the figures. All the authors contributed to the refinement of the manuscript.

Methods

Global fuel consumption modelling in GFED4s. In GFED4s, carbon emissions to the atmosphere are quantified based on burned area and fuel consumption per unit of burned area. Burned area is derived from satellite data[71] and fires that are too small to be detected by regular burned area algorithms are derived statistically based on active fire detections and relations with, among others, vegetation indices[72]. Fuel consumption is modelled using a satellite-driven biogeochemical model[1] and tuned to match observations[73]. Most of the underlying satellite input datasets have a 500 × 500 m resolution but are aggregated to the model resolution of 0.25° × 0.25°. Total fuel consumption is based on the fuel consumption of several fuel components, which include leaves, grasses, litter, fine woody debris, CWD and standing wood. van der Werf et al.[1] give more information on the GFED4s modelling approach.

To calculate the PyC production within GFED4s we added the production factor P_{PyC}, which quantifies the production of PyC per unit carbon emitted. Until now, the principle obstacle to performing a global modelling exercise of this type was the lack of a sufficiently rich and standardized dataset with which to constrain representative values for P_{PyC}.

Our estimates of uncertainty in the annual PyC production relate only to variability in the PyC production factors and interannual variability in emissions and do not include uncertainties in carbon emission estimates propagate from GFED4s. Uncertainties in GFED4s emissions estimates are discussed at length in van der Werf et al.[1,74] and are predominantly the result of uncertainties in the satellite detection of small fires using thermal anomalies and burn scars. As carbon emissions and PyC production are codependent on the burned area, estimation errors that relate to fire detection introduce scalar uncertainties. Uncertainty in the fuel consumption is an additional component of the overall uncertainty in GFED4s emission estimates[1] and has been reduced from previous versions (for example, GFED3) through its incorporation of a global dataset of fuel consumption estimates[73]. As discussed in the primary literature that relates to the development of the GFED4s[1], a formal global-scale assessment of the uncertainties in fuel consumption cannot be completed due to a paucity of ground truth data for some input datasets. For the previous version of GFED (GFED3), Monte Carlo simulations that accounted for uncertainty in both burned area detection and fuel consumption were used to obtain first-order constraints on the uncertainty in carbon emissions, which were ±20–25% at global, annual scales as a 1 s.d. (1σ) value[74]. Developments of GFED4s included the incorporation of small-fire burned area detection, which led to important reductions in the negative bias in the emissions estimates[72]; however, small fires are also challenging to detect and a lack of validation data prevents the formal investigation of uncertainty in burned area for GFED4s[1,72]. Hence, the true uncertainty of GFED4s is not known precisely, but it is likely to be on the same order as that of GFED3 ($1\sigma = \pm 20$–25%). Nonetheless, uncertainty ranges are likely to be greater in regions where small fires are prevalent or where organic soils are affected (for example, Central America, Europe and Equatorial Asia)[1,72].

Regional-scale field studies of fire emissions have served to validate that the GFED modelling framework produces reliable estimates at large scales, for example, in Alaska[75] and the tropics[76]. Studies that involve atmospheric tracers have also provided vital diagnostics for the performance of GFED[1], and generally highlight its proficiency at large scales but reveal some weaknesses in specific regions or during isolated events[77–82]. Overall, GFED4s is highly suited to the investigation of the effects of fire in global-scale biogeochemical cycles and is thus regularly used in GCB assessments[4] and as a reference point for the fire modules of ESMs[7].

Collating a global dataset of PyC production factors. We compiled a new database of P_{PyC} factors (Supplementary Dataset) from a global collection of 22 published studies that reported on PyC production in 91 burn units, as well as two new datasets produced by the authors with 23 burn units reported for the first time here, and we standardized their reporting. All the studies used one of the following two broad approaches to quantify the impacts of fire on the biomass carbon stocks, either prefire and postfire stocks of biomass carbon and PyC are measured or space-for-time substitution is used to constrain burned and unburned stocks of biomass carbon and PyC, which are assumed to be equivalent to prefire and postfire stocks, respectively. Hereafter, the terms 'prefire' and 'postfire' are used to refer to both types of assessment. Here we focus only on PyC present in charcoal and ash[83] on the ground following fire and on charred vegetation. PyC emitted with smoke, transported in the atmosphere and deposited on a regional-scale area is not included as this process has been studied in separate dedicated studies conducted by atmospheric scientists[23] and represents a relatively small flux in comparison (see main text)[12,13].

The P_{PyC} values were calculated for each of the six classes of widely used biomass components: CWSF, which includes CWD or downed wood defined by typical diameter thresholds of >7.6 cm or >10 cm (refs. [84,85]); FWSF, which includes fine woody debris or any other woody debris with diameters below the thresholds for CWSF; CWAGF, which includes trees or branches with diameters greater than the thresholds for CWSF; FWAGF, which includes material described as shrubs, trees or branches with diameters below the thresholds for CWSF; NWSF, which includes litter, understory vegetation, grass, root mat and any other form of non-woody material directly in contact with the ground surface[85,86] and, finally, NWAGF, which includes foliage, leaves, needles, crown fuels and any other forms of non-woody material that attach to standing wood structures above the ground surface.

For each biomass component, P_{PyC} (PyC produced per C emitted) was calculated using the following equation:

$$P_{\mathrm{PyC}} = \frac{C_{\mathrm{Py}}}{C_{\mathrm{PRE}} - C_{\mathrm{POST}} - C_{\mathrm{Py}}}$$

where C_{Py} is the mass of PyC created during the fire that was attributed to the component, C_{PRE} is the prefire stock of biomass carbon in the component and C_{POST} is the postfire stock of biomass carbon in the unburnt component. C_{Py}, C_{PRE} and C_{POST} are all expressed in the units g C km^{-2}.

Criteria were applied as filters to the dataset to ensure that P_{PyC} could be calculated in a consistent and representative manner. Specifically, P_{PyC} was calculated if the following conditions were met: first, both prefire and postfire biomass stocks were reported and the carbon content (%) was either measured or assumed based on representative values from the literature; second, postfire stocks of pyrogenic organic matter (charcoal, ash and the charred components of partially affected vegetation) were reported and their PyC content (%) was either measured or assumed based on representative values from the literature; third, the type of fire that occurred was representative of a widespread regional fire type (for example, wildfires, slash-and-burn deforestation and prescribed fire) and fourth, in experimental fires, the biomass carbon stock was designed to replicate the density and structure of biomass carbon stocks observed in the field and the burning efficiency was not optimized or adapted as a factor of the study design.

The set of criteria outlined above does not exclude studies that assess the PyC content of charcoal using one of the various chemical or thermochemical techniques available for the separation of PyC from bulk organic carbon[87,88]. Such techniques are frequently used for the detection of PyC in well-mixed soil, sediment and aquatic matrices. However, we note that none of the studies included in our dataset utilized a chemical or thermochemical approach to separate PyC from non-PyC; instead, these studies considered all the organic carbon in residual products of interest (charcoal, ash and the charred components of partially affected vegetation) to be PyC. Thus, we highlight that our estimates of P_{PyC} are free of the intermethod variability in PyC quantification that often confounds the comparison of PyC concentration in environmental matrices across studies and contributes to the notable uncertainty in the magnitude of Earth's major PyC stocks[12,13] (Fig. 1).

Like biomass carbon, total PyC stocks are distributed across several components, which include charcoal and ash on the ground, charcoal attached to CWD and charcoal attached to aboveground vegetation[12]. The majority of the studies included in the production factor dataset matched the studied PyC components to individual biomass carbon components from which they were known to derive. However, as some individual components of the PyC stocks can have a mixture of sources that are indistinguishable from their location or appearance alone, it was occasionally necessary to make assumptions about the biomass components that were sources of these components. This was done on a study-by-study basis. In cases where the source of each PyC component was not explicitly stated, the following procedural steps were adhered to. On a first basis, the PyC component was assigned to a biomass component according to the most probable source inferred, but not explicitly stated, in the primary literature. Second, where more than one biomass component was inferred to be a source of the PyC stock in the primary literature, the PyC stock was weighted proportionally to the prefire stock of carbon present in each of the implicated biomass components. Otherwise, if no sources of PyC were inferred in the primary literature it was necessary to make independent assumptions about the source of PyC in a manner that was consistent with the other studies included in the dataset and our collective experience of quantifying PyC production in the field.

Summary of the production factor values for use in GFED4s+PyC. Our global database suggested that CWSF and CWAGF produce significantly more PyC, relative to carbon emitted, than other fuel classes (their P_{PyC} averaged at 0.25 and 0.31 g PyC g^{-1} C emitted, respectively (Fig. 2)). In contrast, the mean P_{PyC} values for FWSF and FWAGF (0.12 and 0.076 g PyC g^{-1} C emitted, respectively) did not differ significantly from those of NWSF and NWAGF (0.099 and 0.062 g PyC g^{-1} C emitted, respectively). These results are consistent with previous studies, which suggest that large-diameter woody fuels burn less completely and produce PyC in greater proportions than finer fuels[34,35].

For each class, the mean PyC production factor was used as the central estimate for P_{PyC} and the confidence interval around the mean P_{PyC} was calculated through a bootstrapping procedure. Specifically, the available PyC production factors from the dataset were resampled 50,000 times, the mean P_{PyC} was calculated for each resample and the 95% confidence interval was calculated as the middle 95% of the observed 50,000 means (that is, those ranked 1,250th to 48,750th).

According to an analysis of variance with a Tukey honest significant difference post hoc test, no significant differences in mean P_{PyC} were observed between the distributions of P_{PyC} for coarse, fine and non-woody fuels positioned at the ground surface and those same fuels located above the ground surface. Therefore, the

P_{PyC} values applied in GFED4s+PyC are based on the distribution of values in three simplified fuel classes (Fig. 2): CWF (mean 0.26 g PyC g^{-1} C; 95% confidence interval, 0.18–0.39 g PyC g^{-1} C), FWF (mean 0.096 g PyC g^{-1} C; 95% confidence interval, 0.064–0.15 g PyC g^{-1} C) and NWF (mean 0.091 g PyC g^{-1} C; 95% confidence interval, 0.074–0.11 g PyC g^{-1} C).

Assigning PyC production factors in GFED4s+PyC. P_{PyC} values were assigned to each of the native fuel classes of GFED4s[1], which are leaves, grasses, surface fuels (which include litter and fine woody debris), CWD and standing wood (which includes trunks, stems and branches). Mean P_{PyC} values and bootstrapped confidence interval values for CWF, FWF and NWF from the global dataset were used to define representative P_{PyC} values for each of the GFED4s fuel classes (Fig. 2). Full details as to the assignment of P_{PyC} values to each GFED4s fuel class are provided in Supplementary Section 3 and Supplementary Table 3). Briefly, leaf, litter and grass were assigned the relevant P_{PyC} values of NWF, fine woody debris and CWD were assigned the values of FWF and CWF, respectively, and P_{PyC} values for standing wood were applied in a spatially explicit manner as weighted combinations of the P_{PyC} values for CWF (carbon in trunks) and FWF (carbon in branches). The weighted CWF:FWF ratio was assigned according to empirical relationships that defined biomass carbon apportionment to branches and trunks in the various forest types of the GFED4s land cover scheme (Supplementary Section 3 and Supplementary Table 4)[89].

Quantifying ENSO impacts on PyC production. To investigate the influence of pantropical climatic variability driven by the ENSO on the production of PyC, we replicated the analysis presented by Chen et al.[46] with a focus on PyC production rather than on carbon emissions. The pantropics were defined as consisting of Central America, Northern Hemisphere South America, Southern Hemisphere South America, Northern Hemisphere Africa, Southern Hemisphere Africa, Southeast Asia, Equatorial Asia and Australia (Supplementary Fig. 6). The PyC production in El Niño and La Niña phases was compared for the major fire season periods defined in each tropical region by Chen et al.[46]; their study gives a thorough explanation of the rationale for selecting these comparison periods. We summed PyC production in the major fire season period of each region and disaggregated this total to forest and non-forest fires according to the dominant land cover type in the GFED4s land cover scheme (based on the MODIS Land Cover Type Climate Modelling Grid product MCD12C1)[90].

Apportioning sources of PyC. After the GFED4s+PyC model runs, PyC production was assigned to specific sources following a method developed previously for use in GFED4s model runs[1,74]. Specifically, PyC production that occurs as a result of non-deforestation fires was disaggregated in each cell to tropical forest, savannah/grassland, boreal forest, temperate forest and agricultural fires using an existing algorithm that utilizes fractional tree cover, climate and fire-persistence variables. van der Werf et al.[74] give a full discussion of this algorithm. We added an additional latitudinal constraint (30° N to 30° S) to further disaggregate the savannah compartment, which thus separates tropical savannahs and grasslands from extratropical grasslands.

Data availability

The global dataset of the PyC production factors is available as a supplementary data file (GlobalPyC_supplementarydataset.xlsx). This dataset will also be uploaded to the GFED website (http://www.globalfiredata.org) and updated with new data as it becomes available. Supplementary Section 4 contains full references to the studies included in the production factor dataset. Burned area and fire emissions data are publicly available at the GFED website. Additional ancillary data are available from the corresponding author on request.

Livestock Impacts on Riparian Ecosystems and Streamside Management Implications... A Review

J. BOONE KAUFFMAN AND W.C. KRUEGER

Historically, riparian vegetation has been defined as vegetation rooted at the water's edge (Campbell and Franklin 1979). Quite often, however, the stream influences vegetation in many ways and well beyond the water line. In lotic systems, the stream is not only responsible for increased water availability, but also for the soil deposition, unique microclimate, increased productivity, and the many consequential, self-perpetuating biotic factors associated with riparian zones. These factors all contribute in the formation of a unique assemblage of plant communities quite distinct from upland communities surrounding the riparian zone. Therefore, along streambanks, other lotic systems, and even ephemeral drainages, riparian ecosystems could best be defined as those assemblages of plant, animal, and aquatic communities whose presence can be either directly or indirectly attributed to factors that are stream-induced or related (Kauffman 1982).

Riparian zones can vary considerably in size and vegetation complexity because of the many combinations that can be created between water sources and physical characteristics of a site (Odum 1971, Platts 1979, Swanson et al. 1982). Such characteristics, include gradient, aspect, topography, soil type of streambottom, water quality, elevation, and plant community (Odum 1971). However, riparian zones, particularly those bordering streams or rivers, have several characteristics in common. They are ecotonal, with high edge to area ratios (Odum 1978). As functional ecosystems they are very open with large energy, nutrient, and biotic interchanges with aquatic systems on the inner margin (Cummins 1974, Odum 1978, Sedel et al. 1974) and upland terrestrial ecosystems on the other margin (Odum 1978).

Thomas et al. (1979) stated that all riparian zones within managed rangelands of the western United States have the following in common: (1) they create well-defined habitat zones within the much drier surrounding areas; (2) they make up a minor proportion of the overall area; (3) they are generally more productive in terms of biomass—plant and animal—than the remainder of the area; and (4) they are a critical source of diversity within rangelands. Both density and diversity of species tends to be higher at the land/water ecotones than in adjacent upland, especially where regional climates are characterized by dry periods (Odum 1978). Ganskopp (1978) described 44 vegetation communities in a 49-hectare riparian zone in the Blue Mountains of northeastern Oregon. Kauffman et al. (1984) stated that the several biotic, environmental and other abiotic factors interacting in a riparian zone in Oregon created a disproportionately greater number of niches compared to surrounding upland ecosystems. Two-hundred and fifty-eight stands of vegetation representing 60 discrete plant communities were identified within this study area. The higher diversity, productivity, and other unique factors associated with the riparian zone when compared to the surrounding uplands are the primary factors that create the importance of these areas as focal points for the management of the livestock, fishery, and wildlife resources.

Authors are former graduate research assistant and professor, Department of Rangeland Resources, Oregon State University, Corvallis, respectively.

Importance of Riparian/Stream Ecosystems

Importance to Instream Ecosystems

Vegetation along small streams is an important component of the riparian/stream ecosystem (Campbell and Franklin 1979, Jahn 1978). Riparian vegetation produces the bulk of the detritus that provides up to 90% of the organic matter necessary to support headwater stream communities (Cummins and Spengler 1978). In these tributaries of forest ecosystems 99% of the stream energy input may be imported from bordering riparian vegetation (i.e., it is heterotrophic) and only 1% derived from stream photosynthesis by attached algae (periphyten) and mosses (Cummins 1974). Berner (in Kennedy 1977) found that even in large streams such as the Missouri River, 54% of the organic matter ingested by fish is of terrestrial origin. The riparian zone vegetation functions both in light attenuation and as the source of allochthonous inputs, including long-term structural and annual energy supplies (Cummins 1974).

Vegetation along streams exercises important controls over physical conditions in the stream environment. It acts as a roughness element that reduces the velocity and erosive energy of overbank flow during floods (Li and Shen 1973). The result is a higher flood peak than a channel without riparian vegetation but lower erosional factors acting on the floodplain and bank (Schumm and Meyer 1979). Healthy riparian vegetation tends to stabilize streambanks, determines bank morphology and may help reduce streambank damage from ice, log debris, and animal trampling (Platts 1979, Swanson et al. 1982).

Channel and floodplain obstructions such as branches, logs, and rocks enhance detention and concentration of organic matter, thereby facilitating its use locally rather than washing downstream (Everest and Meehan 1981, Jahn 1978, Swanson et al. 1982). In addition, wood debris in channel bottoms appears to play an important role in the dynamics of stream morphology. Large pieces of woody debris in streams dissipate stream energy, control routing of sediment and water through channel systems, and serve as substrates for biological activity by microbial and invertebrate organisms (DeBano 1977, Swanson et al. 1982).

Streamside vegetation strongly influences the quality of habitat for anadromous and resident coldwater fishes (Duff 1979, Everest and Meehan 1981, Marcuson 1977, Meehan et al. 1977). Riparian vegetation provides shade, preventing adverse water temperature fluctuations (Meehan et al. 1977). The roots of trees, shrubs, and herbaceous vegetation stabilize streambanks, providing cover in the form of overhanging banks (Marcuson 1977, Meehan et al. 1977). Streamside vegetation acts as a "filter" to prevent sediment and debris from man's activities from entering the stream (Meehan et al. 1977). Riparian vegetation also directly controls the food chain of the ecosystem by shading the stream and providing organic detritus and insects for the stream organisms (Cummins 1974, Meehan et al. 1977).

Importance to Wildlife

It is believed that, on land, the riparian/stream ecosystem is the single most productive type of wildlife habitat, benefiting the greatest number of species (Ames 1977, Hubbard 1977, Miller 1951, Patton 1977). The riparian zone provides an almost classic example of the ecological principles of edge effect (Odum 1978). Riparian habitat provides living conditions for a greater variety of wildlife than any other types of habitat found in California (Sands and Howe 1977), the Great Basin of southeast Oregon (Thomas et al. 1979), the Southwest (Hubbard 1977), the Great Plains (Tubbs 1980), and perhaps the entire North American continent (Johnson et al. 1977).

Examples of the wildlife values of riparian habitat are numerous (Carothers et al. 1974, Carothers and Johnson 1975, Henke and Stone 1978, Hubbard 1977, Thomas et al. 1979). Hubbard (1977) reported that 16-17% of the entire breeding avifauna of temperate North America occurs in 2 New Mexico river valleys over the course of a "few score" miles. Johnson et al. (1977) reported that 77% of the 166 nesting species of birds in the Southwest are in some manner dependent on water related (riparian) habitat and 50% are completely dependent on riparian habitats. In western Montana, 59% of the land bird species use riparian habitats for breeding purposes and 36% of those breed only in riparian areas (Mosconi and Hutto 1982). Thomas et al. (1979) stated that of the 363 terrestrial species known to occur in the Great Basin of southeastern Oregon, 299 are either directly dependent on riparian zones or utilize them more than any other habitats.

When riparian vegetation is eliminated, several wildlife species dependent on riparian ecosystems may be either severely reduced or may disappear altogether. Henke and Stone (1978) found 93% fewer bird numbers and 72% fewer avian species on 2 riprapped plots from which riparian vegetation had been removed, and 95% fewer birds and 32% fewer species on cultivated lands previously occupied by riparian forests.

The influence of riparian ecosystems on wildlife is not limited to those animal species that are restricted in distribution to the streamside vegetation. Population densities of birds in habitats adjacent to the riparian type are influenced by the presence of a riparian area (Carothers 1977). When a riparian habitat is removed or extensively manipulated, not only are the riparian species of the area adversely influenced, but wildlife productivity in the adjacent habitat is also depressed (Carothers 1977).

Riparian ecosystems are valuable to wildlife as a source of water, food, and cover (Stevens et al. 1977, Thomas et al. 1979). They also provide nesting and brooding habitat for avian species (Carothers et al. 1974, Johnson et al. 1977, Tubbs 1980). By furnishing abundant thermal cover and favorable micro-climates, especially when surrounded by nonforested ecosystems, they facilitate the maintenance of of homeostatis, particularly for big game (Thomas et al. 1979). Riparian ecosystems also serve as big game migration routes between summer and winter range (Thomas et al. 1979), and provide routes and nesting cover for migrating avian species (Stevens et al. 1977, Wauer 1977).

Importance to Livestock

Livestock grazing on rangelands is the most extensive form of land use in the interior Pacific Northwest (Skovlin et al. 1977). Cattle tend to congregate on meadows and utilize the vegetation much more intensively than the vegetation of adjacent ranges (Reid and Pickford 1946).

In northeast Oregon, Reid and Pickford (1946) stated that moist meadow soils in riparian ecosystems are generally so highly productive than an acre of mountain meadow has a potential grazing capacity equal to 10-15 acres of forested range. Although riparian meadows cover only about 1-2% of the summer range area of the Pacific Northwest, potentially they can produce 20% of the summer range forage (Reid and Pickford 1946, Roath and Krueger 1982). However, Roath and Krueger (1982) found that because of livestock concentrations, limits on livestock movements imposed by steep slopes, and erratic distribution of watering areas away from the creek, the riparian zone (covering about 2% of a Blue Mountain grazing allotment) accounted for 81% of the total herbaeous vegetation removed by cattle.

Cattle exhibit a strong preference for riparian zones for a number of the same reasons other animals prefer and use these areas. The main attributes believed to attract and hold cattle to riparian areas are the availability of water, shade, and thermal cover, and the quality and variety of forage (Ames 1977, Severson and Boldt 1978). In addition, sedges (Carex spp.) tend to retain relatively constant crude protein levels until the first killing frost. Several sedges common to riparian zones of the Pacific Northwest outrank key upland forage species in sustained protein and energy content (McLean et al. 1963, Paulsen 1969, Skovlin 1967).

Livestock Riparian Relationships

The impact of livestock on riparian zones in public grazing lands of the western states has received much attention recently. Several studies are presently underway examining the impact of livestock grazing on stream ecology, water quality, channel stabilization , salmonid fish habitat and physiology, terrestrial riparian wildlife populations, and riparian vegetation.

It is often difficult for one to interpret science from opinion in the literature. Many of the studies reported in this paper have not necessarily followed the generally accepted "scientific method" for research today. However, it is not the purpose of this paper to determine, even if possible, which published reports represent quality scientific results and which are little more than a forum to express one's opinion. Rather the purpose of this paper is to familiarize the reader with the accepted facts and management theories available today concerning livestock interactions in riparian zones with the other valid resources also dependent or utilizing this resource. Where possible, in this paper, results of properly conducted research are reported using terms such as "significant", referring to a statistically significant result and those of reports relying on observational data or "hearsay" will be reported as suggestions or observations.

General Considerations for Livestock-Riparian Management

The quality of the riparian habitat and its associated aquatic environment, both formed over geologic time, are fragile ecosystems which currently serve as focal points for management of livestock, recreation, and fisheries and timber resources. It has been reported that inappropriate livestock management results in overuse and subsequent degradation of the riparian/stream ecosystem (Behnke and Raleigh 1978, Oregon-Washington Interagency Wildlife Council 1978, Platts 1979). Davis (1982) suggested that one of the most destructive forces in riparian ecosystems is the long-term impact of overgrazing by cattle. Livestock grazing can affect 4 general components of an aquatic system-streamside vegetation, stream channel morphology, shape and quality of the water column and the structure of the soil portion of the streambank (Behnke and Raleigh 1978, Marcuson 1977, Platts 1979, Platts 1981). Improper livestock use of riparian ecosystems can affect the streamside environment by changing, reducing, or eliminating vegetation bordering the stream (Ames 1977, Behnke and Raleigh 1978, Platts 1979). The channel morphology can be changed by widening and shallowing of the streambed, gradual stream channel trenching, or braiding, depending on soils and substrate composition (Behnke and Raleigh 1978, Gunderson 1968, Marcuson 1977, Platts 1979). The water column can be altered by increasing water temperatures, nutrients, suspended sediments, bacterial counts and by altering the timing and volume of water flow (Behnke and Raleigh 1978, Johnsen et al. 1978, Rauzi and Hanson 1966, Platts 1979). Overgrazing can cause bank sloughoff creating false setback banks, accelerated sedimentation, and subsequent silt degradation of spawning and food producing areas (Behnke and Raleigh 1978, Everest and Meehan 1981, Platts 1979, Platts 1981). These impacts on the water column due to abusive livestock practices result in decreased fish biomass and in percent of salmonid fishes in the total fish composition (Behnke and Raleigh 1978, Bowers et al. 1979, Duff 1979, Gunderson 1968, Marcuson 1977).

Livestock abuse of riparian areas can severely impact terrestrial wildlife habitat causing a subsequent decrease in wildlife species and numbers (Ames 1977, Townsend and Smith 1977, Tubbs 1980, Wiens and Dyer 1975).

Improper grazing can have a considerable effect on vegetation, resulting in decreased vigor, biomass and an alteration of species composition and diversity (Ames 1977, Bryant et al. 1972, Evans and Krebs 1977, Knoph and Cannon 1982, Pond 1961).

While various other land management activities have caused serious losses or reductions in wildlife habitat productivity, livestock grazing has been suggested as the major factor identified in numerous studies throughout the 11 western states (Oregon-Washington Interagency Wildlife Council 1978). Conversely, Busby (1979) suggested that it was not reasonable to conclude that livestock grazing is the only, nor necessarily the major cause of impacts to riparian ecosystems.

Impacts of Livestock on the Instream Ecology

A healthy instream environment is vital for the aquatic life forms inhabiting the stream, as well as for various human needs that directly depend on water quality. High concentrations of suspended solids or other sediment loads, and fecal coliforms or fecal streptococci are usually associated with the degree of impact of man's activities, and can have a major impact in altering an existing stream ecosystem or even creating an entirely new ecosystem (Johnson et al. 1977, Johnson et al. 1978, McKee and Wolf 1963).

During the grazing season, Johnson et al. (1978) could not find any significant differences in physical and chemical properties of streamwater (suspended solids, total dissolved solids, and orthophosphates) between an area grazed at 1.2 ha/AUM and an ungrazed area. After the grazing season, however, there was a significant increase in total dissolved solids which indicated that some livestock waste products may have eventually reached and enriched the stream, probably from the action of rain showers. The presence of cattle significantly elevated the fecal coliform and fecal streptococci for about 9 days after cattle were removed.

Winegar (1977) found sediment loads were reduced 48–79% while flowing through 3.5 miles of a stream protected from grazing.

Rauzi and Hanson (1966) found a nearly linear relation between runoff and infiltration to the degree of grazing intensity. They found that runoff from a heavily grazed watershed (1.35 acre/AUM) was 1.4 times greater than from a moderately grazed watershed (2.42 acre/AUM) and 9 times greater than from a lightly grazed watershed (3.25 acre/AUM).

Changes in water temperature have been shown to have drastic effects on fisheries and aquatic insect populations (Johnson et al. 1977). Changes in average temperature or daily fluctuations can in effect create an entirely new aquatic ecosystem (Johnson et al. 1977).

Van Velson (1979) found average water temperatures dropped from 24°C to 22°C after 1 year of livestock exclusion on a creek in Nebraska. Claire and Storch (unpublished) compared stream temperatures between an area that had been grazed season long (June 1–October 15) and an area that had been rested for 4 years and, thereafter, grazed only after August 1. The maximum water temperatures outside and downstream from the exclosure averaged 7°C higher than those sampled within the exclosure. Daily fluctuations of water temperatures averaged 15°C outside the exclosure as compared to 7°C inside the exclosures. Winegar (pers. comm. 1982) observed similar results in an exclosure along Beaver Creek in central Oregon.

The effects of livestock grazing have been shown to vary greatly depending upon several factors, in particular, the nature of the stream studied. Duff (1979) stated that introduction of livestock for 6 weeks into a riparian area rested for 4 years resulted in elimination of overhanging banks and a fracturing of the streambank, causing it to erode into the stream. In contrast, after 6 weeks of mid-summer grazing by cattle, Roath (1980) gave a visual estimate of 90% bank stability with little indication that trampling was contributing to or causing erosion. He attributed nearly all erosion present to geologic erosion caused by the actions of streamflow.

Buckhouse et al. (1981) could find no particular relationship between streambank erosion and various grazing treatments (including nonuse) in northeastern Oregon. There appeared to be no significant patterns of accelerated streambank deterioration due to moderate livestock grazing (3.2 ha/AUM and 60–65% utilization of the riparian vegetation). Most bankcutting losses in this system were associated with over-winter periods where ice floes, high water, and channel physiognomy were critical factors involved in the erosional process.

Hayes (1978) found that stream channel movement did not occur more frequently in grazed riaprian meadows under a rest-rotation grazing scheme compared to ungrazed meadows after 1 year of study. Rather, streambank degradation appeared to occur more often and to a greater magnitude along ungrazed streams. However, Hayes stated that sloughoff increased as forage removal was above 60%. High forage removal, high amount of foraging time along banks, and high percentages of palatable sedges along the bank were shown to significantly increase the probability of sloughoff occuring during the grazing season.

Kauffman et al. (1983b) measured significantly greater streambank losses in grazed areas (1.3–1.7 ha/AUM) compared to ungrazed areas in northeastern Oregon. The grazed pastures had utilization levels greater than 35% and less than 85% on the different vegetation stands while utilization by native animals was less than 20% on every stand. During 2 late season grazing periods (late August–mid-September), a mean of 13.5 cm of streambank was lost in grazed areas and 3.0 cm was lost in ungrazed areas. Total annual streambank losses were 30 cm in grazed areas and 9 cm in ungrazed areas.

Marcuson (1977) found the average channel width to be 53 meters in an area grazed season long at 0.11 ha/AUM and an average channel width of only 18.6 meters in areas that were ungrazed. Marcuson (1977) also recorded 224 meters of undercut bank/km in the grazed area and 686 meters of undercut bank/km in the ungrazed area. Heavy grazing and trampling by cattle were suggested to cause the excessive erosion.

Duff (1979) found the stream channel width in a grazed area was 173% greater than the stream channel not grazed for 8 years inside an exclosure. Similar results have been reported (Behnke and Zarn 1976, Dahlem 1979, Gunderson 1968, Heede 1977) where overgrazing and excessive trampling caused a decrease in bank undercuts, increases in channel widths, and a general degradation of fish habitat.

Claire and Storch (unpublished) stated that the production of game fish in headwater streams can be used as a biological indicator of the quality of land management that is occurring within the watershed and/or streamside. Overgrazing, causing a reduction in vegetative cover and the caving in of overhanging banks, has been suggested as one of the principal factors contributing to the decline of native trout in the West (Behnke and Zarn 1976).

Bowers et al. (1979) reported an average increase in fish production of 184% for 5 independent studies where livestock use was light or eliminated by fencing. They concluded with a prediction that trout production in streams currently being heavily grazed could be increased about 200% if management decisions were made to optimize habitat conditions for trout.

Van Velson (1979) found rough fish made up 88% of a fish population before relief from grazing and only 1% of the population after 8 years' rest. Rainbow trout *(Salmo gairdneri)* made up 1% of the fish population before cessation of grazing and 97% of the population after relief from grazing. Marcuson (1977) found that an overgrazed section (.11 ha/AUM) of Rock Creek, Montana, supported only 71 kg of brown trout *(Salmo trutta)* per hectare; whereas an ungrazed section produced 238.8 kg of brown trout per hectare. Claire and Storch (unpublished) found in the Blue Mountains of Oregon that game fish were 24% of the total population in area grazed season long, contrasted to a 77% game fish composition within a livestock exclosure.

Chapman and Knudsen (1980) found 8 sections of streamside vegetation in western Washington, judged to be moderately to heavily affected by livestock, had significant reductions in total biomass for Coho salmon *(Oncorhychus kisutch),* Cutthroat trout *(Salmo clarki),* and all salmonids compared to those areas that had not been grazed. Similar relationships between livestock grazing and salmonid fish populations have been reported by Dahlem (1979), Duff (unpublished), Gunderson (1968), Keller et al. (1979), and Lorz (1974).

Impacts of Livestock on Terrestrial Wildlife

Riparian zones are the most critical wildlife habitats for many species in managed rangelands (Thomas et al. 1979). It is readily apparent that riparian ecosystems are of paramount importance in producing and maintaining a large degree of biotic diversity in North America (Hubbard 1977, Johnson et al. 1977).

Changes in plant vigor, growth form and species composition due to grazing have frequently been related to the increase or decline of various species of birds (Townsend and Smith 1977). Several studies have shown a negative impact on certain avian populations due to grazing (Dambach and Good 1940, Overmire 1963, Owens and Meyers 1973, Reynolds and Trost 1980, Smith 1940). The tendency for livestock to congregate and linger around ponds and streambanks may result in the elimination of food and cover plants and reduces nest sites and habitat diversity (Buttery and Shields 1975, Behnke and Raleigh 1978, Crouch 1978, Evans and Krebs 1977). However, grazing may improve habitat for some avian species (Burgess et al. 1965, Crouch 1982, Kirch and Higgins 1976). In areas of higher precipitation (or productivity), grazing may be highly desirable to open up "roughs" and provide more diversity and patchiness (Ryder 1980). Grazing effects on breeding avifaunas are not uniform nor easily defined, primarily because grazing varies so much in its local intensity and because of the general difficulties in unraveling cause-effect relationships in rangeland faunas (Wiens and Dyer 1975).

Several studies have shown wildlife numbers increased when a riparian area that was abused by improper grazing practices was fenced and allowed to recover (Crouch 1978, 1982, Duff 1979, Van Felson 1979, Winegar 1977). Duff (1979) reported a 350% increase in small mammal songbird and raptor use after 8 years' rest from grazing. Van Velson (1979) reported increased pheasant *(Phasianius colchicus)* production, increased deer populations, and that watefowl production occurred for the first time in the rested area. Crouch (1982) found more ducks (primarily mallards) *(Anas platyrhynchos),* more upland game animals, and twice as many terrestrial birds in an ungrazed bottomland rested for 7 years compared to adjacent grazed bottomlands on the South Platte River in northeastern Colorado. The grazed areas, utilized at "varying intensities, provided habitat for significantly more aquatic species of birds.

Mosconi and Hutto (1982) found no significant differences in total bird densities between heavily grazed riparian communities (2.5 cow-calf units/ha) and lightly grazed riparian communities (0.3 cow-calf units/ha). However, significant differences were recorded in bird species composition and foraging guilds. The majority of the bird species significantly affected were of the flycatcher, ground-foraging thrust, or foliage-gleaning insectivore guilds.

Similar results were reported by Kauffman (1982) and Kauffman et al. (1982). No significant differences in total avian densities were noted between riparian communities grazed under a late-season grazing scheme (2.0–2.5 ha/AUM) and those totally excluded from grazing. However, forage removal causing a change in habitat physiognomy did appear to cause some differential use in species and foraging guilds. These differences were particularly evident immediately after forage removal and negligible during seasons when cover and plant growth were similar between treatments. The grazed riparian communities were preferred by birds of insect foraging guilds; ungrazed riparian communities were preferred by birds of herbivorous/granivorous foraging guilds.

Livestock grazing and the subsequent removal of forage in the riparian zone has been shown to cause significant short-term decreases in small mammal composition and densities (Kauffman et al. 1982). When mammal densities before and after the grazing season in 1979 (stocking rate of 2.0–2.5 ha/AUM) were compared, small mammal communities decreased from 800 to 83 mammals/ha in Douglas hawthorn *(Crataegus douglasii)*-dominated communities; from 450 to 60 mammals/ha in riparian meadow communities; and from 129 to 42 mammals/ha in black cottonwood *(Populus trichocarpa)*-mixed conifer communities. By late summer the following year (10 months after grazing) and just prior to the grazing season, small mammal densities were not significantly different between grazed and ungrazed areas.

When properly managed, the grazing of domestic livestock is generally compatible with wildlife, and may even increase the numbers of some species (Tubbs 1980). Nongame wildlife which depend on riparian ecosystems have intangible values which are very hard to evaluate (Peterson 1980). It has been demonstrated that livestock can graze streamsides without causing serious damage, and the capability to achieve positive on-site livestock control appears to be the limiting factor (Claire and Storch unpublished).

Impacts of Livestock on Riparian Vegetation

Recently there has been much published research and opinion on the effects of livestock in riparian ecosystems. Specifically, these reports have dealt with soil compaction and its relationship to root growth; plant succession and productivity; and species diversity and vegetation structural diversity. Opinions on the subject have varied from there being no evidence of heavy, season-long cattle grazing affecting the productivity of a riparian zone, or causing bank deteriorations by trampling (Roath 1980) to grazing only a few days seriously impairing a riparian zone's reproductive capability.

Impacts to riparian vegetation induced by livestock can basically be separated into: (a) compaction of soil, which increases runoff and decreased water availability to plants; (b) herbage removal, which allows soil temperatures to rise and increases evaporation to the soil surface; and (c) physical damage to vegetation by rubbing, trampling, and browsing (Severson and Boldt 1978).

Impacts of Trampling

The impact of livestock trampling on soil compaction bulk density and subsequent effects on forage growth have been documented. Alderfer and Robinson (1949), Bryant et al. (1972), Orr (1960), and Rauzi and Hanson (1966) all found soil compaction increased linearly with increases in grazing intensity.

Alderfer and Robinson (1949) found grazing and trampling Kentucky bluegrass *(Poa pratensis)* upland pastures to a 1-inch (2.5 cm) stubble height reduced vegetation cover, lowered yields, decreased noncapillary porosity, and increased the volume weight of the 0-1 inch (0-2.5 cm) layer of soil.

Rauzi and Hanson (1966) found water intake rates on silty clay and silty clay loam soils to be 2.5 times greater in an area grazed at 1.35 acres/AUM compared to an area grazed at 3.25 acres/AUM. After 22 years of grazing at this intensity, not only had species composition been altered but soil properties had been changed as well.

In a riparian zone continuously grazed season long, Orr (1960) found bulk density and macropore space to be significantly greater in grazed areas over exclosures. Differences in total pore space (both macro- and micro-pores) between grazed and exclosed areas were small because of a transformation of macropore spaces to micropore spaces by trampling. Macropore space is a more sensitive indicator of compaction or recovery from compaction than either micro or total pore space (Orr 1960).

Bryant et al. (1972) found increasing trampling pressure had an adverse effect on Kentucky bluegrass swards, particularly during the months of June and September. After one overwinter period, there was a significant difference in soil compaction between an area trampled by 120 cow trips over bluegrass plots and an area that was untrampled.

Impacts of Herbage Removal

Impacts of herbage removal can be divided into 2 categories according to vegetation structure: (1) utilization of herbaceous vegetation and subsequent impacts on species composition, species diversity, and biomass produced and (2) utilization of woody vegetation and subsequent impacts on foliage cover, structural height diversity and stand reproduction.

A major vegetation change that has taken place in mountain riparian systems of the Pacific Northwest is replacement of native bunchgrass with Kentucky bluegrass. It has successfully established itself as a dominant species in native bunchgrass meadows as a result of overgrazing by herbivores and subsequent site deterioration (Volland 1978).

Pond (1961), in Wyoming, found clipping native bunchgrass meadows every 2 weeks for 4 years caused a marked reduction in native sedges (*Carex* spp.), tufted hairgrass *(Deschampsia caespitosa)* and fostered the appearance of Kentucky bluegrass where it was not present before. Kauffman et al. (1983a) found that when grazing was halted in moist meadows, succession towards a more mesic/hydric plant community occurred. Exotic grasses such as meadow timothy *(Phleum pratense)* and forbs more attuned to drier environments were decreasing and were being replaced by native sedges and mesic forbs.

In central Oregon, Evenden and Kauffman (unpublished) compared plant communities on each side of a fence that was heavily grazed on one side and protected from grazing on the other. The grazed site was dominated by Kentucky bluegrass and Baltic rush *(Juncus balticus),* while the ungrazed site was dominated by panicled bullrush *(Scirpus microcarpus).* Twenty herbaceous species were recorded in the grazed area with 12 herbaceous species recorded in the ungrazed area. Dobson (1973) also found an increase in species numbers due to grazing in a riparian zone in New Zealand. He concluded the effect of grazing had been to open up the vegetation, creating more niches in which weeds could establish themselves. Hayes (1978) in central Idaho also observed that the abundance of forb species appeared to be higher in grazed areas than in pristine areas.

The impact of cattle on herbaceous productivity in riparian zones has been examined along several streamsides in the western United States. Duff (1979), Gunderson (1968), Kauffman et al. (1983a), Marcuson (1977), McLean et al. (1963), and Pond (1961) found either decreases in biomass due to herbage removal or increases in biomass due to cessation of grazing in riparian ecosystems.

Kauffman et al. (1983a) compared grazed and ungrazed responses on 10 riparian plant communities in northeastern Oregon from 1978 to 1980. Three of 10 communities displayed significant standing biomass differences. Production in ungrazed moist meadows dominated by Kentucky biomass, meadow timothy, and sedges was significantly less after 2 years of rest compared to grazed meadows but was not significantly different after 3 years of rest. Standing biomass in a Douglas hawthorn-dominated community and in a Kentucky bluegrass-dominated community was significantly greater in ungrazed stands compared to grazed stands after 3 years. Conversely, Volland (1978) could find no significant differences in biomass between a Kentucky bluegrass meadow grazed annually and one that had been rested for 11 years.

Effect of herbivory on shrub and tree production is a critical impact in riparian ecosystems, because of the importance of the woody vegetation to wildlife habitat and its dominant influence in altering the riparian microclimate. While mature vegetation approaches senescence, excessive grazing pressures have prevented the establishment of seedlings, thus producing an even-aged nonreproducing vegetative community (Carothers 1977, Glinski 1977).

The effects of excessive herbivore use on woody vegetation bordering streamsides can generally be termed as negative. Knopf and Cannon (1982) found that cattle significantly altered the size, shape, volume, and quantities of live and dead stems of willows. Cattle grazing was also found to influence the spacing of plants and the width of the riparian zone. Marcuson (1977) found shrub production to be 13 times greater in an ungrazed area than in a severely overgrazed area. Cover was 82% greater in the natural area. On a stream rested from continuous grazing for 10 years, Claire and Storch (unpublished) found alders (*Alnus* sp.) and willows (*Salix* spp.) provided 75% shade cover over areas that had been devoid of shrub canopy cover before exclosure. Similar herbivore-woody vegetation relations have been reported by Crouch (1978), Davis (1982), Duff (1979), Evenden and Kauffman (1980), Gunderson (1968), and Kauffman (1982).

Management of Riparian Ecosystems

Recognizing and understanding the impacts on the streamsides which resulted from all previous land use practices is a prerequisite to streamside planning (Claire and Storch unpublished). Because of their small extent, riparian zones in the past were considered "sacrifice areas" (Oregon-Washington Interagency Wildlife Council 1978, Skovlin et al. 1977). Riparian vegetation has been intensively used by livestock over several decades causing a reduction in the productivity of fish and wildlife habitats and degrading water quality as well as promoting increases in flow fluctuations (Oregon-Washington Interagency Council 1978).

Platts (1979) indicated that riparian ecosystems are the most critical zones for multiple-use planning and offer the most challenge for proper management; therefore, stream habitats should be identified as separate management units from the surrounding upland ecosystems. Even among riparian zones the need to identify and classify them adequately is important for proper stewardship of these systems (Claire and Storch unpublished, Platts 1978, 1979).

However, there have been few attempts to come up with a viable classification scheme of riparian vegetation that is feasible for land management activities (Cowarden 1978, Norton et al. 1981, Padgett 1982, Pase and Layser 1977, Tuhy and Jenson 1982). The major problem has been the lack of successional knowledge to formulate classification schemes based upon potential climax communities. Other problems have been the lack of continuity of terminology. For example, terms such as riparian dominance type (Padgett 1982), community type (Tuhy and Jenson 1982), and riparian type (USFS-R-4 file data) have all been used to define the basic unit of land which supports a riparian community.

Land management agencies responsible for managing livestock grazing have not adequately considered the influence of grazing on the other uses and users of riparian ecosystems (Platts 1979). Often what is good range or timber management (in short-term economic terms) is not good riparian or stream management (Platts 1979). On the other hand, it has been suggested that proper stream management practices that protect stream banks from damage also improve the potential for riparian zones to enhance fisheries, wildlife, and livestock uses (Gunderson 1968, Marcuson 1977).

Methods discussed for riparian zone rehabilitation include exclusion of livestock grazing, alternative grazing schemes, changes in the kind or class of animals, managing riparian zones as "special use pastures," in-stream structures and several basic range management practices (eg. salting, alternative water sources, fencing, range riders, etc.).

The use of instream structures as a method of riparian rehabilitation has met with some success where instream structures are combined with rest from livestock grazing (Duff unpublished, Heede 1977). Bowers et al. (1979) indicated that some instream structures (e.g., trash catchers, gabions, small rock dams, individual boulder placement, rock jetties, and silt log drops) could serve the dual purpose of increasing the water table in areas of former wet meadows as well as improving salmonid habitat.

Heede (1977), combining rest from grazing with construction of check dams, obtained vegetation cover improvements, a change from an ephemeral stream flow to a perennial flow and a stabilization of gully erosion.

After losing 23 out of 26 instream structures in a grazed area in Utah, Duff (unpublished) suggested that stream improvement structures cannot work effectively to restore pool quality and streambank stability as long as livestock grazing continued. Keller et al. (1979) in Idaho found that rest from grazing negated the need for artificial instream structures intended to enhance trout production for stream ecosystems. Kimball and Savage (in Swan 1979) found aquatic ecosystems can be restored through intensive livestock management at a lower cost than through installation of instream improvement structures.

Grazing systems have achieved some success in riparian rehabilitation and much success in riparian ecosystem maintenance. The damage caused by heavy season or yearlong grazing is well documented (Evans and Krebs 1977, Gunderson 1968, Marcuson 1977, Severson and Boldt 1978). It appears that rest-rotation grazing schemes and/or specialized grazing schemes in which riparian zones are treated as special use pastures have been the most successful.

Hayes (1978), in Idaho, stated that species composition appeared to be improved under a rest-rotation grazing system and bank sloughoff occurrences were not increased if utilization was under 60%. In other Idaho mountain grazing studies, Platts (1982) stated that when rest-rotation strategies call for livestock to utilize riparian vegetation at a rate of 65% or more, some riparian habitat alteration occurs. He also indicated that riparian alteration may be insigificant when utilization is equal to 25% or less.

Claire and Storch (unpublished) found a rest-rotation system to be favorable for achieving desired streamside management objectives if 1 year's rest out of 3 is included in the scheme.

Davis (1982), in Arizona, found that a four-pasture rest-rotation system was a cost-effective and successful method for rehabilitation of the riparian resource when each pasture received spring-summer rest for 2 years out of 3. On 2 grazing allotments, cottonwood and willows had a mean increase from 78 plants/ha to 2,616 plants/ha, 2 years after implementation of the system. A rest-rotation system also obtained a very favorable response for vegetation surrounding a livestock pond in South Dakota (Evans and Krebs 1977).

Criticism of rest-rotation systems includes reports that objectives for herbaceous vegetation were not being achieved within desired time limits (Storch 1979), and that rest-rotation systems may increase trailing and trampling damage, causing streambank erosion and instability (Meehan and Platts 1978).

Fencing and managing riparian zones separately from terrestrial upland sites as special use pastures has been shown to be an adequate multiple use system of riparian zone management (Kauffman 1982, Winegar 1977). Simulated grazing of a fenced riparian zone annually after August 1 had no measurable effect on production or species composition in riparian meadows, contrasted to decreased production and composition in a simulated season-long scheme in northcentral Wyoming (Pond 1961).

Kauffman (1982) suggested that positive characteristics of a late season grazing scheme on a riparian zone in Oregon included increased livestock production, good plant vigor and productivity, minimal soil disturbance, and minimal short-term disturbance to wildlife populations dependent on riparian ecosystems.

Another grazing system for fenced riparian zones includes winter grazing, where possible, to minimize damage (Severson and Boldt 1978). For riparian meadows dominated by Kentucky bluegrass, Volland (1978) recommended an initial year's rest, then late spring grazing alternated with late fall grazing to discourage flowering, increase tiller development, maintain plant vigor, and maximize productivity.

Changes in the kind or class of animal as well as selective culling and breeding may be another positive tool for riparian rehabilitation or maintenance. Roath (1980) found that cattle exhibited distinctive home range patterns in which certain groups of cattle preferred upland sites and groups preferred riparian sites. As forage became limiting on stream bottoms, some cattle actually decreased intake rather than move away from the riparian zone. Selective culling of these cattle and replacing them with those that prefer uplands may be beneficial for the livestock operator as well as for the riparian zone.

Platts (1982) stated that because sheep grazing on public lands is usually controlled by the use of herders, it may be possible to graze a watershed without exerting direct significant influence on riparian habitats. May and Davis (1982) suggested that sheep have been shown to exert a lesser influence on certain riparian and aquatic ecosystems and converions back to a sheep operation may be necessary to improve some riparian areas.

The most successful riparian management alternative on public lands to date has been intensive livestock management by permit holders (Storch 1979). Herding livestock on a somewhat daily basis has been successful in limiting the number of livestock that visit streambottoms and improving utilization of upland areas. Proper stewardship of riparian ecosystems is, in effect, money in the bank for the floodplain rancher (Marcuson 1977). Proper management of riparian zones means decreased streambank erosion and floodplain losses (Duff 1979, Gunderson 1968, Marcuson 1977), increased forage production (Evans and Krebs 1977, Pond 1961, Volland 1978), and an increased wildlife and fisheries resource (Buttery and Shields 1975, Duff 1979, Tubbs 1980, Van Velson 1979).

In conclusion, public grazing lands must be managed on a true multiple use basis that recognizes and evaluates the biological potential of each ecological zone in relation to the present and future needs of our society as a whole (Behnke et al. unpublished). Management strategies that recognize all resource values must be designed to maintain or restore the integrity of riparian communities (Behnke et al. unpublished).

The Status of Our Scientific Understanding of Lodgepole Pine and Mountain Pine Beetles – A Focus on Forest Ecology and Fire Behavior

A synthesis of our current knowledge about the effects of the mountain pine beetle epidemic on lodgepole pine forests and fire behavior, with a geographic focus on Colorado and southern Wyoming.

The status of our scientific understanding of lodgepole pine and mountain pine beetles – a focus on forest ecology and fire behavior. The Nature Conservancy, Arlington, VA. GFI technical report 2008-2.]

Introduction

Major lodgepole pine forest changes and how they affect us. Mountain pine beetle populations have reached outbreak levels in lodgepole pine forests throughout North America. The geographic focus of this report centers on the southern Rocky Mountains of Colorado and southern Wyoming. The epidemic extends much more widely, however, from the southern Rocky Mountains in Colorado in the United States to the northern Rocky Mountains in British Columbia and Alberta, Canada.

Worries about large-scale tree mortality in lodgepole pine forests have created public concerns across the West. The appearance of red trees during the last decade, a clear sign of recent beetle attack, has been followed by bare dead tree skeletons throughout this large area. Unquestionably, millions of dead trees foretell large forest changes in the near future, and more might be anticipated in areas where the mountain pine beetle has not yet reached epidemic levels.

People are concerned for many reasons. At a minimum, the loss of mature lodgepole pine trees will significantly change the present and future appearance of affected forests for half a century or more. Extensive areas of dead trees and snags are not as aesthetically appealing as live forests. Perhaps more seriously, dying and dead trees raise fears of increased fire danger. Some people worry that the dead needles and wood generated by the mountain pine beetle epidemic will lead, perhaps quickly, to severe wildfires that threaten lives, property, wildlife, and watersheds. Many are concerned that trees not yet attacked will succumb to the epidemic. Some people worry that the forest in and around our communities and recreation areas will become sparse or disappear forever, and that these forest changes will affect timber commodities, game habitat, and recreation resources.

Some contend that the current epidemic with synchronous outbreaks at many locations is unprecedented and a clear warning of global climate change impacts on ecosystems around the world. Scientists and others point to other changes occurring in our region – *Ips* beetle-caused mortality of piñon pine in the Southern Rocky Mountains, aspen decline, and large fires in Front Range ponderosa pine forests and elsewhere. It is difficult to prove cause and effect, but all of these changes began during the last 10-15 years, coinciding with recent warm climatic conditions, increasing numbers of large trees, and advancing age of many forests. Whether or not the current epidemic is unprecedented is a question to which there is currently no clear answer because of the lack of precise information on extent and severity of beetle outbreaks prior to the early 1900s. Nevertheless, many in the scientific community believe the probability of a similar event historically over at least the past few 100 years is low.

There are many insights and opinions about lodgepole pine being discussed by stakeholders of all kinds -- forest managers, agency administrators, researchers, policy-makers, politicians, the news media, industries, and the general public. Some concerns and fears are supported by scientific evidence. Others are probably justified given the current status of our scientific knowledge, but lack clear scientific support. Still others are myths with little or no basis in science. A further complication is that some of the information emerging from the science community has appeared on the surface to be somewhat contradictory.

The reason for this report. This document is written to report our current scientific understanding of the ecology and fire behavior of lodgepole pine, with a focus on the direct and indirect effects of the current mountain pine beetle epidemic that is so dominant in our minds. We recognize that important socio-economic implications stemming from the mountain pine beetle epidemic exist, and we hope that examining the status of science will aid in addressing these issues. While this document focuses on lodgepole pine and mountain pine beetles, there are also many other forest types and non-forested systems subject to extreme or at least unexpected impacts of climate, other insect and pathogen species, and other disturbances including fire and wind.

This report results from a meeting in January 2008 convened in Colorado by The Nature Conservancy, bringing together expertise of scientists who study lodgepole pine throughout its geographic range. We hope to provide as much scientific help to stakeholders as possible by sorting out what is known with a high degree of certainty, what we are confident about but with less certainty, and what is truly not understood and in need of more research. While our primary geographic focus during the workshop was Colorado and southern Wyoming, some of the findings may be appropriate for lodgepole pine throughout much of its natural range of distribution. *We urge caution, however, in applying our findings beyond our initial area of focus or to other forest types in the region.*

During the workshop and through subsequent email dialogue, the lodgepole pine team reached consensus on nine key points. As always, science is a work in progress, and uncertainties surfaced during discussion of some key points. For some points we provide what is known with adequate confidence rather than waiting for more definitive information, when this information is useful to interested stakeholders. This report provides the nine key points along with explanatory material intended to help the reader understand the degree of confidence we have from scientific study for these key points. To help the reader, we provide a list of suggested reading at the end of this report for more detailed information on many of the topics discussed. We begin with the obvious.

A. Lodgepole pine forests are being heavily impacted by the ongoing mountain pine beetle epidemic.

From British Columbia to Colorado, forests are experiencing high mortality of lodgepole pine trees from attack by mountain pine beetles. An insect epidemic with multiple outbreaks at this scale has not been observed during the last century of scientific study, though small outbreaks have occurred. This mortality is changing forest structure and composition, and modifying fuels in ways that will affect fire behavior for decades.

Many believe the mountain pine beetle epidemic, now nearly a decade in duration, might be unprecedented at least in recent centuries, stemming from a unique alignment of factors. These factors include extensive forests of trees at the right age, size, and density to support large numbers of mountain pine beetles, and a climate warm enough over the last decade to favor beetle reproduction and survival. But records are short. Modern records cover little more than a century, and for this period there is no account of a similar severe mountain pine beetle epidemic in lodgepole pine over such a large area.

For earlier periods, however, little scientific evidence exists to suggest that severe mountain pine beetle outbreaks either did or did not occur. Forest fires, another important natural disturbance, often scar living trees, which provides physical evidence indicating dates, locations, and severity of fires back through much of the last millennium. Fire-scarred wood is often resistant to rot and may persist for centuries, preserving a record of fire. But mountain pine beetle attacks that might have occurred more than a century ago leave little or no physical evidence helpful for determining dates or severity of such attacks. Wood from trees killed by beetles rots quickly, especially where wood moisture is high (e.g. fallen trees). Both stand-replacing fires and beetle epidemics that kill large numbers of trees allow stands of trees of the same age to establish in the wake of the disturbance. The ages of these trees can be used to estimate the time of the last stand-replacing disturbance, but it is often not possible to tell what kind of disturbance initiated the stand, and disturbances such as beetles, fire, and wind may act synergistically. Thus we cannot exclude the possibility that factors aligning so perfectly to result in the current epidemic could not have aligned equally in past centuries or millennia.

Regardless of whether or not the current mountain pine beetle epidemic and lodgepole pine mortality are within the historical range of variability at some time scale, the epidemic and associated tree mortality are large and are having immediate effects on forest structure and function over a vast area.

B. Not all lodgepole pine forests are the same.

Some forests are composed of nearly pure lodgepole pine established following large fires decades or centuries ago. Others are mixtures of lodgepole pine with subalpine species such as Engelmann spruce, subalpine fir, and aspen at higher elevations, or with mixed conifer species such as ponderosa pine, Douglas-fir, and aspen at lower elevations. Each type of forest has unique features of ecology and fire behavior. And lodgepole pine trees in all three types are vulnerable to attack by mountain pine beetles.

Lodgepole Pine Ecology 101. Lodgepole pine is found over a large area in western North America, from northwestern Canada in the northern Rocky Mountains; Washington, Oregon, and California in the Cascades and Sierra Nevada; Idaho, Montana, and Wyoming in the central Rockies; down to Colorado and even northern New Mexico in the southern Rockies. It comes as no surprise that across this large area and also locally, lodgepole pine trees are found in diverse forest conditions. In Colorado and southern Wyoming, pure stands of lodgepole pine occur. Even where pure stands occur, lodgepole pine forests may range from extremely dense to open and savanna-like. Elsewhere, lodgepole pine is mixed with other species. These differences in species composition of forests influence the way forests are affected by mountain pine beetles and fire, and how forests may change in the future.

Two key features of lodgepole pine are especially important in the way the species interacts with the environment and with other trees. Lodgepole trees are relatively intolerant of shade, and they are adapted to reproduce prolifically after fire. Unshaded lodgepole trees survive and grow more readily than trees overtopped either by larger lodgepole pines or by other species. Fire adaptation in trees occurs in two primary forms: the capacity to survive fire, or the ability to reproduce after fire even if killed. While species like ponderosa pine are adapted to survive fire, lodgepole pine is adapted to reproduce readily after fire.

Many lodgepole pine trees have serotinous cones that remain closed and store viable seeds in the crowns of trees for years, actually requiring the heat of a fire for seed release and dispersal. When crown fires kill trees, the resin sealing the cones melts, allowing the cones to open shortly after the fire. Huge numbers of seeds are released at once to the forest floor, falling on exposed soil that is an excellent seedbed for germination and seedling establishment. It is not uncommon to find 50,000 or more seedlings per acre several years after a stand-replacing fire. Competition then thins out trees naturally as these young forests grow to maturity. After a mountain pine beetle epidemic, lodgepole pine stands also generally regenerate, because serotinous cones on branches that have fallen near the ground heat adequately to release seeds, and seeds previously released from non-serotinous cones may exist in the forest litter. However, the role of serotinous and non-serotinous cones as seed sources, and the effect of cone serotiny on subsequent stand density, are not well understood.

The three most common natural agents influencing lodgepole pine in Colorado and southern Wyoming other than fire are mountain pine beetles, dwarf mistletoe, and wind. Of these, mountain pine beetles have the capacity like fire to change forests at large scales. Beetle populations can occasionally reach epidemic densities over large areas, though not usually as large as the current epidemic. The spatial extent of the current epidemic is probably related to large numbers of suitable host trees existing over much of the range of lodgepole pine in the West. Mountain pine beetles are a native insect that has evolved with lodgepole pine. They normally exist in endemic populations that kill a few trees but are regulated by weather. Endemic populations of beetles typically infest diseased or stressed trees. Because temperature regulates beetle development, prolonged warm periods may help trigger outbreaks. Natural enemies also help regulate endemic bark beetle populations but their role under epidemic populations is not as effective.

Dwarf mistletoe typically occurs in localized patches. While mistletoe slowly spreads, it often remains only locally significant, and trees may live for decades with mistletoe. This native parasite, which also evolved closely with lodgepole pine, is periodically reduced by fires that kill the infected trees. Major wind events may topple trees and create small to large openings. In many places lodgepole pines are shallowly rooted in rocky soils or on steep slopes. Typically even the largest blowdowns affect forests only locally, and while they contribute to the landscape mosaic of forest age and composition, they are unlikely to affect forests regionally unless they become centers of another disturbance agent (e.g. spruce beetle).

Three kinds of lodgepole pine forest. Lodgepole pine forests occur along gradients of elevation and latitude that control the length of growing season, available moisture, and frequency of natural disturbances. Fire and mountain pine beetles affect forest structure and composition differently in each ecosystem, just as environmental conditions regulate the occurrence and intensity of the disturbances. To understand this, it is useful to identify three specific types of forest in which lodgepole pine occurs. In Colorado and southern Wyoming, these are pure lodgepole pine, subalpine forest, and mixed conifer forest.

Pure lodgepole pine forests may occur where environmental conditions are poorly suited for other tree species, or where human impacts such as logging followed by burning eliminate other species. Lodgepole pines are tolerant of cold, dry conditions and poor, rocky soils. Individuals rarely live more than 400 years. Typically, pure lodgepole pine stands result after stand-replacing fires have killed all or most trees, leaving behind lodgepole seeds stored in serotinous cones as the only significant seed source. Alternatively, fire-killed stands without serotinous cones may still reproduce if lodgepole pine seeds are blown in from unburned trees nearby. Stand-replacing fires may occur in healthy, green forests under extreme weather conditions. Similar fires might occur under more moderate conditions when mountain pine beetle mortality or mistletoe infestation in stands creates additional dry fuels, though there is no firm evidence thus far confirming this. Pure lodgepole pine stands are often established within a few years after the fire and have one dominant age class or cohort for the life of the new stand, although some stands may develop continuously over longer periods of time and have multiple age classes. However, if aspen is present even in small amounts before large fires, its sprouting capability may lead to aspen patches which often give way over time to slower-growing lodgepole pine.

The spatial extent of pure lodgepole pine forests typically reflects the size of the fires that established them. As a general rule, pure lodgepole pine forests occur more commonly at upper elevations in the mixed conifer (upper montane) zone and the lower portion of the subalpine forest zone, between 9,000 and 10,000 feet elevation in Colorado and southern Wyoming. Less commonly, pure stands exist because sites are unsuitable for other tree species. Historically, past fires may have been tens to hundreds of thousands of acres in size, resulting in large lodgepole pine stands that dominate the landscape for several hundred years. However, even large intense fires do not burn uniformly, and within a fire perimeter, some patches of trees or individuals may survive intact. The 1988 Yellowstone fires are a good example of this. Alternatively, smaller crown fires may have created patches of pure lodgepole pine as small as an acre or less.

If not renewed by fire every few centuries, pure lodgepole pine stands often but not always experience ingrowth by other tree species, especially those tolerant of moderate shade. Ingrowth of other species depends strongly on site suitability for the other species, and availability of seeds. Eventually these species may replace lodgepole pine as the dominant trees in the stand. Lodgepole pine may persist in these mixed stands even if only a limited number of seedlings become established periodically, usually as a consequence of minor local disturbances such as very small fires, wind, insects, or disease.

Subalpine forests at higher elevations (usually above 10,000 feet elevation but as low as 9,000 feet) often include lodgepole pine as a component along with Engelmann spruce, subalpine fir, and aspen. Stand-replacing fires may occur in subalpine forests, but intervals between fires are usually several to many centuries (compared to one to several centuries for pure lodgepole pine forests). After stand-replacing fire, lodgepole pine seedlings grow faster than spruce or fir seedlings and may dominate stands during early developmental stages, even when spruce and fir seeds are available nearby. When aspen is present, however, creation of openings by fire or other disturbances may shift species dominance to aspen because of its sprouting ability.

Mixed conifer forests at lower elevations (usually between 7500 and 9000 feet elevation) often include lodgepole pine along with ponderosa pine, Douglas-fir, aspen, and perhaps small amounts of subalpine fir, Engelmann spruce, and limber pine. Large stand-replacing fires can occur in mixed conifer forests and may lead to pure lodgepole pine stands. More typically, however, mixed-severity fires create smaller openings providing opportunities for patches of lodgepole pine establishment and persistence within the complex landscape mosaic of mixed conifer. Once again, aspen may become temporarily dominant if it existed prior to the fire.

C. Forests are living systems subject to constant change.

It is normal and expected that many natural agents, including mountain pine beetles, fire, and wind, change forests over time. Some changes are so gradual that we barely notice them, while others are relatively sudden and extensive. The forests that are presently losing many trees to insect attack will not look the same in our lifetimes, but healthy and vigorous forests will eventually return in most locations.

We tend to think of forests as static over time because their change is slow relative to human time scales. Yet forests are non-equilibrium systems, and we should expect them to change. Our adult human experience is measured in years or decades at most, and we often fail to notice all but the more dramatic changes that occur in forests. Thus we may believe that the structure and composition of forests typically do not (and even should not) change, and, when they do, it means something alarming has happened. However, lodgepole pine and other tree species live several centuries or more and during their life cycles a number of very natural, and ecologically predictable, forest-changing events or processes often occur. The 1988 Yellowstone fires are often cited as an example of natural change in lodgepole pine ecosystems.

Taking this more comprehensive view, it is clear that combinations of fire and other natural disturbance agents, along with differences in ecological characteristics of the various tree species suited for the landscape, result in frequent changes in forest landscapes over time. The overall forest mosaic is in fact not static, but rather experiences significant shifts and adjustments, all a part of the natural ecology of forests. Thus at any location in a given landscape, the species composition, distributions of tree sizes and ages, and stand density all are subject to change, even if in our memory they do not appear to.

Understanding and predicting the consequences of natural disturbance effects on landscapes is difficult. All of the natural disturbance factors – fire, insects, pathogens, wind, drought, etc. – are capable of affecting forest landscapes at various scales and may act individually or in combination. In the current mountain pine beetle epidemic, interactions between fire and beetle effects are certain, because the insects are changing fuel characteristics of forests significantly.

D. Lodgepole pine will not disappear from the southern Rocky Mountains.

The make-up of our forests is already changing where mountain pine beetles cause high mortality of lodgepole pine. However, this event will not cause the extinction or disappearance of lodgepole pine, and forests dominated by or including lodgepole pine will persist in the southern Rockies, though they may look different from those of the past due to changing climate. Future forests will continue to provide valuable ecological services and aesthetic and recreational benefits.

When viewed from a distance, it may appear that many pure lodgepole pine forests in Colorado and southern Wyoming are being completely killed. It even appears that in some places all the lodgepole pine trees in subalpine or mixed conifer forests are being killed. Yet there is wide variability in the amount of tree mortality, and even where all the mature trees have died, understory saplings may be released and new lodgepole pine seedlings are likely to emerge. Thus it is untrue that lodgepole pine will disappear from our forests.

Scientific knowledge is not complete, however, and there is considerable uncertainty about the composition of future forests after the epidemic. Clearly, major changes in these forests are occurring, but multiple factors will affect what kind of new forest will result. A high proportion of larger lodgepole pine trees (diameters greater than six inches) are dying, and in many places many smaller trees are being killed as well. Mortality may approach 100% in pure lodgepole pine stands having few small trees.

Recovery of lodgepole pine forests following previous beetle outbreaks suggests, however, that in many places significant numbers of lodgepole seedlings and small saplings will survive. These may produce new pure stands of lodgepole pine if no other species are present, or help sustain a lodgepole component in stands of mixed species. Height growth of Engelmann spruce or subalpine fir seedlings is slow compared with that of lodgepole seedlings. Where small seedlings of spruce or fir existed beneath a pure lodgepole pine overstory, lodgepole pine may still predominate after the first decade because of their more rapid growth. However, if saplings of spruce and fir trees are left under the dead pines, they may grow quickly into the canopy and dominate the site. If aspen is present, sprouting and rapid early growth may result in an aspen forest, perhaps with the shade tolerant conifer species in the understory. However, aspen sprouting after mountain pine beetle mortality is not as well understood as it is for disturbances that more directly affect aspen trees or roots.

In pure lodgepole pine forests with few or no surviving trees, it is reasonable to expect a new lodgepole forest to regenerate on suitable sites, but difficult to predict with certainty. The existing seed bank (seeds stored in cones of dead trees and in the litter) or seeds produced by non-serotinous trees near the time of tree death may produce enough new seedlings to regenerate a new lodgepole pine forest. It is also possible that other species will colonize the sites, including other wind-dispersed trees such as spruce and fir, ponderosa pine and Douglas-fir, or bird-dispersed trees such as limber pine. Grasses, forbs, and shrubs may flourish in the new openings for periods of time, and tree establishment may be limited or slowed. Under such conditions, the landscape is likely to become more diverse than it was in the previously pure, single-aged lodgepole forests. This in itself may be beneficial for reducing the risk of a future large-scale mountain pine beetle epidemic or other monolithic disturbance.

E. Active vegetation management is unlikely to stop the spread of the current mountain pine beetle outbreak.

Mountain pine beetles are so numerous and spreading so rapidly into new areas that they will simply overwhelm any of our efforts where trees have not yet been attacked, and no management can mitigate the mortality already occurring. However, judicious vegetation management between outbreak cycles may help mitigate future bark beetle-caused tree mortality in local areas.

In the current epidemic, it is impractical to expect that silvicultural treatment of lodgepole pine forests will prevent or even impede the advance of the epidemic in Colorado and southern Wyoming. There are simply too many suitable host trees over too large an area, and unusually high insect populations. Unless climatic conditions become less favorable for beetle reproduction and spread, the most likely scenario is that the epidemic will be sustained until host trees are depleted.

Preventive spraying of high-value trees with insecticides is effective in protecting trees from bark beetle attack. Direct control measures such as removing infested trees may provide some mitigation on a small local scale but are not be effective at a landscape scale.

The current epidemic is so extensive and severe in part because large areas of lodgepole pine forest are suitable hosts for mountain pine beetles. As noted earlier, it is unclear if epidemics occurred at such a large scale historically, though smaller-scale or less severe epidemics most likely did occur and are expected in the future. Active vegetation management *between* periods when lodgepole pine forests are vulnerable to a mountain pine beetle epidemic may reduce the magnitude of future landscape-scale outbreaks, if that is chosen as a management objective. Creating diverse patch ages and sizes (including young patches) and perhaps more mixed-species forests across the landscape may or may not reduce the spread of future mountain pine beetle outbreaks, but it likely would reduce the amount of forest susceptible through time to a monolithic disturbance, including mountain pine beetle attack or fire. Thus while unproven, this increased landscape heterogeneity may be effective for limiting the scale and severity of future mountain pine beetle impacts. The effectiveness of such measures cannot be assured, nor are all the ecological consequences known, though even in the current epidemic, stands and patches of younger lodgepole pine trees appear to have survived the epidemic with no or only limited mortality.

F. Large intense fires with extreme fire behavior are characteristic of lodgepole pine forests, though they are infrequent.

Very dry and windy conditions can lead to large intense fires in lodgepole pine forests. Such fires are a natural way for lodgepole pine to be renewed and are largely responsible for extensive pure lodgepole pine forests.

Fire history studies based on fire scars and stand structure evidence extending over at least the past 500 years show that large, severe fires (often involving multiple ignitions) occurred in subalpine lodgepole pine forests of Colorado and southern Wyoming during periods of exceptionally warm and dry weather. These studies also show that long intervals (e.g. of 80 to 100 years) during which large fires were absent from study areas extending over 10,000 or more acres were common during the past five centuries in subalpine lodgepole pine forests. Climatic variation at annual and multi-decadal time-scales has been the major driver of fire occurrence in these forests and is the key explanation for the non-equilibrium behavior of these ecosystems. Large fires shaped the amounts and locations of extensive lodgepole pine forests on the landscape and this process is relatively well understood, but additional research would be helpful to characterize stand history in local areas, especially in relation to past climate.

Fire is complex, and its behavior varies with variations in weather, ignitions, fuel amounts and arrangement, and fuel moisture. Historically, most ignitions in lodgepole pine forests were caused by lightning. The role of Native American ignitions is unknown, but given that extensive fire occurs in these forests only under dry and windy conditions, their contribution was probably small. Young and mature stands of pure lodgepole pine are relatively unlikely to burn except under the most extreme weather conditions. Unless residual fuels remain from the effects of previous fire or insect epidemic, fuels commonly are sparse in the understory, and closed canopies help keep the forest floor cool and somewhat moist. The snow-free period above 9000 feet elevation is relatively short, leaving little time for fuels to dry. The term “asbestos forest” has been applied to these forests, attesting to their low probability of an intense crown fire except under extreme weather conditions.

As lodgepole pine forests mature they become increasingly vulnerable to natural disturbances such as mountain pine beetles and wind. Even with only partial overstory mortality, openings created in the forest canopy allow more air circulation beneath the canopy, and drying of surface fuels. In addition, fuel amounts may be increased by the localized tree mortality, including fuel ladders provided by fallen trees, young understory trees, and shrubs that may help fire reach the overstory. Such changes may increase the probability of fuel ignition from lightning and may alter fire behavior in several ways. Fire behavior in maturing stands is not fully understood, however, and more research would be beneficial.

These remarks about fire behavior apply especially to pure lodgepole pine forests. In subalpine mixed forests, the likelihood of dry fuels is even less as the snow-free period is shorter. In mixed conifer forests below 9000 feet, the complexity of the landscape, greater productivity and longer and more frequent fire season encourages mixed-severity fires which have both surface and stand-replacing components. Even in the mixed conifer forests, however, fire extent is highly variable due to climatic variation, and fire-scar studies show that years of widespread fires during past centuries were dependent on exceptional drought. Typically, lodgepole pine occurrence can be suppressed with shortened fire intervals because its long-term presence depends on seed germination after fire and trees growing to reproductive maturity before the next fire. In general, fire history and potential fire behavior are less well understood in mixed conifer forests than in pure lodgepole pine forests.

G. In forests killed by mountain pine beetles, future fires could be more likely than fires before the outbreak.

Large intense fires with extreme fire behavior are again possible.

There is considerable uncertainty about fire behavior following a mountain pine beetle epidemic on this scale. In pure lodgepole pine forests, crown fires are possible both before an epidemic and after while needles are still on trees. Intense surface fires are possible after most dead trees have fallen to the ground. The probabilities of such fires are uncertain, and more research is needed to learn in what ways and how long the fuels and fire environment are altered by the beetles. Nevertheless, protection of communities and other values at risk continues to be imperative.

More research is required to fully understand fire behavior over time following a mountain pine beetle attack. Nonetheless, the extensive epidemic now occurring is precipitating enormous changes in fuel structure over large areas in Colorado and southern Wyoming, through changes in the condition and arrangement of the forest biomass (which is fuel for forest fires). The mature lodgepole pine trees that provided abundant but moist living fuels are now dead, dry, and falling, and have the potential to contribute to extreme fire behavior in post-beetle forests similar to historical fires in lodgepole pine forests. However, the realization of that potentially extreme fire behavior will depend on a number of contingencies, particularly future climatic conditions.

Empirical data are very limited. One study of fire extent and severity of wildfires that burned in subalpine forests in Colorado in the extreme drought of 2002 did not find that fire extent or severity were greater in stands recently killed by mountain pine beetle. The authors cautioned, however, that the conclusions regarding the influence of the recent beetle outbreak on fire extent and severity are limited by spatial and temporal limitations associated with aerial detection of the outbreak. More importantly, any broader applications of this case study would need to be tested by additional studies considering different initial forest (fuel) conditions and especially weather conditions that drive fire behavior. Even though only limited scientific information is available to predict likely fire behavior during and in the decades following a mountain pine beetle epidemic and under varying climate conditions, we believe that both field observations of fire behavior and modeling provide some insights into what could be expected. We offer these insights as preliminary guidance for those concerned with management of beetle-killed forests, even as new research is being conducted to clarify our scientific understanding.

Pure lodgepole pine. In the initial phases of the epidemic when trees are being killed, needles die, turn red and dry out but persist on trees for two or three years. During this phase, needles and small branches provide dry fine fuel that could burn in a crown fire. The amount of fuel is relatively unchanged compared with the pre-epidemic forest. However, fuel moisture is lower, and some think it likely that a crown fire could ignite and spread under somewhat less extreme fire weather conditions than were required for initiating a crown fire in an equivalent forest of live trees.

The fuel structure of dead lodgepole pine stands changes significantly when needles fall to the ground. During this phase, little fine fuel remains in the forest canopy to support an active crown fire that spreads from tree to tree. Furthermore, the fallen needles lie close to the ground surface and, in the absence of other fuels near the ground, provide a relatively poor fuel bed for generating significant flame heights. Increased growth of grasses, low shrubs and forbs may create a moist fuel bed during the growing season but provide dry fine fuels near the end of the growing season. However, large amounts of biomass in the boles and branches of standing trees remain well above typical flame heights, and without needles these canopy fuels are relatively unlikely to burn. Thus surface fires in years following needle fall may not be intense and crown fires may be nearly impossible (assuming the forest is relatively pure lodgepole pine and most or all large trees are dead). In some areas, rapid development of a tall shrub community (which may precede tree regeneration) may provide shade and protection from drying of fuels on or near the ground. However, this is unlikely in most lodgepole pine forests in Colorado and southern Wyoming (the focus area of this report), because few tall shrub species occur in these relatively dry forests. Instead, low shrubs such as huckleberry and buffaloberry are more common.

Trees killed by mountain pine beetle may remain standing for a number of years, but as they progressively decay and fall to the ground (often aided by wind), the fuel structure changes once again. In this phase (typically 10-20 years or more after death), a large amount of biomass becomes available as fuel within flame heights that can be generated by the fine surface fuels. Some of the biomass is elevated above the ground where it dries out more easily and becomes available to support intense fire with a large release of heat. Such a fire is relatively hard to control and nearby structures may be hard to protect. Furthermore, fire intensities under these conditions could cause high mortality of young trees that survived or regenerated after the mountain pine beetle attack. If widespread fire mortality occurs before trees have matured to cone production age, rapid re-establishment of lodgepole pine on this site is less likely.

At the scale of a stand, none of the changes in fire behavior that we have described would be outside the historical range of variability for this ecosystem. Even in stands with tremendous wood accumulation on the ground, fire behavior may differ little from historical fires within blow-downs or areas recently burned by stand-replacing fires. However, we are uncertain about fire behavior at landscape or regional scales because we have not seen systems with such heavy fuel loads over such extensive areas; and we know little about the ecological consequences of such fires at these scales.

Lodgepole pine with other species. Similar transitions in fuel structure also will occur in the lodgepole pine-dominated component of subalpine and mixed conifer stands. But the mixture of dead lodgepole pine with live trees of other species creates a more complex fuel structure. An important effect of lodgepole pine mortality in mixed stands is a change in the environmental conditions and thus the fuel moisture near the forest floor. Prior to beetle mortality of the overstory, solar radiation is largely intercepted by the forest canopy, and air movement beneath the forest canopy is moderated by the overstory. The understory beneath the canopy remains relatively cool and moist.

When lodgepole pine trees die and needles fall from dead trees, radiation reaching the forest floor and air movement beneath the residual live tree canopy are increased, and both contribute to fuel drying. More open canopies also contribute to greater understory vegetation growth. The consequences of these changes on fire behavior are not fully understood, but such conditions may favor ignition and spread of fire more readily than in forests having few canopy gaps or fuels created by mountain pine beetle mortality, particularly later in the growing season when fuels near the ground become drier. Because several associated species, firs and spruces, typically have low crown bases due to poor self-pruning, higher surface fire intensity from added lodgepole pine fine fuels coupled with drier, warmer, windier surface conditions, could lead to an increase in potential for passive crown fire (torching). Furthermore, increased human activity in today's forests has increased fire ignitions compared with the historical period.

H. Mountain pine beetle outbreaks are not likely to cause increased erosion.

Soils are not disturbed and protective ground cover is not reduced when mountain pine beetles kill lodgepole pine trees. If anything, understory plants may grow more vigorously in the increased light and with the higher available soil moisture and nutrients. Where tree mortality is high, annual streamflow may increase and the timing of water delivery may be changed, because of reduced canopy interception of precipitation and reduced water uptake by the trees.

Interactions between forest structure and hydrology have been studied extensively, and there is little question that major changes in the structure of Colorado and southern Wyoming forests alter several key hydrologic characteristics of these forests. Forests are widely viewed as important for protecting sloping terrain in watersheds from extreme runoff and erosion. Wildfire severe enough to kill forests is viewed as a major threat to watersheds, because protective vegetation, litter, and duff are often consumed. In many cases, fire exposes soils directly to precipitation, and runoff during heavy precipitation events (often exacerbated when fire makes soils temporarily hydrophobic) can result in extreme erosion for several months following a fire.

Soil type, steepness of slope, precipitation intensity and duration, and timing of understory vegetation recovery all affect the severity of erosion after fire.

Death of forest trees during a mountain pine beetle epidemic affects the forest floor and soil much differently than fire. Tree mortality caused by beetles leaves behind protective layers of litter and duff, and often quickly results in more productive understory vegetation. Thus severe erosion events are not expected as a result of the mountain pine beetle epidemic. In fact, mulching and seeding after fire often are used in attempts to mimic the stabilizing effects of litter, duff, and understory vegetation found after overstory mortality by beetles.

The potential for erosion from wildfire still exists, however, if extensive fire occurs in the decades following the epidemic, when large amounts of fuel are on the ground. Thus while the mortality of trees does not increase erosion significantly, erosion remains a possibility if a post-beetle fire occurs with heavy fuel loading on the ground. We note, however, that erosion is a natural process, and concerns about extreme erosion may be more a human issue than an ecological one.

There may be other hydrologic effects of mountain pine beetle mortality. Paired watershed studies around the world support the conclusion that substantially decreasing forest density results in increased runoff, though many factors affect the degree to which this occurs. Subalpine forest studies in Colorado and elsewhere are among the best examples supporting these findings. While no empirical studies of runoff in relation to the current mountain pine beetle epidemic have been completed in Colorado and southern Wyoming, it is reasonable to expect that the total annual runoff will increase where pure stands of lodgepole pine are killed by mountain pine beetles. More research is needed to determine how the hydrologic features of watersheds change during and after such epidemic changes in forest structure.

I. Climate changes will most likely contribute to substantial forest changes in the decades ahead.

Given the climate changes in the last several decades and projected changes for coming decades, large fires and other natural disturbances and shifts in vegetation composition and distribution are anticipated in many ecosystems of Colorado and southern Wyoming. These large disturbances and other changes in growing conditions will likely contribute to restructuring many forest landscapes.

Many uncertainties about climate and vegetation exist for the years, decades, and centuries ahead. As noted in our introduction, we have seen a number of significant ecological events in the last decade, including the mountain pine beetle epidemic in lodgepole pine. All of them coincide with warmer climatic conditions than were typical for the past century or more for which we have records. Warming temperatures (especially winter minimum temperatures), longer growing seasons, and growing season drought may be playing major roles in the widespread bark beetle outbreaks in Colorado and southern Wyoming and elsewhere. Fuel quantity and arrangement and fire behavior may be influenced directly or indirectly by the same variables. Germination and establishment success of new seedlings may be affected. However, it is difficult to prove whether climate changes, consequences of past forest management practices on forest conditions, or both are the primary causes of these ecological changes.

Implications for future forests. Models for predicting future climates have progressed dramatically in recent years, but their accuracy is questionable for planning purposes, particularly at local levels. Nonetheless, model predictions suggest significant alterations in climate from past observed patterns. These predictions are supported by recent climate events that themselves had largely been predicted several years ago. Therefore, the potential for future changes justifies thinking about future ecosystem dynamics that are very different from what we have seen in the last few centuries, including vegetation responses involving natural disturbance agents, species distribution, habitat suitability, and conservation of biodiversity. Areas at the elevational and latitudinal edges (ecotones) of lodgepole pine distribution may be the most likely to experience notable changes following the beetle epidemic.

Our understanding of natural disturbance phenomena such as fire, drought, and insect epidemics under new climatic scenarios is inadequate for us to judge the likely consequences of future climatic conditions. We all observe and acknowledge that natural disturbances can be major change agents regardless of their cause. Climate warming may be contributing to substantial forest changes now, but there may be more subtle changes in the future as well. Through time forest species (including insect associates and other animal species, shrubs, grasses, and forbs as well as trees) may shift to other elevations and latitudes where habitats have become more suitable for them. Some species with rapid generation times, such as mountain pine beetle, may adapt to the changing climate. Alternatively, without adaptation local extinction in bark beetle populations could occur with increased warming due to a disruption of their tightly coupled developmental timing with local weather. Groups of species may migrate together or separately, perhaps leading to unanticipated new forest communities. We cannot make firm predictions about the makeup of future forests or the biodiversity associated with these forests. Regeneration and plant community restructuring in the landscape may follow novel pathways. Information is lacking, however, and extensive research (including use of monitoring data and reconstructions of past changes) is needed to relate potential future climate and the requirements and environmental amplitudes of species and communities.

Is re-establishment of lodgepole pine assured after the mountain pine beetle epidemic? Undoubtedly, but subtle or even large shifts in its location and plant associations are not out of the question. Nonetheless, most of the area experiencing a mountain pine beetle epidemic will likely remain forest. Even if future forests differ from those of today, such forests are likely to provide valuable (if different) benefits and opportunities, both ecologically and socially. Monitoring of changes in forests as they occur is important for enabling research on such changes, and to allow managers to adapt practices to achieve desired effects as conditions change and consequences of past actions are better understood.

J. Summary

The current mountain pine beetle epidemic affecting lodgepole pine forests is an important ecological event with significant socio-economic implications. What will be the consequences for the affected ecosystems? How do we protect our communities and other human values at risk in ways that are socially and economically (as well as ecologically) feasible? These are difficult questions. This report has focused specifically on the ecology and fire behavior issues associated with lodgepole pine and the mountain pine beetle epidemic. We recognize that the socio-economic aspects are as important as the ecological issues, but they are beyond the scope of this report.

Ecologically, much is known about lodgepole pine and mountain pine beetles. Even though the scale of the current epidemic is unprecedented over the past approximately 100 years of reliable observations, beetle-caused tree mortality at some scale has long been part of the dynamics of the lodgepole pine ecosystems. Similarly, fire behavior and its role in ecological processes and fuel management practices are relatively well understood. While we are confident about our general understanding, we have identified at least some scientific uncertainties about lodgepole pine, mountain pine beetle effects, and fire behavior that should be acknowledged and further researched.

We are most concerned about several wildcard issues that create some uncertainty in applying what we know from science. The scale of this epidemic is larger than any mountain pine beetle epidemic studied thus far. We do not fully understand if or how the magnitude of this ecological event will affect future forests in terms of regeneration of the present species or transitions to different vegetation types. Furthermore, there is the question – both tantalizing and troubling – about possible climate change (including its rate, direction and magnitude) and the degree to which scientific findings need to be qualified as they are applied.

If humans were not a part of the equation, forests would simply mature, die, and regenerate or be replaced by other vegetation types, following ecological trajectories over time driven by climate, environment, and species capabilities.

Because humans cause changes in forests by choosing to live there and deriving economic services from them, our communities are impacted by forest changes, whether they are natural or not. Thus both the scale of the mountain pine beetle epidemic and the uncertainties about future forests leave us with questions that are important to us but may not be answerable with the knowledge we have now.

Knowledge from scientific research about lodgepole pine and mountain pine beetles is valuable in two ways. It offers answers to some of the questions we have about forest ecology and provides valuable insight for management of these forests for ecological and community protection purposes. It also clarifies what we do not know. This is valuable not just to direct new research, but also to inform stakeholders of the degree of confidence they should have as land and natural resource management practices are considered.

As noted in the introduction, science is a work in progress. Many of the scientific uncertainties discussed in this report already are receiving attention in the research community. Even as research continues, however, the scientific knowledge already available is usable by a wide variety of stakeholders and in the collaborative and adaptive management process. Adaptive management is perhaps best described as managing while learning on the fly. In this report, the scientific community provides information to managers and other stakeholders, but the scientific community also will help advance the knowledge base through lessons learned as management practices are planned, implemented, monitored, and evaluated. We humans must decide how to manage forests based upon their intrinsic value and natural processes as well as some desired future condition contingent on human wants and needs. We must be realistic about the degree to which we as observers, managers and stewards of the forest can affect what is happening now and what will happen in the future. Whatever we do from here should be done together.

Using Bird Ecology to Learn About the Benefits of Severe Fire

Richard L. Hutto, Monica Bond and Dominick DellaSala Au1

s0010
3.1 INTRODUCTION

p0010 In this chapter we do not provide an encyclopedic review of the more than 450 published papers that describe some kind of effect of fire on birds. In other words, we are not systematically proceeding through a litany of fire effects on birds of southeast pine forests, California chaparral, Australian eucalypt forests, South African fynbos, and so forth. Instead, we have chosen to highlight underappreciated principles or lessons that emerge from selected studies of birds in ecosystems born of, and maintained by, mixed- to high-severity fire. Those lessons show how important and misunderstood basic fire ecology is when it comes to managing fire-dependent forest lands and shrublands, and the lessons apply to all fire-dependent ecosystems that have historically experienced severe fire—fires that are severe enough to stimulate an ecological succession of plant communities (as described in Chapter 1). We also focus our attention primarily on conifer forest ecosystems of the western United States because they undergo an amazing transformation following severe fire and because studies of these systems clearly reveal how birds evolved with, and now require, severe fire. Insight that emerges from the study of bird populations is overlooked in management circles worldwide. This is unfortunate because the insight one can gain by studying the ecology of individual bird species argues strongly that severe fire needs to be maintained in the landscape if we hope to maintain the integrity of most fire-dependent ecological systems.

p0015 Most studies of fire effects on birds are disappointingly "empty" because they are merely lists of birds that benefit from or are hurt by fire; they are not placed in the broader context of what a self-sustaining fire-dependent system looks like. To understand whether a particular change in abundance is "good" or "bad" requires insight into what ought to be, which requires an understanding of the patterns that occur under conditions that are as natural as possible for any given vegetation system. That, in turn, requires replicated study of what we can expect to find after "natural" fire in any given system.

The Ecological Importance of Mixed-Severity Fire: Nature's Phoenix.

B978-0-12-802749-3.00003-7, 00003

Thus, a study of the effects of, say, prescribed understory fire on birds is meaningless without knowing what a "natural" fire in that system would ordinarily produce. Many studies might show that bird species A increases after a prescribed fire, but is that a good thing? If bird species B increases after postfire salvage logging, is that a good thing? If bird diversity is higher in one fire treatment versus another, is that a good thing? For studies of fire effects to be useful, we need to address questions that inform management by tapping into a solid understanding of what constitutes a "natural" response to fire, and that requires knowing something about the fire regime under which a given system evolved. Only through distribution patterns and adaptations of individual species (not through effects on bird guilds or on diversity and similar composite metrics) can we begin to understand which kind of fire regime necessarily gave rise to specific patterns of habitat use and to adaptations that have evolved over millennia. Birds are excellent messengers; they carry all the information we need to reconstruct the historical conditions under which they evolved. All we have to do is listen.

s0015 3.2 INSIGHTS FROM BIRD STUDIES

s0020 Lesson 1: The Effects of Fire Are Context Dependent; Species Respond Differently to Different Fire Severities and Other Postfire Vegetation Conditions

p0020 One extremely important lesson that has emerged from studies of the fire effects on birds is that a given effect depends entirely on the vegetation type, the kind of fire, and the time since the fire (Recher and Christensen, 1981; Woinarski and Recher, 1997). For years, individual bird species have been labeled as "positive responders" or "negative responders" or "mixed responders" when, in fact, any species can be all of the above. The actual response of a bird species (or of any species) to fire, then, is dependent on context. The earliest papers on fire effects rarely provided details about the nature of the fire being studied, so the first attempt to conduct a meta-analysis based on a compilation of published results of fire effects (Kotliar et al., 2002) necessarily generated a lot of "mixed" responses by birds because some papers said a species was positively affected and others said the same species was negatively affected by fire. The seeming disagreement among studies was, in most cases, a simple result of researchers looking at different postfire vegetation conditions and times since fire. It was not until Smucker et al. (2005) separated their data into categories of fire severity and time since the fire that responses began to look much more consistent among studies that share a particular vegetation type, fire type, and time since the fire. As soon as one accounts for these factors, it becomes clear that the responses of most bird species are quite consistent and that most bird species benefit from severe fire (as we discuss below).

s0025 *Time Since Fire*

p0025 Species that benefit from severe fire are not only those that flourish during the first year or two following the disturbance event. The same can be said for species that are restricted to years 2-4, years 5-10, or even years 50-100 following severe fire. In fact, *most* plant and animal species are present only during a limited time period following a disturbance. Therefore, *most* plant and animal species in disturbance-based systems depend on disturbance to periodically create the conditions they need. Many bird species that thrive after fire have been mislabeled as species hurt by fire because studies of bird response to fire typically involve only a brief period of time soon after the fire. For example, although Williamson's sapsucker (*Sphyrapicus thyroideus*) was labeled a "mixed responder" and brown creeper (*Certhia americana*) a "negative responder" in the meta-analysis by Kotliar et al. (2002), and the change in house wren (*Troglodytes aedon*) abundance was labeled "insignificant" in a recently published study by Seavy and Alexander (2014), each of these species typically reaches its peak abundance several years after a fire, as revealed in an 11-year postfire study conducted after the Black Mountain fire, which burned near Missoula, Montana, in 2003 (Figure 3.1). Thus, each species clearly benefits from severe fire when viewed in the proper (and perhaps very restricted) time frame after fire.

p0030 By extending the duration of a postfire study beyond the first few years after a fire, most bird species reveal a unimodal response to time since fire, and most benefit from fire; they reveal a greater probability of detection in the burned forest at some point during that postfire period than in the same forest before fire or in the surrounding unburned forest (Taylor and Barmore, 1980; Reilly, 1991a, 2000; Taylor et al., 1997; Hannon and Drapeau, 2005; Saab et al., 2007; Chalmandrier et al., 2013; Hutto, 2015). These results force one to appreciate that if for a period of time after a fire conditions remain better than they are in very old plant communities near the end of the late seral stage of succession, then disturbance is periodically necessary to create the conditions needed by that species. Thus a species being "hurt" in the short term by fire is not evidence that fire is somehow "bad" for that species and that it would have been better off without fire. In fact, once a system is beyond the ideal postdisturbance time period for a species, the only way to periodically "restore" conditions needed by that species is to disturb the system with another severe fire and then wait for the appropriate time period following disturbance again. The lesson is this: one cannot assess the effects of fire on any plant or animal species without examining whether the species is restricted to a period of time preceding the oldest possible vegetation condition.

p0035 A necessary consequence of different species occurring at different points in time following fire (in association with changes in vegetation type and structure) is that we must embrace natural severe disturbance processes because they create starting points for the development of the full range of vegetation-age

f0010 **FIGURE 3.1** The probabilities of occurrence of Williamson's sapsucker (~~*Sphyrapicus thyroideus*~~), brown creeper (~~*Certhia americana*~~), and house wren (~~*Troglodytes aedon*~~) were significantly greater several years after the 2003 Black Mountain fire than they were either before the fire (as determined from survey data "outside" the burn perimeter in unburned, mixed-conifer forest of the same type) or during the first 2 years following the fire (R.L. Hutto, unpublished data; sample sizes exceed 150 point counts for each time period; $P < 0.05$, log linear analyses). Therefore, the benefit of severe fire for some species cannot be detected without restricting data collection to within a specific time period after the fire event.

categories, which, in turn, are needed for the maintenance of biological diversity (in particular beta diversity, the turnover in species number across gradients). Moreover, mixed-severity fires (which can result only from high-severity fire events) help provide a variety of kinds of starting points, which, in turn, also help maintain biological diversity (Smucker et al., 2005; Haney et al., 2008; Rush et al., 2012; Sitters et al., 2014; see also Chapters 4-6).

s0030 Old Growth

p0040 As already emphasized, most bird species clearly depend on severe fire to reset the clock, which stimulates development of the particular postdisturbance "age" to which they are best adapted. Still, many bird species are restricted in their habitat distribution to an end-of-the-line successional stage—they are dependent on old growth. There are also ecosystems (e.g., eucalyptus forests, chaparral) where severe fire is natural but where there are few, if any, early

Comp. by: Gunalan Stage: Revises1 Chapter No.: 3 Title Name: Dellasala
Date:28/4/15 Time:12:06:26 Page Number: 58

f0015 **FIGURE 3.2** Resprouting eucalyptus trees following a severe fire that burned through the area only months earlier. *(Photograph by Richard Hutto, taken in November 1999 near −34.284030°S, 150.725373°E in the tablelands above Wollongong, New South Wales, Australia.)*

fire-dependent bird species because many of the dominant plant species resprout, yielding a plant community structure and composition that "recovers" rapidly after fire (Figure 3.2). In these instances most bird species are associated with "mature" forms of those plant communities and would appear to do well if there were no fire at all (e.g., Taylor et al., 2012).

p0045 In all vegetation types that undergo plant succession following mixed- to high-severity fire, there will always be some bird species that depend on long-unburned vegetation. Therefore, discovering that those species are absent in the short term or "hurt" by fire is not unexpected, nor is it a necessarily a problem that needs to be addressed. The fact that fire temporarily removes large parts of a landscape from the pool of suitable conditions for those species is not a problem because the loss of suitable conditions is temporary, and there are usually nearby "refuges" of suitable conditions in places that have not burned for a long time (Bain et al., 2008; Leonard et al., 2014; Robinson et al., 2014; Winchell and Doherty, 2014). Natural systems exist as an ever-changing mosaic of different postfire ages—all vegetation ages are present at some point in space all the time. A significant problem emerges only when humans remove or degrade so much of the older vegetation through timber harvesting or land conversion that there is now a perceived risk of fire to those species that depend on older vegetation stands that are too few and far between. Understand clearly, however, that the absence of late-succession forest refuges is a problem that stems from excessive logging or development, not from the presence of fire per se.

p0050 Now that we are down to the last remaining old-growth forest remnants in California and Oregon l~~andscapes that have been subjected to excessive logging~~, some feel that we should thin the forests around those remnants to protect them from fire. The effect of altering mature forest surrounding the last remaining old-growth remnants on the remnants themselves is, however, unknown.

B978-0-12-802749-3.00003-7, 00003

Moreover, as has been discussed in reference to eucalyptus forest systems, many old-growth forest patches are old precisely because they are situated in places that are relatively immune to severe fire (Bowman, 2000); the same is undoubtedly true of many old-growth mixed-conifer forest patches. Unburned forest patches surrounding unburned, old-growth forest patches also have been suggested to be important as dispersal corridors across which old-growth species may recolonize recently burned areas as succession proceeds toward later stages (Pyke et al., 1995; Robinson et al., 2014; Seidl et al., 2014). Therefore, proposals to thin the forest around remaining old-growth stands may be well intentioned but reflect a lack of appreciation for the resilience associated with plant communities born of, and maintained by, natural disturbance processes (a case in point is the spotted owl [*Strix occidentalis*]; see Box 3.1).

s0035 *Postfire Vegetation Conditions*

p0070 One must account not only for time since fire but also for fire severity and other forest conditions (e.g., vegetation composition and tree density) to adequately assess fire effects on animal species. Smucker et al. (2005) accounted for both time since fire and fire severity in an analysis of bird occurrence patterns following the Bitterroot fires of 2000 in Montana, and the results were profound.

b0010 BOX 3.1 Old-Growth Species and Severe Disturbance Events

p0055 There are a number of old-growth-dependent species in North American conifer forests, but severe fire may not pose anywhere near the threat to those species that one might suppose. Consider the spotted owl ~~(*Strix occidentalis*)~~, one of the most iconic old-growth-dependent bird species in the Pacific Northwest, California, and Southwest (extending into northern Mexico). This federally listed threatened raptor typically nests, roosts, and forages in dense conifer and mixed-conifer-oak forests dominated by large (>50-cm diameter at breast height), older trees and peppered with big decadent snags and fallen logs. High levels of canopy cover (generally >60%) from overhead foliage is an important component of nesting and roosting stands; thus, spotted owls were long presumed to be seriously harmed where severe fire burned the forest canopy. Indeed, over the past several decades, most forest management efforts in the range of the spotted owl (a Forest Service management indicator species) has been driven by logging to prevent or reduce fire to "save" the owl, including the latest U.S. Fish & Wildlife Service recovery plans for the northern and Mexican spotted owls. Yet, the forests where the owl dwells have experienced mixed- and high-severity fire for millennia. So how do these birds actually respond when severe fire affects habitat within their home ranges?

p0060 Several studies have demonstrated that all three subspecies of spotted owl can survive and thrive (i.e., successfully reproduce) within territories that have experienced moderate- and high-severity fire (Bond et al., 2002; Jenness et al., 2004;

Continued

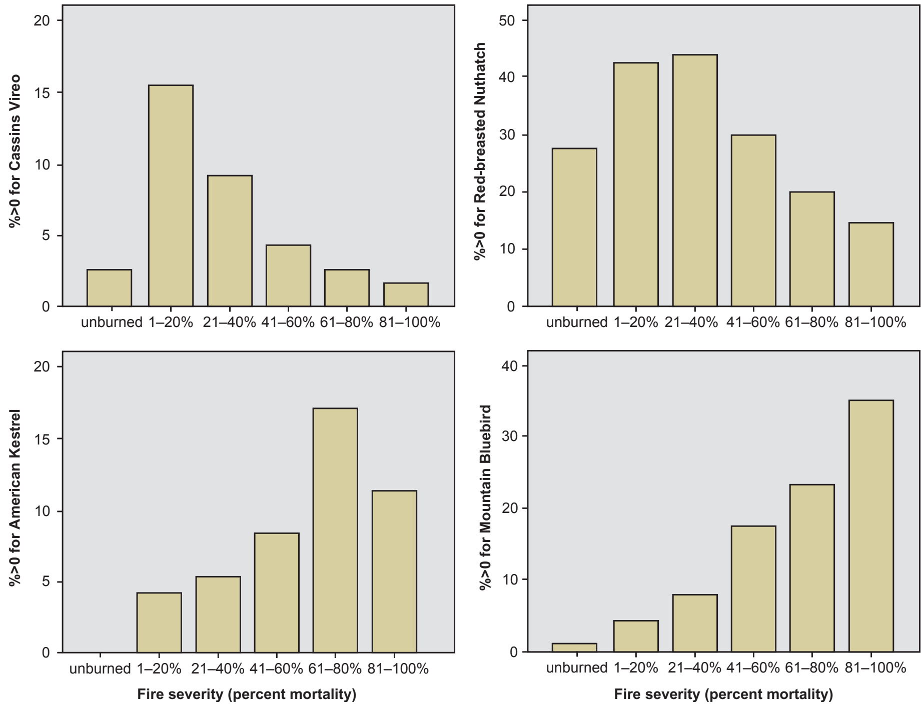
b0010 **BOX 3.1 Old-Growth Species and Severe Disturbance Events—Cont'd**

Roberts et al., 2011; Lee et al., 2012, 2013). Exceptionally high levels of severe fire in a nest stand can cause spotted owls to abandon that territory (Lee et al., 2013), but only a small fraction of sites ever exceed that threshold in any given fire. Moreover, a higher probability of abandonment after fire was documented only in a geographical region where prefire forest patches were limited or isolated; this did not occur in areas where prefire forest cover was more abundant (Lee et al., 2012, 2013) or in areas that were ~~salvage~~ logged after fire (Lee et al., 2013; Clark et al., 2013). For example, the year after the 2013 Rim Fire—one of the largest fires to occur in California within the past century—at least six pairs of California spotted owls were detected in sites where >70% of the "suitable habitat" around their nest stands burned at high severity. (At one occupied site severe fire burned 96% of the habitat!) Why do they stick around in burned territory? One study found California spotted owls selectively hunted (mostly for woodrats and gophers) in stands recently burned by severe fire when those burned forests were available to them and relatively near the nest or roost stand (Bond et al., 2009, 2013). Another study showed that during winter, Mexican spotted owls moved up to 14 km into burned forests where prey biomass was 2-6 times greater than in their breeding-season nesting areas (Ganey et al., 2014). Spotted owls are perch-and-pounce predators, so it is not surprising that they avoided foraging in areas that were logged after fire, as there were no longer any perch trees (Bond et al., 2009), nor is it surprising that postfire logging reduced site occupancy and survival rates (Clark et al., 2013; Lee et al., 2013). In these studies, spotted owls still preferred to nest and roost in green forests, underscoring the importance of unburned/low-severity refuges within the larger landscape mosaic of mixed-severity fire. Still, the point is that where severe fire is natural, even old-growth species can partake of its bounty. The spotted owl, too, is sending a message here: A natural fire regime provides a bedroom, nursery, and kitchen for even old-growth-dependent species, as long as the burned forest is left standing.

p0065 Despite this evidence, the U.S. Fish & Wildlife Service is now calling for aggressive, large-scale thinning in northern spotted owl habitat in dry forests as a means of reducing fire intensity (U.S. Fish and Wildlife Service, 2011). This "recovery" objective for the owl was developed over objections raised by scientists (Hanson et al., 2009, 2010) and professional societies such as The Wildlife Society and Society for Conservation Biology. Notably, Odion et al. (2014b) simulated changes in owl habitat over a four-decade period following fire and the kind of thinning proposed by federal land managers. The simulation study showed that thinning over large landscapes would remove 3.4-6.0 times more of their dense, late-successional habitat in the Klamath and dry Cascades, respectively, than forest fires would, even given a future increase in the amount of high-severity fire. Further, Baker (2015) documented that before extensive Euro-American settlement, mixed- and high-severity fires shaped dry forests in the Eastern Cascades of Oregon and provided important habitat for northern spotted owls there. These studies challenge the paradigm that severe fire is a serious threat to spotted owls, which evolved in landscapes shaped by such fire, and that extensive logging is needed to ameliorate this widely believed but overstated threat.

B978-0-12-802749-3.00003-7, 00003



f0020 **FIGURE 3.3** Example plots of the percentage occurrence of four mixed-conifer bird species in relation to fire severity in the first few years after fire. Data were drawn from 7043 survey points distributed across 110 different fires that burned since 1988 in western Montana. Sample sizes exceed 700 point counts per severity category. All patterns are significant ($P < 0.05$, log linear analyses). Note that each species [illegible] abundant in burned than in unburned forest, and each is relatively abundant at a level o[illegible]everity (percentage of tree mortality) that differs from that occupied by the other species.

Once they accounted for fire severity alone, it became abundantly clear that many of the same bird species that had been labeled as “mixed responders” to fire by others (e.g., Kotliar et al., 2002) were not at all mixed in their response to fire. The importance of fire severity is strikingly apparent in even the simplest graphs of percentage occurrence across severity categories (Figure 3.3).

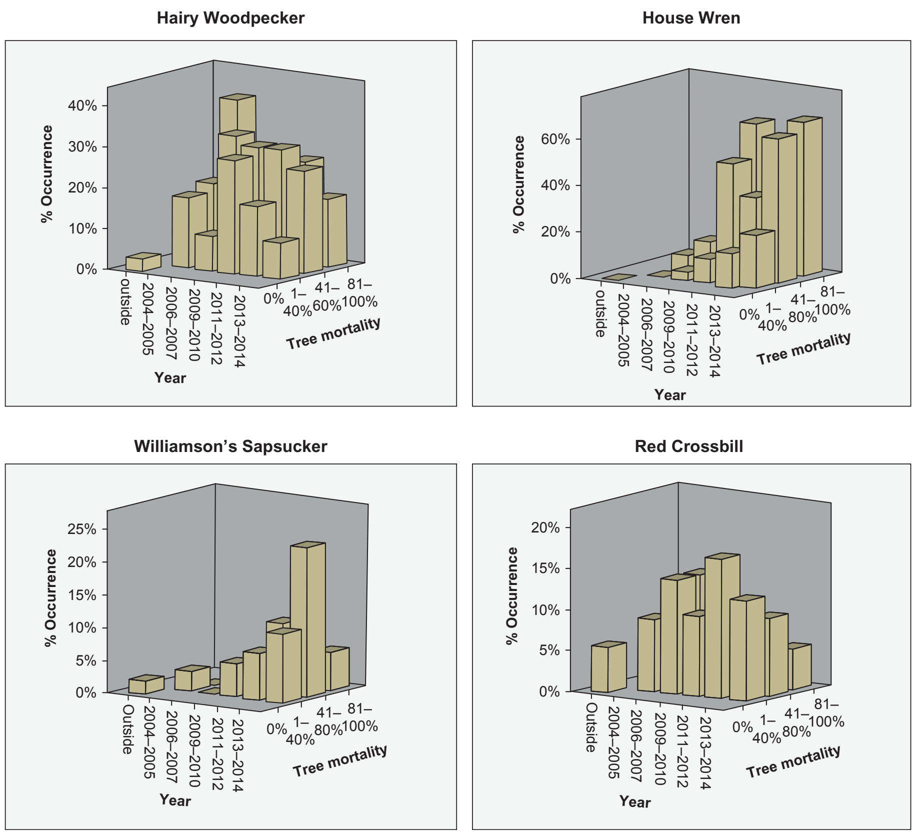
s0040 Lesson 2: Given the Appropriate Temporal and Vegetation Conditions, Most Bird Species Apparently Benefit from Severe Fire

p0075 After we combine information on the time since fire, fire severity, and perhaps one or two additional vegetation variables, most bird species apparently benefit from severe fire. For each species there is a particular combination of burned forest variables that creates ideal conditions for that species, as evidenced by an abundance that exceeds that in a long-unburned patch of the same vegetation type. Indeed, when Hutto and Patterson (2015) considered just two fire-context variables (time since fire and fire severity), they found 46 of 50 species to be

B978-0-12-802749-3.00003-7, 00003

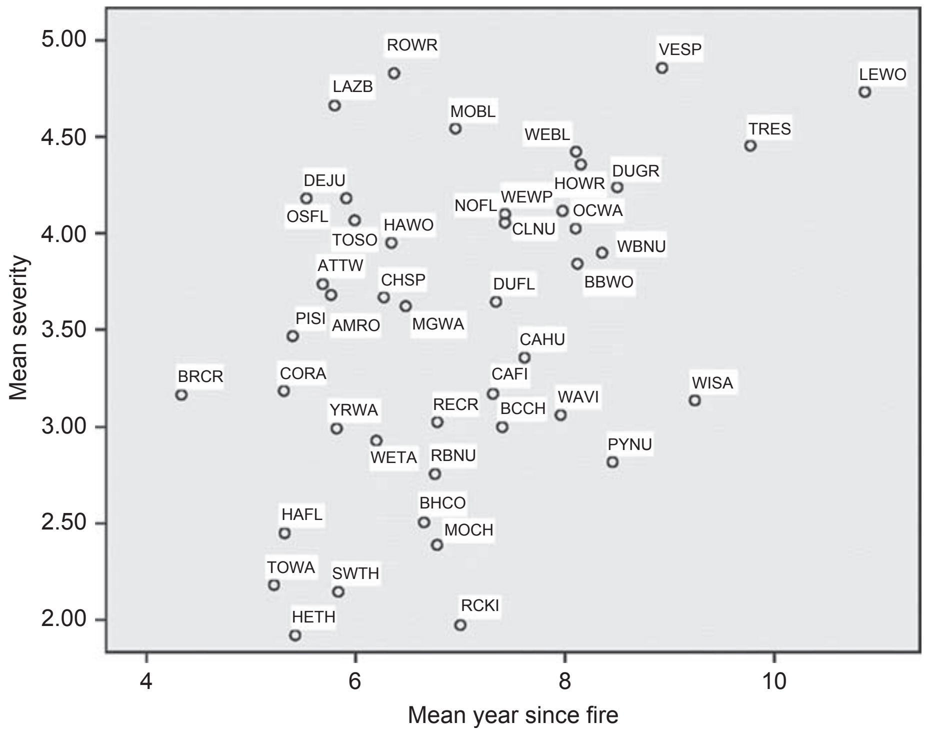
more abundant in some combination of those two variables than in long-unburned stands (Figure 3.4). Thus, not only are most species relatively abundant in one burned forest condition or another, but the average point in space and time occupied by each species is also species specific (Figure 3.5).

p0080 As an introduction to some of the fascinating biology surrounding severely burned forests, consider the following bird species. The black-backed woodpecker (*Picoides arcticus*), American three-toed woodpecker (*Picoides dorsalis*), hairy woodpecker (*Picoides villosus*), northern flicker (*Colaptes auratus*), and Lewis's woodpecker are all more abundant in severely burned than unburned mixed-conifer forest (see patterns of habitat occurrence for four of the five species in Figures 3.11 and 3.12) because of an abundance of food (beetle larvae and ants) and potential nest sites associated with standing dead trees.



f0025 **FIGURE 3.4** Example plots of percentage occurrence for various mixed-conifer bird species in relation to both time since fire and fire severity after the 2003 Black Mountain fire near Missoula, Montana (R.L. Hutto, unpublished; sample sizes exceed 35 point counts for each time-by-severity category; all patterns are significantly nonrandom as determined by log linear analyses [$P < 0.05$]). The examples were selected to illustrate that each species is more abundant in burned than in unburned forest (the occurrence rate in unburned forest shown in the first time period), and each is most abundant in a different combination of time since fire and burn severity (percentage of tree mortality).

Comp. by: Gunalan Stage: Revises1 Chapter No.: 3 Title Name: Dellasala
Date:28/4/15 Time:12:06:26 Page Number: 63



f0030 **FIGURE 3.5** In combination, the mean time since fire and mean fire severity at points of occurrence for each of 46 (mnemonically coded) species differs from that of every other species. Mean values were calculated from the kind of data presented in Figure 3.4.

The Williamson's sapsucker and olive-sided flycatcher (*Contopus cooperi*) find the abrupt edges between severely burned and unburned forest to be ideal nest locations (Figure 3.6). A host of secondary cavity-nesting and snag-nesting species (e.g., northern hawk owl [*Surnia ulula*], great gray owl [*Strix nebulosa*], mountain bluebird [*Sialia currucoides*], western bluebird [*Sialia mexicana*], house wren, and tree swallow [*Tachycineta bicolor*]) benefit from new forest openings, where they find a mature-forest legacy of already existing broken-top snags (Figure 3.7), where a disproportionately large number of nest sites are located (Hutto, 1995). These species depend on the kinds of snags that become common only after a forest reaches the mature- to old-growth stage and then burns in a severe fire. A variety of species (e.g., flammulated owl [*Psiloscops flammeolus*], mountain bluebird, Townsend's solitaire [*Myadestes townsendi*], and dark-eyed junco [*Junco hyemalis*]) make use of the cavities created by burned-out root wads or uprooted trees that happen to blow down in the first few years after severe fire (Figure 3.8). Many species (e.g., Clark's nutcracker [*Nucifraga columbiana*], Cassin's finch [*Haemorhous cassinii*], red crossbill (*Loxia curvirostra*], and pine siskin [*Spinus pinus*]) take advantage of seeds that are released or made available in cones that open after severe fire

f0035 **FIGURE 3.6** Williamson's sapsucker ~~(*Sphyrapicus thyroideus*~~; left) and olive-sided flycatcher (~~*Cont*~~ ~~*pperi;*~~ right) are known to nest disproportionately often near the abrupt edges between severely burned and unburned forest. *(Photographs by Richard Hutto (left) and Bruce Robertson (right).)*

f0040 **FIGURE 3.7** Compared with burned trees with intact tops, broken-top snags that were already snags before the fire burned are used disproportionately more often as nest sites by cavity-nesting bird species. The black-backed woodpecker also roosts almost entirely in burned-out hollows, forked trunks, or other relatively unusual structures that create crevices in "deformed" snags that existed before the forest burned (Siegel et al., 2014). Pictured (left to right) are a young hairy woodpecker ~~(*Picoides villosus*)~~ in its nest cavity, an American robin (*Turdus migratorius*) nest, and a northern flicker ~~(*Colaptes auratus*)~~ nest. The implications are profound—old-growth elements (snags) are really important to birds that depend on burned forest conditions, so burned, old-growth forests are as valuable to wildlife as unburned old-growth forests. *(Photographs by Richard Hutto.)*

f0045 **FIGURE 3.8** The architecture of a burned forest becomes modified after trees begin to blow down in the first few years after a fire, and a number of bird species make use of the root wads as nest sites. A Townsend's solitaire ~~(*Myadestes townsendi*~~) nest is highlighted here. *(Photograph by Richard Hutto.)*

f0050 **FIGURE 3.9** Few people seem to realize how i[illegible]t Clark's nutcrackers ~~(*Nucifraga columbiana*~~) are as seed dispersers after severe fire in pond[illegible]pine forests. Pictured here are examples of a nutcracker extracting seeds from a ponderosa pine cone that opened after fire (left) and a nutcracker with a throat pouch full of seeds in the scorched ground beneath a ponderosa pine canopy. *(Photographs by Richard Hutto.)*

(Figure 3.9). Still more bird species (e.g., calliope hummingbird [*Selasphorus calliope*], lazuli bunting [*Passerina amoena*], and MacGillivray's warbler [*Geothlypis tolmiei*]) use the shrub-dominated early seral stage for feeding and nesting and as display sites (Hutto, 2014).

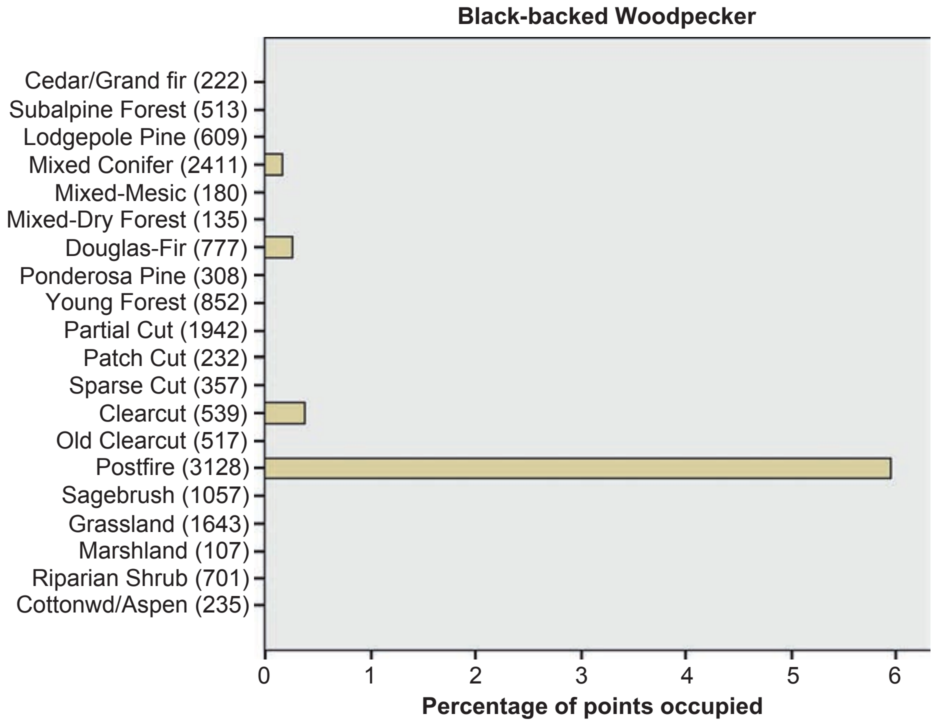
s0045 Lesson 3: Not only Do Most Bird Species Benefit from Severe Fire, but Some also Appear to *Require* Severe Fire to Persist

p0085 The black-backed woodpecker has become an iconic indicator of severely burned forests because its distribution is nearly restricted to such conditions. Bent (1939) provided the first description of the unusual association between this woodpecker species and burned forests when he noted that Manly Hardy wrote to Major Bendire in 1895 about finding the woodpecker to be "… so abundant in fire-killed timber areas that I once shot the heads off six in a few minutes when short of material for a stew." This anecdote, reflecting the importance of severe fire, went largely unnoticed until the 1970s, when Dale Taylor undertook a study of birds in relation to time since fire in the Yellowstone and Grand Teton National Parks. His more systematic study uncovered the same remarkable pattern. Taylor was the first person to evaluate data drawn from a series of burned conifer forest stands of differing ages, and he found the appearance of the black-backed woodpecker to be restricted to the first few years after fire (Taylor and Barmore, 1980). A subsequent before-and-after fire study by Apfelbaum and Haney (1981) and studies of burned versus adjacent unburned forest by Niemi (1978), Pfister (1980), and Harris (1982) provided additional evidence that this bird species is strongly associated with burned forest conditions. Following the Rocky Mountain fires of 1988, Hutto (1995) conducted a more comprehensive study of the distribution of black-backed woodpeckers across a broad range of vegetation types. That study served to reinforce the notion that this species is an ideal indicator of severely burned mixed-conifer forest. More specifically, Hutto provided a meta-analysis of his own and already published bird survey data collected from burned forests and from more than a dozen unburned vegetation types; those data showed the black-backed woodpecker to be relatively restricted to burned forests. To address the potential problem of putting too much faith in distribution patterns derived from bird occurrence rates that were based on a variety of study durations and methods, Hutto subsequently coordinated the collection of standardized bird survey data from more than 18,000 points distributed across every major vegetation type in the U.S. Forest Service Northern Region. The results (Hutto, 2008) were strikingly similar to what earlier studies showed: one is hard pressed to find a black-backed woodpecker anywhere but in a recently burned forest (Figure 3.10).

p0090 Numerous studies (most published just in the past decade) provide additional detail that can help us better understand this remarkable association between the black-backed woodpecker and severely burned forests. Here we list some of the insights we have gained:

o0010 1. The magical appearance of woodpeckers within weeks of a fire (Blackford, 1955; Uxley, 2014) suggests that either smoke, or perhaps the fire or burned landscape itself, provides a stimulus for birds to colonize newly burned forests.

B978-0-12-802749-3.00003-7, 00003



f0055 **FIGURE 3.10** Histogram bars indicate the percentage of points (sample sizes in parentheses) at which the black-backed woodpecker was detected in each of 21 distinct vegetation types within northern Idaho and western Montan[illegible] distribution is nonrandom ($X^2 = 559.43$; $df = 19$; $P < 0.0001$) and reveals that the black-[illegible] woodpecker is highly specialized in its use of burned conifer forest. *(Data from Hutto (2008).)*

o0015 **2.** Breeding and nest densities increase more rapidly than expected on the basis of recruitment alone (Yunick, 1985; Youngman and Gayk, 2011), which suggests that the process of immigration after fire is significant.

o0020 **3.** Woodpecker diet, which is based mainly on wood-boring beetle larvae that feed almost exclusively on recently burned and killed trees (Murphy and Lehnhausen, 1998; Powell et al., 2002; Fayt et al., 2005), reflects the broad postfire change in animal community composition that accompanies severe fire.

o0025 **4.** The woodpecker's nonrandom use of forest patches containing dense, larger-diameter trees (Saab and Dudley, 1998; Saab et al., 2002, 2009; Nappi and Drapeau, 2011; Dudley et al., 2012; Seavy et al., 2012) that have burned at high rather than low severity (Schmiegelow et al., 2006; Koivula and Schmiegelow, 2007; Hanson and North, 2008; Hutto, 2008; Nappi and Drapeau, 2011; Youngman and Gayk, 2011; Siegel et al., 2013) is striking and consistent among studies.

o0030 **5.** The window of opportunity for occupancy by this species is not only soon after fire, but generally lasts only about a half-dozen years before the birds

Comp. by: Gunalan Stage: Revises1 Chapter No.: 3 Title Name: Dellasala
Date:28/4/15 Time:12:06:27 Page Number: 68

B978-0-12-802749-3.00003-7, 00003

(and the abundant native beetle populations) disappear (Taylor and Barmore, 1980; Apfelbaum and Haney, 1981; Murphy and Lehnhausen, 1998; Hoyt and Hannon, 2002; Saab et al., 2007; Nappi and Drapeau, 2009; Saracco et al., 2011).

o0035 **6.** The size of the home ranges of black-backed woodpeckers within burned forests are significantly smaller (indicating better quality habitat) than those outside burned forests (Rota et al., 2014b; Tingley et al., 2014). Even more telling is that nest success is significantly higher inside than outside burned forests (Nappi and Drapeau, 2009; Rota et al., 2014a).

o0040 **7.** Estimated population growth rates are insufficient to maintain a growing population outside burned forests (Rota et al., 2014a). Thus, although one could argue that low woodpecker densities in green-tree forests multiplied by a much larger unburned forest area might yield even more woodpeckers in green forests (Fogg et al., 2014), a sink area alone (no matter how large) can never yield a viable population of woodpeckers (Odion and Hanson, 2013).

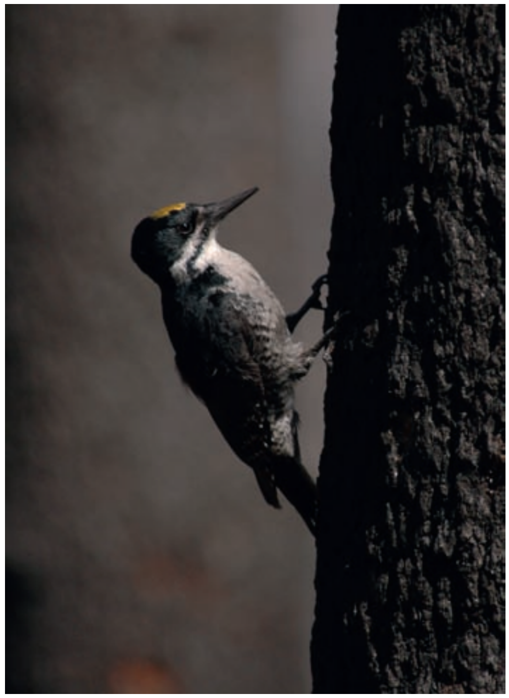
o0045 **8.** The importance of severely burned forests as foraging locations for wintering black-backed woodpeckers is virtually unknown; the only detailed work so far (Kreisel and Stein, 1999) revealed densities that were an order of magnitude greater in burned than in unburned forests.

p0135 The biology surrounding this single bird species clearly reflects not only the ecological importance but also the necessity of severely burned forests, but major environmental organizations have yet to focus conservation efforts on burned forests (Schmiegelow et al., 2006), and management guidelines developed by state agencies to designate important wildlife habitats (e.g., https://www.dfg.ca.gov/biogeodata/cwhr/) do not even have burned conifer forests on their radar.

p0140 The distributional stronghold of the black-backed woodpecker might be considered to lie within the boreal forests of Canada, which nobody doubts are among the most severe-fire-dependent ecosystems in the world, but the bird's distribution south into the California Sierras and Rocky Mountains of the Intermountain West confirms that severe fires in those areas have been historically important as well. A North American forest bird species that is more narrowly restricted to a single forest condition does not exist; the black-backed woodpecker is the definition of a specialist. Everything about this bird species, including its distribution, territory size, breeding success, and even coloration pattern (which matches blackened trees), all indicate that this species needs expansive patches of severely burned forest to persist (Figure 3.11).

p0145 We have taken the liberty to provide extensive detail on this particular species because its ecological story carries significant management implications. Because public land managers have a responsibility to manage for the maintenance of all vertebrate species, finding even a single species that depends on severe fire should be enough to raise their awareness that severely burned

B978-0-12-802749-3.00003-7, 00003



f0060 **FIGURE 3.11** Black-backed woodpecker—a species that is relatively restricted in its distribution to severely burned forests. *(Photograph by Richard Hutto.)*

mixed-conifer forests provide necessary habitat as well. Thus the black-backed woodpecker is an ideal focal species for bringing attention to the fact that burned forest conditions are important to maintain in the landscape (DellaSala et al., 2014). The evolutionary history that has led to a strong association between burned forests and the woodpecker also raises questions about whether (as many assume) severe fires in mixed-conifer forests are really beyond the historical natural range of variation, whether we need to be thinning forests outside the wildland-urban interface to reduce fire severity, whether we need to be suppressing fire outside the wildland-urban interface, and whether we should "salvage" logging trees (including important legacy trees; see Chapter 11) after fire. Yes, the story surrounding this focal species is important.

s0050 *Bird Species in Other Regions That Seem to Require Severe Fire*

p0150 Do any other bird species seem not only to benefit from but also to require severe fire to persist? The presence of a species in a specific environment and its absence elsewhere would be a clear indication that it depends on that particular environment. For species that occur across a range of environmental conditions, the places where they are relatively abundant are also likely to represent places that are required for population persistence because they persist in source areas and they are generally less abundant in, and their abundance is

B978-0-12-802749-3.00003-7, 00003

more variable through time in, more marginal areas (Pulliam, 1988; Sergio and Newton, 2003). Although the same level of biological detail that has been amassed for the black-backed woodpecker has not been collected for most other fire-associated bird species, the habitat distribution patterns of numerous bird species reveal that they are nowhere more abundant than in recently burned forests. For example, Hutto (1995) listed 15 species that were more abundant in recently burned forests than in any of 14 other vegetation types. Graphs generated from surveys conducted across an even broader range of vegetation types show just how striking these habitat distribution patterns can be: numerous species are nowhere more abundant than they are in severely burned forests (Hutto and Young, 1999) (Figure 3.12).

p0155 Many mixed-conifer bird species (e.g., black-backed woodpecker, American three-toed woodpecker, hairy woodpecker, northern flicker, olive-sided flycatcher, western wood-pewee [*Contopus sordidulus*], dusky flycatcher [*Empidonax oberholseri*], mountain bluebird, Townsend's solitaire, house wren, tree swallow, lazuli bunting, Clark's nutcracker, red crossbill) fall consistently into a short-term "benefit" category, as revealed either by some measure of abundance or nest success in studies of burned versus unburned or before versus after fire (Bock and Lynch, 1970; Bock et al., 1978; Taylor and Barmore, 1980; Apfelbaum and Haney, 1981; Raphael et al., 1987; Hutto, 1995; Kotliar et al., 2002; Hannah and Hoyt, 2004; Smucker et al., 2005; Mendelsohn et al., 2008; Seavy and Alexander, 2014). Even severely burned patches within conifer forests that we have come to associate with low-severity fire can provide critically important habitat for species like the buff-breasted flycatcher (Kirkpatrick et al., 2006; Conway and Kirkpatrick, 2007; Hutto et al., 2008).

p0160 One of the most celebrated examples of a fire specialist involves the federally endangered Kirtland's warbler (*Setophaga kirtlandii*). It occurs almost exclusively in young (5- to 23-year-old) jack pine (*Pinus banksiana*) forest historically created by severe fire (Walkinshaw, 1983). In addition, pairing success is significantly higher in burned than in unburned forests (98% vs. 58% success; Probst and Hayes, 1987). The need for severe fire is obvious not only because, historically, it must have taken severe fires to stimulate forest succession but also because of how its critically endangered population increased dramatically after a fire accidentally escaped within its breeding range (James and McCulloch, 1995). Managers have had difficulty trying to recreate conditions that mimic natural postfire conditions through the use of logging techniques (Probst and Donnerwright, 2003; Spaulding and Rothstein, 2009), and efforts to use these artificial means to maintain warbler populations miss the point. Conservation efforts should be directed toward maintaining severely burned forests, not toward finding a way around the natural fire disturbance process.

p0165 In Australia, where few species are thought to be restricted to recently burned shrubland or forest conditions, early colonists are viewed as generalists, and management concerns are focused on postfire decreases in late-succession specialists (Serong and Lill, 2012). Nevertheless, recent data from Lindenmayer

Data were drawn from a subset of the Northern Region Landbird Monitoring Program database consisting of 20,000 survey points distributed across northern Idaho and western Montana.

Comp. by: Gunalan Stage: Revises1 Chapter No.: 3 Title

et al. (2014) show that a number of bird species decline in abundance 1-2 years after moderate to severe fire but then return to levels comparable to, or *higher* than, those in unburned forests within 3 years following fire. Indeed, upon further inspection, we found that the superb fairywren (*Malurus cyaneus*), gray fantail (*Rhipidura albiscapa*), yellow-faced honeyeater (*Lichenostomus chrysops*), white-fronted honeyeater (*Purnella albifrons*), dusky robin (*Melanodryas vittata*), flame robin (*Petroica phoenicea*), willie wagtail (*Rhipidura leucophrys*), gray shrike-thrush (*Colluricincla harmonica*), varied sittella (*Daphoenositta chrysoptera*), apostlebird (*Struthidea cinerea*), white-browed scrubwren (*Sericornis frontalis*), brown thornbill (*Acanthiza pusilla*), spotted pardalote (*Pardalotus punctatus*), welcome swallow (*Hirundo neoxena*), dusky woodswallow (*Artamus cyanopterus*), black-faced woodswallow (*Artamus cinereus*), and silver-eye (*Zosterops lateralis*) each have been shown by one or more authors to be more abundant in severely burned than in long unburned, dry sclerophyll forests (Christensen and Kimber, 1975; McFarland, 1988; Reilly, 1991a,b, 2000; Turner, 1992; Taylor et al., 1997; Fisher, 2001; Leavesley et al., 2010; Recher and Davis, 2013; Lindenmayer et al., 2014). Thus many eucalyptus forest species also seem to require severe fire to create the early successional forest conditions within which they are most abundant, but most of those species are not restricted to conditions that occur during the first year or two after fire. In comparison with the dramatic change in bird species composition following severe fire in mixed-conifer forests, there is, in fact, a notable lack of turnover in bird species composition following severe fire in eucalyptus forests (compare before-and-after fire data from Australia and the western United States in Figure 3.13). This difference in response to fire is presumably because eucalyptus trees resprout rapidly from epicormic shoots (Figure 3.2). Lindenmayer et al. (2014) also note that in montane ash forests, "... very rapid vegetation regeneration and canopy closure on severely burned sites ... may limit the influx of open-country birds and preclude the evolutionary development of early successional species" (p. 474). Nevertheless, the bird species listed above suggest that many may depend on slightly later stages of succession before the development of a fully mature forest and that a slightly different perspective might be needed to expose the ecological importance of severe fire to birds of Australian eucalypt forests.

p0170 Taken together, we hope we have provided enough ecological information derived from birds to solidify the notion that severe fire in most severe-fire-dependent shrublands and forests is both natural and necessary for maintenance of the ecological integrity of such systems.

s0055 Postfire Management Implications

p0175 Severe fire is natural and necessary in most—not relatively few—conifer forest types and in many other vegetation types worldwide as well (see Chapters 1 and 2). Current management practices designed to prevent fire,

f0070 **FIGURE 3.13** Probabilities of the occurrence of bird species in burned and unburned Australian eucalypt forests in the tablelands above Wollongong, New South Wales, and in burned and unburned mixed-conifer forests in western Montana (R.L. Hutto, unpublished data). Numbers of survey points are given in parentheses. Birds are ordered by the unburned-to-burned ratio of abundance, and species that are completely absent from or are significantly (Mann-Whitney *U* tests) less abundant in the opposite condition are highlighted in yellow. In both locations are bird species restricted to either early or later successional stages, but the amount of species turnover (degree of replacement of late with early succession specialists) is less pronounced after severe fire in Australia than after severe fire in the western United States.

suppress fire, mitigate fire severity, "restore" or "rehabilitate" burned forests after fire, and mimic the effects of severe fire are incompatible with the maintenance of ecosystem integrity (Chapter 13). Below we use results from bird research as evidence to support this statement, and we offer positive suggestions about what land managers could be doing differently.

s0060 *Fire Prevention Should Be Focused on Human Population Centers*

p0180 The dependence of so many bird (and many other plant and animal) species on conditions created by severe fire is clear. It necessarily follows that we cannot prevent fire and still retain anything close to a natural world. The obvious

Comp. by: Gunalan Stage: Revises1 Chapter No.: 3 Title Name: Dellasala
Date:28/4/15 Time:12:06:28 Page Number: 74

alternative is to focus prevention efforts toward population centers that are most at risk from severe fire so that fire can be left to periodically restore forest conditions elsewhere. Smokey Bear needs to refine his message so that it reflects a desire to save human lives and property, *not* a desire to save trees from fire in our wildlands (see Chapter 13).

s0065 *Fire Suppression Should Be Focused on the Wildland-Urban Interface (or Fireshed)*

p0185 Because many species depend on severe fire, it also necessarily follows that we should focus suppression efforts on areas immediately adjacent to human settlements (see Chapter 13). Wildland firefighters should serve primarily as support for firefighters who defend homes and human lives. Efforts to suppress fire beyond settled areas should be viewed as little more than efforts to save the forest from itself—forests need fire in the same way that they need sunlight and rain.

s0070 *High-Severity Fires Beget Mixed-Severity Results*

p0190 In contrast with high-severity fire, low-severity understory fires cannot create as broad a range of postfire conditions as severe fires can, nor can they stimulate the postfire process of ecological succession like a severe fire can. Therefore, managing for the maintenance of biodiversity requires more conscientious management for the maintenance of severe fires and the mixed-severity landscape effects that result from such fires (Nappi et al., 2010; Taylor et al., 2012).

s0075 *Mitigate Fire Severity Through Thinning only Where such Fuel Reduction Is Appropriate*

p0195 Because many species depend on severe fire, it necessarily follows that we should focus forest-thinning efforts in the wildland-urban interface and perhaps beyond that in what are basically artificial tree plantations that have resulted from past timber harvesting (see Odion et al., 2014a for review of this topic). The distributions of black-backed woodpeckers and many other fire-dependent plant and animal species make it abundantly clear that a reduction in fire severity is ecologically justified in only a very small proportion of vegetation types (Odion et al., 2014a; Sherriff et al., 2014). The presence of numerous fire-dependent species in most conifer forests throughout the American West (as illustrated by the abundance of bird research results considered in this chapter) is the strongest possible indication that the same forests have burned severely for millennia and are well within the historical range of natural variation.

p0200 The distribution of birds like the black-backed woodpecker and other fire-dependent plant and animal species, which blanket most of the forested land in the American West, are clearly at odds with claims (e.g., Haugo et al., 2015) that as much as 40% of public forested lands in parts of the United States are in need of restoration to prevent or mitigate the effects of severe fire. Lower-severity fires do not produce the mixed- and high-severity conditions needed by the most

B978-0-12-802749-3.00003-7, 00003

fire-dependent bird species, so efforts to mitigate fire severity in most places is incompatible with maintenance of the ecological integrity of most conifer forest systems (Odion et al., 2014a). So, what should we be doing differently? We could realize that modeled estimates indicating that our forests are in conditions that lie beyond the historical natural range of variation are just that—modeled estimates that rest strongly on many untested assumptions. We should always compare modeled results with insight gained by ecologists who can also draw strong inferences about historical conditions and, more specifically, about the kind of environments that necessarily led to adaptations of plants and animals—adaptations that reflect the distant past much more accurately than other methods commonly used to reconstruct natural fire regimes.

s0080 *Postfire "Salvage" Logging in the Name of Restoration or Rehabilitation Is Always Inappropriate*

p0205 Postfire "salvage" logging, seeding, planting, and shrub removal have overwhelmingly negative effects on natural systems (Lindenmayer et al., 2004; Lindenmayer and Noss, 2006; McIver and Starr, 2006; Swanson et al., 2011; DellaSala et al., 2014; Hanson, 2014), and birds have been instrumental in uncovering that fact. There is nothing as obvious to a birdwatcher as the negative effect of postfire salvage logging on the most fire-dependent birds (Uxley, 2014), and these anecdotal impressions are backed up by the strongest and most consistent scientific results ever published on any wildlife management issue (Hutto, 1995, 2006; Morissette et al., 2002; Nappi et al., 2004; Hutto and Gallo, 2006; Koivula and Schmiegelow, 2007; Hanson and North, 2008; Cahall and Hayes, 2009; Saab et al., 2009; Rost et al., 2013). One look at (Figure 3.14), or one walk through, a salvage-logged forest after knowing

f0075 **FIGURE 3.14** A vivid view of what can only be described as an ecological disaster following this postfire salvage logging operation, which took place after the 1988 Combination fire in Montana. *(Photograph by Richard Hutto.)*

Comp. by: Gunalan Stage: Revises1 Chapter No.: 3 Title Name: Dellasala
Date:28/4/15 Time:12:06:29 Page Number: 76

something about the biological wonder associated with a severely burned forest should be enough to convince any thinking person that there is no justification for this kind of land management activity.

p0210 It is bad enough that forests logged after fire are made unsuitable for black-backed woodpeckers and other early postfire specialists, but much worse is that postfire logging and shrub removal through mechanical or chemical means may also act as an "ecological trap" (Robertson and Hutto, 2006). This can occur when birds are attracted to burned areas that seem to be suitable and then those areas are suddenly transformed by logging or shrub removal into unsuitable habitat in an unnaturally rapid period of time. This is the most reasonable explanation for why black-backed woodpeckers are more abundant in dense, burned forests that are logged after fire than they are in burned forests that are logged before fire—birds are not attracted to the latter, where tree densities are too low and sizes are too small to provide suitable habitat, but they are attracted to the former before the trees are unexpectedly removed (Hutto, 2008). Similarly, the disproportionate use of recently logged, unburned, old-growth forests in Canada (Tremblay et al., 2009) suggests that black-backed woodpeckers sometimes make the best of a marginal situation, not that they "prefer" recently logged forests.

p0215 Although the ecological responses of birds to postfire salvage logging may differ among globally different ecosystems (Rost et al., 2012), there is absolutely no ecological justification for this kind of logging in the mixed-conifer forests of the western United States, nor is there an economic justification to salvage log after fire, because there are always better places to harvest timber without anywhere near the negative ecological consequences associated with postfire salvage logging. This is a matter of setting priorities for timber harvest, and burned forests should be at the bottom of the list. Burned forests not only provide unique ecological value, they also set the stage for the development of a variety of future forest conditions—conditions that are much more varied than those associated with development after artificial disturbance from logging. Forests have their own rules and timetables associated with the natural process of ecological succession, and we should embrace that variety and complexity. What could be done differently? Postfire rehabilitation should focus on roads, culverts, and other infrastructure issues, and nothing else. We need to recognize that new forest conditions get created after fire, and a disturbance-dependent forest does not need to be "fixed" after disturbance takes place.

s0085 *We Can Do more Harm Than Good Trying to "Mimic" Nature*

p0220 Prescribed burning, forest thinning, and the use of other forms of artificial disturbance in an effort to mimic nature are often poor substitutes for natural disturbance processes. Prescribed burning is usually done out of season, too frequently, and in a manner that is far too mild to have the necessary effects in most systems that evolved with fire (England, 1995; Tucker and

Robinson, 2003; Penman and Towerton, 2008; Peters and Sala, 2008; Arkle and Pilliod, 2010; Rota et al., 2014a). Thinning forests in a manner thought to mimic disturbance effects is also likely to be problematic because natural disturbance (the process of fire itself) produces effects that cannot be emulated through artificial means (Schieck and Song, 2006; Reidy et al., 2014). Moreover, a thinned forest that subsequently burns in a natural fire event will not be suitable as postfire habitat for early postfire specialists because of the reduction in tree densities and sizes (Hutto, 2008). Finally, the use of forest thinning in the name of forest restoration is inappropriately applied to relatively mesic mixed-conifer forests that are unlikely to be in need of restoration, as indicated by a lack of posttreatment change in bird communities toward what one would expect if the forests were actually outside the historical range of natural variation (Hutto et al., 2014).

p0225 Except in the case of an endangered species, the worst management approach is one that focuses narrowly on creating *artificial* conditions needed by a single species. This is "single-species management," which is not the same thing as using a "management indicator approach." Management indicators are not meant to be tools that enable land managers to artificially modify land conditions to benefit a single species. Instead, a management indicator species should be used as an indication of a particular kind of "natural" condition that needs to be maintained on the landscape and as a check that the land condition is indeed acceptable to a species that requires such conditions [illegible] for an endangered species, we should always be thinking about maintaining the "natural" conditions that historically maintained its population. Thus, although artificial tree plantations may provide conditions used by Kirtland's warbler (Spaulding and Rothstein, 2009), the bird historically nested beneath the canopy of young trees born of fire. Therefore we should create conditions safe enough to allow natural severe fire events to unfold throughout most of its historical range. As clearly stated in the Endangered Species Act (ESA, Section 2), "the purposes of this act are to provide a means whereby the *ecosystems upon which endangered species and threatened species depend* may be conserved . . ." (our italics). Conservation should be about the larger system (e.g., maintaining a fire disturbance-based jack pine forest system), not about ~~a~~ finding a way to maintain a species through artificial means. Thus the black-backed woodpecker is an "indicator" or "focal species" that should be used to inform us about a critically important "natural" disturbance process and vegetation condition we need to maintain—severely burned forests and all the associated organisms that thrive within them.

p0230 What could we be doing differently? We need to trust that disturbance-dependent systems need severe disturbance (yes, that means a lot of tree death) to stimulate ecological succession in a manner that is indeed natural. We also need to appreciate that modeled *means and standard deviations* associated with measures of forest structure are not the same things as historical *ranges of variation* associated with the same measures. While some places have tree densities that exceed some estimated historical average value, it does not mean they fall outside the historical range of natural variation. Land managers need to relax in response to severe fire. As long as we can reduce the frequency of human-caused fires and remain safe during naturally ignited fire events, a management option that lets nature take its course will work just fine (Gill, 2001; Bradstock, 2008). In this context, noting that safety is best achieved through mechanical treatments in small areas immediately adjacent to structures (Cohen, 2000; Cohen and Stratton, 2008; Winter et al., 2009; Stockmann et al., 2010; Gibbons et al., 2012; Syphard et al., 2014), and not through mechanical treatments in more remote wildlands, is important. Given this fact, why treatments in relatively remote, publicly owned wildlands have become the tactic most commonly used to reduce wildfire risk is puzzling (Schoennagel et al., 2009).

s0090 *Concluding Remarks*

p0235 The most important ecological lessons we can take away from the bird research described in this chapter are that (1) many species have evolved to the point where they now require severe fire to create the conditions they need, and (2) even though some ecological systems may have departed significantly from what are believed to be historical conditions (e.g., tree plantations in the Pacific Northwest), birds are telling us (through their behavior and distribution patterns) that the vast majority of fire-dependent ecosystems are still well within the historical range of natural variation, are plenty "resilient," and are fully capable of proceeding quite naturally through the process of succession following a severe-fire event. Therefore, thinning forests in the name of restoration is largely unnecessary. If this were not true, the world would be full of places that experienced a severe fire disturbance and then underwent an unnatural transformation or "type conversion" following the disturbance event, never to return to what was there before disturbance. It is most telling that those kinds of places are rare indeed.

p0240 For those who would like to read, view, or hear more about the relationship between birds and severe fire, there are excellent children's books (e.g., Peluso, 2007; Collard, 2015); several informative videos, including a field trip that illustrated many of the patterns discussed here (listed in the Preface); and a Fire Ecology Lab Facebook page (https://www.facebook.com/FireEcologyLab) devoted to building an appreciation for the role of severe fire in our forests.

Abstract

Important lessons emerge from studies of birds in ecosystems born of, and maintained by, mixed- to high-severity fire. Specifically, (1) the effect of fire on any one species is context dependent. It depends on the time since the fire, the fire severity, and vegetation type and condition. (2) Bird species respond differently to any given postfire condition and, given an appropriate time since the fire and postfire vegetation conditions, most benefit from severe fire. (3) Some bird species (the black-backed woodpecker being iconic) seem to *depend* on conditions created by severe fire, as evidenced by their distribution patterns, territory sizes, nest success, and other adaptations. (4) Given these facts, current management practices designed to prevent fire, suppress fire, mitigate fire severity, "restore" or "rehabilitate" burned forests after fire, and mimic the effects of severe fire are incompatible with the maintenance of bird populations and, therefore, ecosystem integrity.

Keywords: Adaptation; Bird; Disturbance; Fire severity; Forest restoration; Salvage logging; Severe fire.

CONSERVATION

A global map of roadless areas and their conservation status

Pierre L. Ibisch,[1,2]* Monika T. Hoffmann,[1] Stefan Kreft,[1,2] Guy Pe'er,[2,3,4] Vassiliki Kati,[2,5] Lisa Biber-Freudenberger,[1,6] Dominick A. DellaSala,[7,8] Mariana M. Vale,[9,10] Peter R. Hobson,[1,2,11] Nuria Selva[12]*

Roads fragment landscapes and trigger human colonization and degradation of ecosystems, to the detriment of biodiversity and ecosystem functions. The planet's remaining large and ecologically important tracts of roadless areas sustain key refugia for biodiversity and provide globally relevant ecosystem services. Applying a 1-kilometer buffer to all roads, we present a global map of roadless areas and an assessment of their status, quality, and extent of coverage by protected areas. About 80% of Earth's terrestrial surface remains roadless, but this area is fragmented into ~600,000 patches, more than half of which are <1 square kilometer and only 7% of which are larger than 100 square kilometers. Global protection of ecologically valuable roadless areas is inadequate. International recognition and protection of roadless areas is urgently needed to halt their continued loss.

The impact of roads on the surrounding landscape extends far beyond the roads themselves. Direct and indirect environmental impacts include deforestation and fragmentation, chemical pollution, noise disturbance, increased wildlife mortality due to car collisions, changes in population gene flow, and facilitation of biological invasions (*1–4*). In addition, roads facilitate "contagious development," in that they provide access to previously remote areas, thus opening them up for more roads, land-use changes, associated resource extraction, and human-caused disturbances of biodiversity (*3*, *4*). With the length of roads projected to increase by >60% globally from 2010 to 2050 (*5*), there is an urgent need for the development of a comprehensive global strategy for road development if continued biodiversity loss is to be abated (*6*). To help mitigate the detrimental effects of roads, their construction should be concentrated as much as possible in areas of relatively low "environmental values" (*7*). Likewise, prioritizing the protection of remaining roadless areas that are regarded as important for biodiversity and ecosystem functionality requires an assessment of their extent, distribution, and ecological quality.

Such global assessments have been constrained by deficient spatial data on global road networks. Importantly, recent publicly available and rapidly improving data sets have been generated by crowd-sourcing and citizen science. We demonstrate their potential through OpenStreetMap, a project with an open-access, grassroots approach to mapping and updating free global geographic data, with a focus on roads. The available global road data sets, OpenStreetMap and gROADS, vary in length, location, and type of roads; the former is the data set with the largest length of roads (36 million km in 2013) that is not restricted to specific road types (table S1). OpenStreetMap is more complete than gROADS, which has been used for other global assessments (*7*), but in certain regions, it contains fewer roads than subglobal or local road data sets [see the example of Center for International Forestry Research data for Sabah, Malaysia (*8*); table S1]. Given the pace of road construction and data limitations, our results overestimate the actual extent of global roadless areas.

The spatial extent of road impacts is specific to the impact in question and to each particular road and its traffic volume, as well as to taxa, habitat, landscape, and terrain features. Moreover, for a given road impact, its area of ecological influence is asymmetrical along the road and can vary among seasons, between night and day, according to weather conditions, and over longer time periods. We conducted a comprehensive literature review of 282 publications dealing with "road-effects zones" or including the distance to roads as a covariate, of which 58 assessed the spatial influence of the road (table S2). All investigated road impacts were documented within a distance of

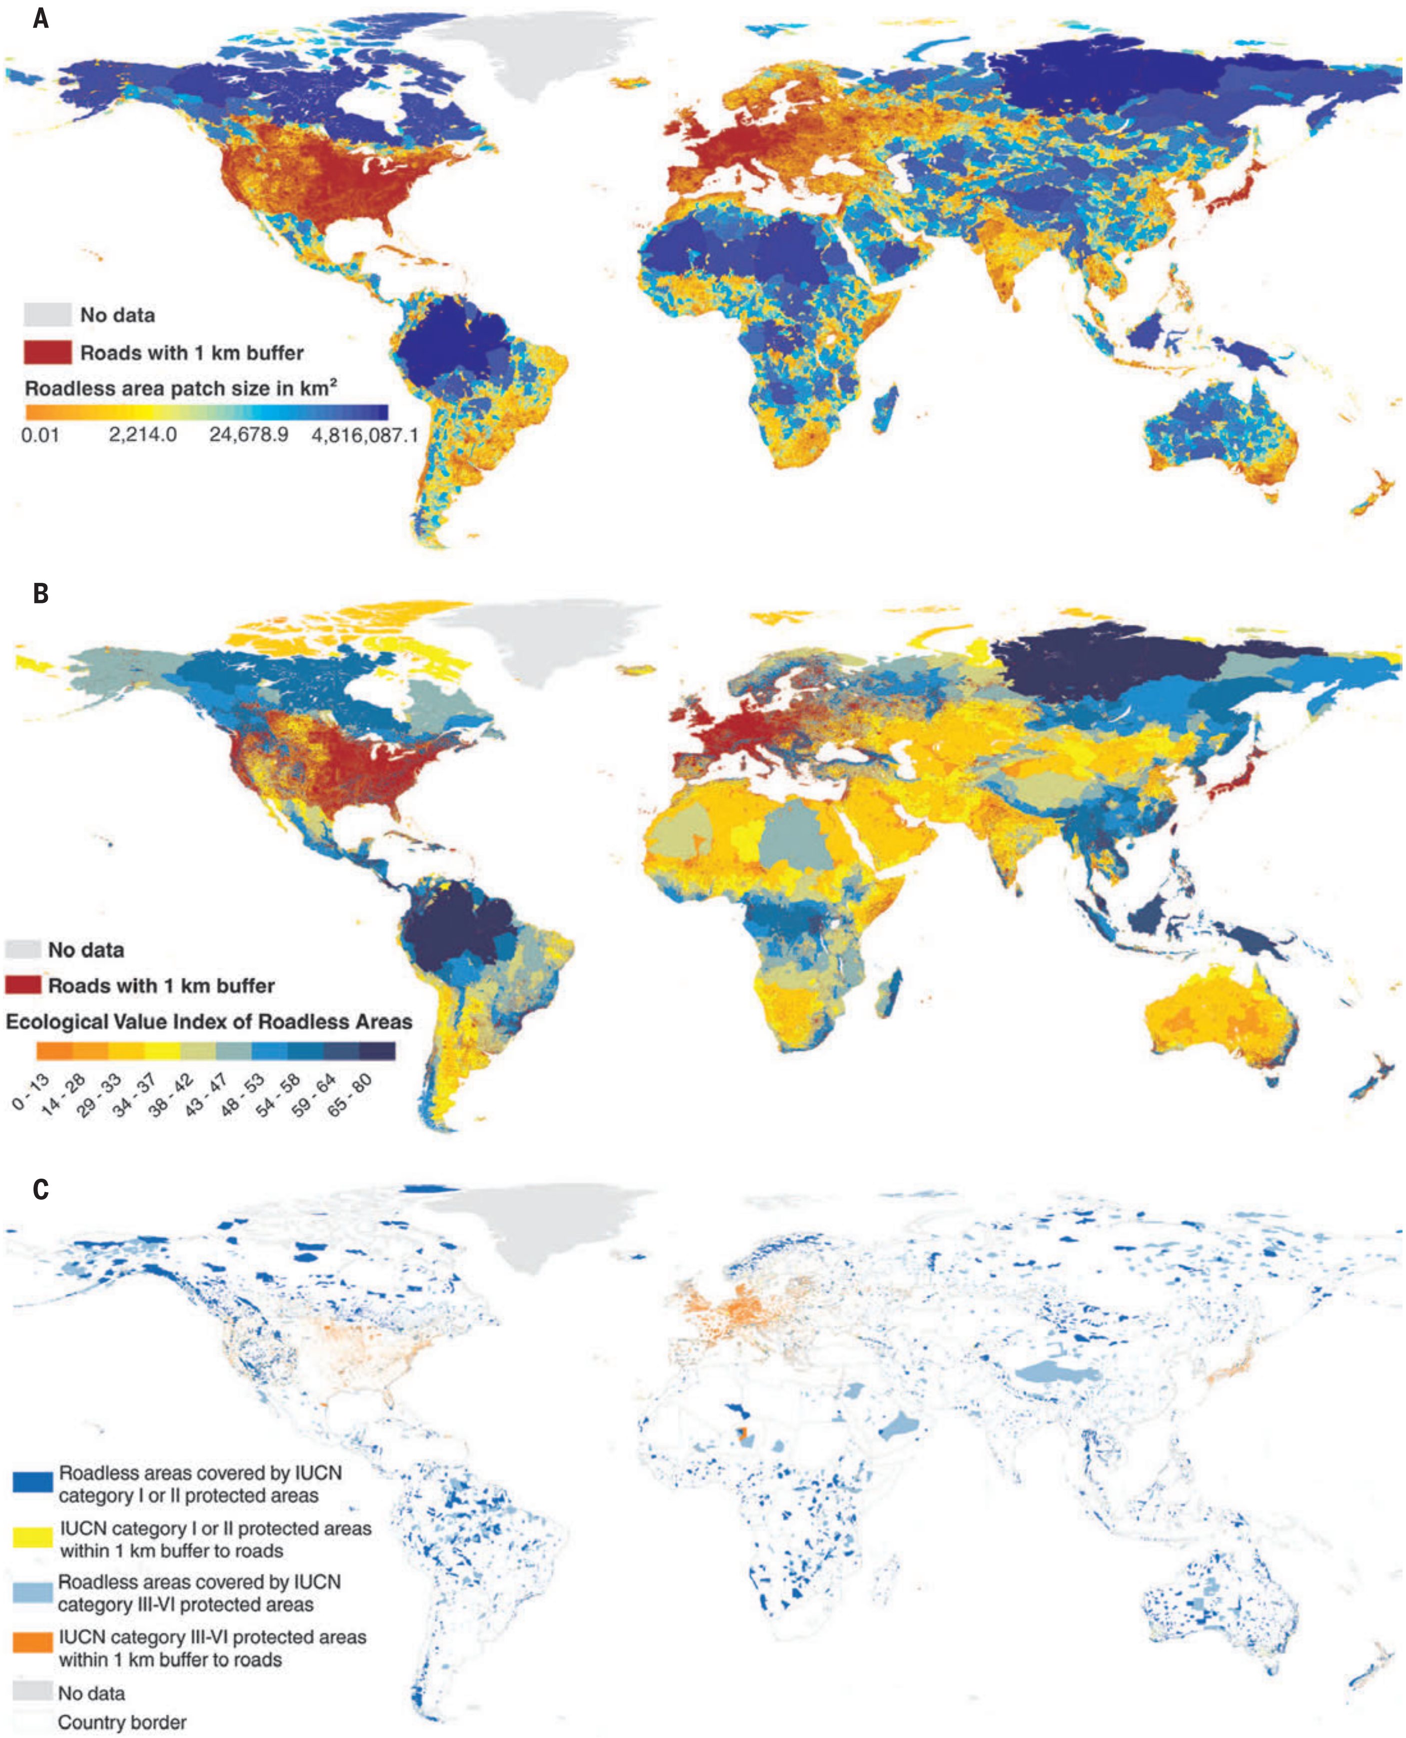

Fig. 1. The global distribution of roadless areas, based on a 1-km buffer around all roads. The distribution is depicted according to (**A**) size classes, (**B**) the ecological value index of roadless areas (EVIRA; based on patch size, connectivity, and ecosystem functionality), and (**C**) representation in protected areas (*8*).

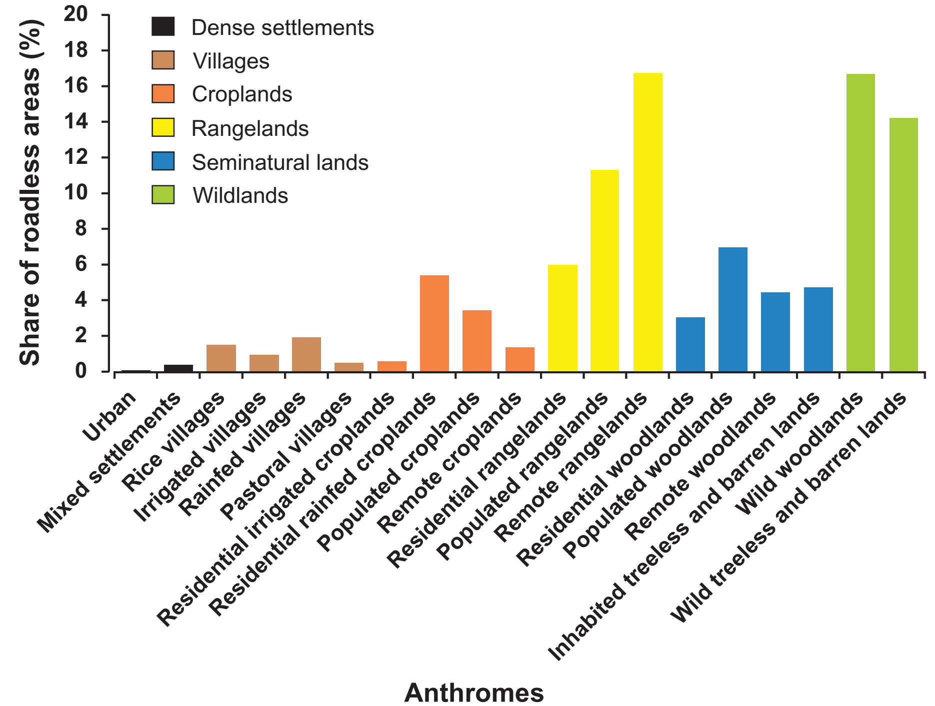

Fig. 2. Extent of roadless areas (1-km buffer) across anthromes. The majority of the world's roadless areas are in remote and unmodified landscapes, but they also occur in anthropogenically modified landscapes. The so-called anthromes were mapped according to (*10*).

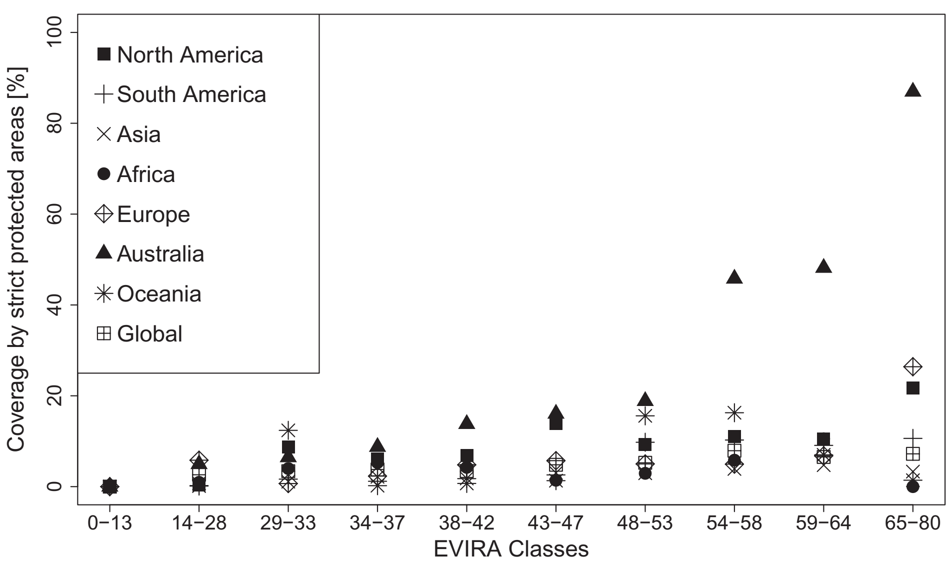

Fig. 3. Coverage of roadless areas by strictly protected areas (IUCN categories I and II) compared with global and continental EVIRA values. If priority were given to protecting roadless areas with high ecological functionality, we should see a positive correlation, with higher coverage associated with higher EVIRA values.

1 km from the road, 39% reached out to 2 km from the road, and only 14% extended out to 5 km from the road (fig. S1). Because the 1-km buffer along each side of the road represents the zone with the highest level and variety of road impacts, we defined roadless areas as those land units that are at least 1 km away from all roads and, therefore, less influenced by road effects. We compared results from using this criterion with the outcomes from using an alternative 5-km buffer (see fig. S2 and table S3). We excluded all large water bodies, as well as Greenland and Antarctica, which are mostly covered by ice, from the analyses.

Roadless areas with a 1-km buffer to the nearest road cover about 80% of Earth's terrestrial surface (~105 million km^2). However, these roadless areas are dissected into almost 600,000 patches. More than half of the patches are <1 km^2; 80% are <5 km^2; and only 7% are >100 km^2 (table S4 and fig. S3). If the buffer is extended to 5 km, there is a substantial reduction in roadless areas to about 57% of the world's terrestrial surface (~75 million km^2), dissected into 50,000 patches (fig. S2 and table S3). The occurrence, distribution, and size of roadless areas differ considerably among continents (Fig. 1A and fig. S4). For instance, the mean size of roadless patches (1-km buffer) is 48 km^2 in Europe, compared with >500 km^2 in Africa. Because of comparatively large gaps in available spatial data on roads in many segments of the tropics, the number and size of roadless areas are overestimated and should be treated with caution (e.g., Borneo; table S1).

All identified roadless areas were assessed for a set of ecological properties that were selected to reflect their relative importance to biodiversity, ecological functions, and ecosystem resilience: patch size, connectivity, and ecosystem functionality (*9*) (table S5). We normalized these three indicators to between 0 and 100 to calculate an additive and unitless index of the ecological value of each roadless area identified (termed the ecological value index of roadless areas, or EVIRA) [Fig. 1B and fig. S5; the specific rationale and technicalities of the chosen indicators are described in table S5 (*8*)]. The EVIRA values range from 0 to 80. A sensitivity analysis shows that ecosystem functionality and patch size are the best single indicators for the final index values (table S6 and figs. S6 to S8). Areas with relatively high index values tend to have a lower coefficient of variation (fig. S9).

We used the International Union for Conservation of Nature (IUCN) and UN Environment Programme–World Conservation Monitoring Centre data set of global protected areas to determine the extent of roadless areas that are protected (*8*) (Fig. 1C). The roadless areas distribution across human-dominated landscapes was determined following the classification of so-called anthromes, defined as biomes shaped by human land use and infrastructure (*10*) (Fig. 2 and table S7).

When examining the density of roads within different biomes, large discrepancies in distribution are apparent. The tundra and rock and ice-covered biomes are nearly entirely roadless, whereas temperate broadleaf and mixed forests have the lowest share of roadless areas (41%; figs. S9 and S10). Boreal forests of North America and Eurasia still retain large tracts of roadless areas (figs. S10 and S11). In the tropics, large roadless landscapes (>1000 km^2) remain in Africa, South America, and Southeast Asia, with the Amazon having the single largest roadless segment. In relation to the anthromes (*10*), about two-thirds of the world's roadless areas can be described as remote and unmodified landscapes [26% uninhabited or sparsely inhabited treeless and barren lands; 21% natural and remote seminatural woodlands, with 17% wild woodlands therein (*8*); Fig. 2 and table S7]. The remaining one-third consists of rangelands, indicating that roadless areas can also occur in anthropogenically modified landscapes.

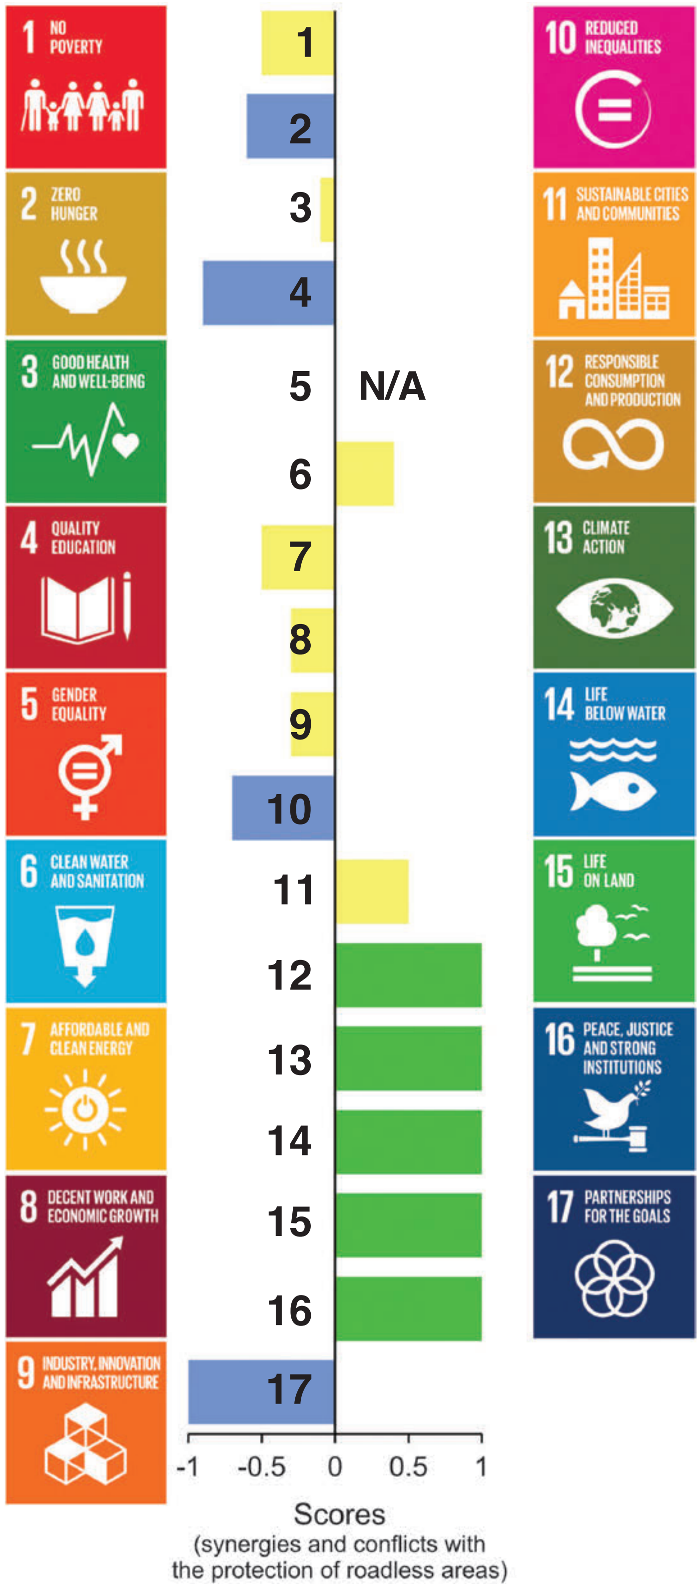

Fig. 4. Synergies and conflicts between conservation of roadless areas and the United Nations' Sustainable Development Goals. Scores <–0.5 (blue bars) indicate that conflicts with the goal prevail; scores between –0.5 and 0.5 (yellow) indicate a mixture of synergies and conflicts with the goal; and scores >0.5 (green) indicate prevailing synergies with the goal [for details, see table S11 (*8*)]. The scores reflect substantial imminent conflicts between various Sustainable Development Goals and conservation of roadless areas (table S11).

About one-third of the world's roadless areas have low EVIRA values. Patches with relatively low EVIRA values (ranging from 0 to 37; namely, <50% of the maximum value) account for 35% of the overall roadless area distribution, because most are small, fragmented, isolated, or otherwise heavily disturbed by humans. Some large tracts of roadless areas, such as arid lands in northern Africa or central Asia, occur in areas of sparse vegetation and low biodiversity and, thus, have low index values for ecosystem functionality (*9*) (Fig. 1B). High EVIRA values occur both in tropical and boreal forests. The relative conservation value of roadless areas is context-dependent. Comparatively small or moderately disturbed roadless areas have higher conservation importance in heavily roaded environments, such as most of Europe, the conterminous United States, and southern Canada.

Although the world's protected areas cover 14.2% of the terrestrial surface, only 9.3% of the overall expanse of roadless areas is within protected areas (all IUCN categories; Fig. 1C and table S8). There is no major difference in the coverage of roadless areas by strictly protected areas (IUCN categories I and II) versus the coverage of the overall landscape by strictly protected areas (3.8% roadless versus 4.2% overall). Only in North America, Australia, and Oceania are more than 6% of roadless areas under strict protection (table S8). If conservation efforts were to prioritize functional, ecologically important roadless areas, we would find a positive relation between strict protection coverage and EVIRA values of roadless areas. However, with the exception of Australia, this is not the case (Fig. 3 and table S9). Asia and Africa have particularly low protection coverage for roadless areas with high EVIRA values. For instance, we found gaps in the Asian tropical southeast, as well as in boreal biomes.

The recent Global Biodiversity Outlook (*11*) gives a bleak account of the progress made toward reaching the United Nations' biodiversity agenda as specified in the 20 Aichi Targets of the Convention on Biological Diversity (*12*). Governments have failed on several accounts to keep their use of natural resources well within safe ecological limits (target 4); to halt or at least halve the rate of habitat loss and substantially reduce the degradation and fragmentation of natural habitats (target 5); and to appropriately protect areas of particular importance for biodiversity and ecosystem services (target 11). To achieve global biodiversity targets, policies must explicitly acknowledge the factors underlying prior failures (*13*). Despite increasing scientific evidence for the negative impacts of roads on ecosystems, the current global conservation policy framework has largely ignored road impacts and road expansion. Furthermore, key policies on road infrastructure and development, such as the Cohesion Policy of the European Union, fail to take into account biodiversity.

In the much wider context of the United Nations' Sustainable Development Goals, conflicting interests can be seen between goals intended to safeguard biodiversity and those promoting economic development (*14*). We analyzed how roadless areas relate to the global conservation and sustainability agendas. As a transparent synthesis, we calculated simple scores of conflicts versus synergies of Sustainable Development Goals and Aichi Targets with the conservation of roadless areas (tables S10 and S11). Roads are explicitly mentioned in the Sustainable Development Goals only for their contribution to economic growth (goal 8), promoting further expansion into remote rural areas, and consideration is given neither to the environmental nor the social costs of road development. The resulting scores reflect substantial imminent conflicts (Fig. 4 and table S10); only in five Sustainable Development Goals do synergies with conservation of roadless

areas prevail, and four Sustainable Development Goals are predominantly in conflict with conservation of roadless areas. Maybe even more surprisingly, several of the Aichi Targets are ambivalent with respect to conserving roadless areas, rather than being in synergy entirely [six conflicting versus 11 synergistic targets (*8*); table S11].

There is an urgent need for a global strategy for the effective conservation, restoration, and monitoring of roadless areas and the ecosystems that they encompass. Governments should be encouraged to incorporate the protection of extensive roadless areas into relevant policies and other legal mechanisms, reexamine where road development conflicts with the protection of roadless areas, and avoid unnecessary and ecologically disastrous roads entirely. In addition, governments should consider road closure where doing so can promote the restoration of wildlife habitats and ecosystem functionality (*4*). Our global map of roadless areas represents a first step in this direction. During planning and evaluation of road projects, financial institutions, transport agencies, environmental nongovernmental organizations, and the engaged public should consider the identified roadless areas.

The conservation of roadless areas can be a key element in accomplishing the United Nations' Sustainable Development Goals. The extent and protection status of valuable roadless areas can serve as effective indicators to address several Sustainable Development Goals, particularly goal 15 ("Protect, restore and promote sustainable use of terrestrial ecosystems, sustainably manage forests, combat desertification, and halt and reverse land degradation and halt biodiversity loss") and goal 9 ("Build resilient infrastructure, promote inclusive and sustainable industrialization and foster innovation"). Enshrined in the protection of roadless areas should be the objective to seek and develop alternative socioeconomic models that do not rely so heavily on road infrastructure. Similarly, governments should consider how roadless areas can support the Aichi Targets (see tables S10 and S11). For instance, the target of expanding protected areas to cover 17% of the world's terrestrial surface could include a representative proportion of roadless areas.

Although we acknowledge that access to transportation is a fundamental element of human well-being, impacts of road infrastructure require a fully integrated environmental and social cost-benefits approach (*15*). Still, under current conditions and policies, limiting road expansion into roadless areas may prove to be the most cost-effective and straightforward way of achieving strategically important global biodiversity and sustainability goals.

PLANT PATHOLOGY

Regulation of sugar transporter activity for antibacterial defense in *Arabidopsis*

Kohji Yamada,[1,2]* Yusuke Saijo,[3,4] Hirofumi Nakagami,[5]† Yoshitaka Takano[1]*

Microbial pathogens strategically acquire metabolites from their hosts during infection. Here we show that the host can intervene to prevent such metabolite loss to pathogens. Phosphorylation-dependent regulation of sugar transport protein 13 (STP13) is required for antibacterial defense in the plant *Arabidopsis thaliana*. STP13 physically associates with the flagellin receptor flagellin-sensitive 2 (FLS2) and its co-receptor BRASSINOSTEROID INSENSITIVE 1–associated receptor kinase 1 (BAK1). BAK1 phosphorylates STP13 at threonine 485, which enhances its monosaccharide uptake activity to compete with bacteria for extracellular sugars. Limiting the availability of extracellular sugar deprives bacteria of an energy source and restricts virulence factor delivery. Our results reveal that control of sugar uptake, managed by regulation of a host sugar transporter, is a defense strategy deployed against microbial infection. Competition for sugar thus shapes host-pathogen interactions.

Plants assimilate carbon into sugar by photosynthesis, and a broad spectrum of plant-interacting microbes exploit these host sugars (*1*, *2*). In *Arabidopsis*, pathogenic bacterial infection causes the leakage of sugars to the extracellular spaces (the apoplast) (*3*), a major site of colonization by plant-infecting bacteria. Although leakage may be a consequence of membrane disintegration during pathogen infection, some bacterial pathogens promote sugar efflux to the apoplast by manipulating host plant sugar transporters (*4*, *5*). Interference with sugar absorption by bacterial and fungal pathogens reduces their virulence, highlighting a general

Editor's Summary

Too many roads

Roads have done much to help humanity spread across the planet and maintain global movement and trade. However, roads also damage wild areas and rapidly contribute to habitat degradation and species loss. Ibisch *et al*. cataloged the world's roads. Though most of the world is not covered by roads, it is fragmented by them, with only 7% of land patches created by roads being greater than 100 km^2. Furthermore, environmental protection of roadless areas is insufficient, which could lead to further degradation of the world's remaining wildernesses.

Abstract. We use the historical presence of high-severity fire patches in mixed-conifer forests of the western United States to make several points that we hope will encourage development of a more ecologically informed view of severe wildland fire effects. First, many plant and animal species use, and have sometimes evolved to depend on, severely burned forest conditions for their persistence. Second, evidence from fire history studies also suggests that a complex mosaic of severely burned conifer patches was common historically in the West. Third, to maintain ecological integrity in forests born of mixed-severity fire, land managers will have to accept some severe fire and maintain the integrity of its aftermath. Lastly, public education messages surrounding fire could be modified so that people better understand and support management designed to maintain ecologically appropriate sizes and distributions of severe fire and the complex early-seral forest conditions it creates.

Key words: early succession; ecological integrity; ecological system; fire management; fire regime; forest resilience; forest restoration; severe fire; wildfire.

Introduction

The spatiotemporal expression of fire events over time in any landscape produces a "fire regime" that influences ecosystem dynamics in that area (Heinselman 1981, Kilgore 1981). Even though the various characteristics of a fire regime (Table 1) are continuous in nature, the traditional approach in representing this variation has been to create a small number of discontinuous categories. Fire regimes in western North America, for example, are often classified into as few as three categories: (1) low-severity, (2) mixed-severity, and (3) high-severity or stand-replacement (Agee 1998, Brown 2000). Our attempt to categorize fire regimes is ". . . an oversimplification…for the convenience of humans" (Sugihara et al. 2006; p. 62), and has had the unfortunate consequence of minimizing rather than emphasizing variation in fire behavior and fire outcomes among vegetation types and across spatial scales (Morgan et al. 2014). In reality, relatively few forest types fit entirely within either of the two extremes—the low-severity (e.g., some interior ponderosa pine) or the stand-replacement (e.g., Rocky Mountain lodgepole pine) categories. Instead, as a simple analysis

Table 1. Characteristics or descriptors often used to describe disturbance regimes (from Keane 2013).

Disturbance Characteristic	Description	Example
Agent	Factor causing the disturbance	Fire is an agent that can kill trees
Source, Cause	Origin of the agent	Lightning is a source for wildland fire
Frequency	How often the disturbance occurs or its return time	Years since last fire (scale dependent)
Intensity	A description of the magnitude of the disturbance agent	Wildland fire heat output
Severity	The level of impact of the disturbance on the environment	Fuel consumption in wildland fires; change in biomass
Size	Spatial extent of the disturbance	Tree kill can occur in small patches or across entire landscapes
Pattern	Patch size distribution of disturbance effects; spatial heterogeneity of disturbance effects	Fire can burn large regions but weather and fuels can influence fire intensity and therefore the patchwork of tree mortality
Seasonality	Time of year of that disturbance occurs	Spring burn vs. fall burn
Duration	Length of time of that disturbances occur	Fires can burn for a day or for an entire summer
Interactions	Disturbance types may interact with each other, or with climate, vegetation and other landscape characteristics	Mountain pine beetles may create fuel complexes that facilitate or exclude wildland fire
Variability	The spatial and temporal variability of the above factors	Each of the above characteristics has variation associated with it

using LANDFIRE data (Rollins 2009, <http://www.landfire.gov>) reveals, roughly 85% of all forested lands within the western US fit within the mixed-severity category, which includes proportions of low-, moderate-, and high-severity (lethal to more than 70% of all trees) fire that vary widely across vegetation types and biophysical settings.

Agee (1993) captured the essence of this important idea in a graph depicting the proportion of low-, moderate-, and high-severity fire across the range of fire regimes (Fig. 1). Note that change from one fire regime to the next (movement along the x-axis) is accompanied not by the sudden appearance of a different fire severity, but by continuous changes in the proportions of each fire severity category. Thus, fire regimes blend imperceptibly into one another. More importantly, except for the two end points on the graph where the proportion of high-severity fire would be either 0% or 100%, most fire regimes consist of a mix of fire severities so, technically speaking, they fit best within a mixed-severity regime (Fig. 2). It is not the presence of a particular fire severity, but the proportion (and, presumably, the distribution and patch sizes) of each severity component that distinguishes regimes. Indeed, empirical

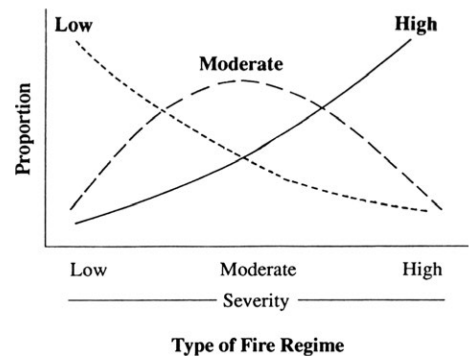

Fig. 1. This graph (from Agee 1993) illustrates that fire regimes are not characterized by the presence of only one kind of fire. Rather, it is the relative frequency of low-, moderate-, and high-severity fire in an average burn that varies among fire regimes.

data drawn from recent fires across the western United States between 1984 and 2008 (Fig. 3) reveal this continuous variation in proportions of different fire severities among fires. Thus, a more continuous view of fire regimes might be a better way to appreciate the infinite variability in fire behavior among forest types and geographic locations, and it might also promote a greater appreciation of severe fire as an integral

Fig. 2. Mixed-severity fires (fires that leave recognizable patches of low-severity, medium-severity, and high-severity effects) typify the majority of mixed-conifer forest systems in the western United States. The brown-needled and blackened areas harbor unique sets of plant and animal species found in no other forest conditions. This photograph of the North Fork of the Blackfoot River was taken 10 months after the 1988 Canyon Creek fire in Montana. Many fire-dependent plant and animal species were present in the more severely burned areas until they were helicopter logged, suggesting that unburned forests might be a better alternative for timber harvest.

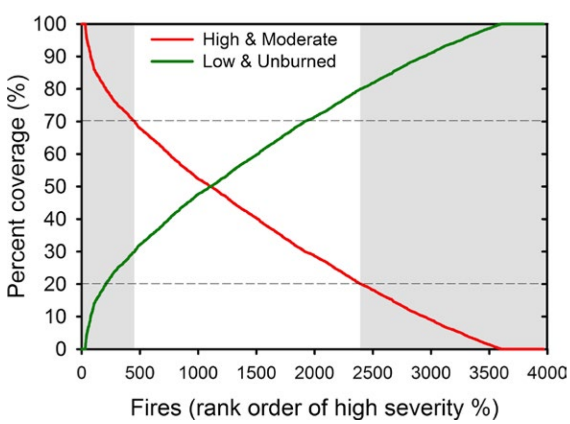

Fig. 3. The percent area within a fire perimeter that burned at low (green line) and at moderate to high (red line) severity is shown for a series of 3696 fires that burned in the western United States between 1984 and 2008 (after Belote 2015). The figure shows that the proportions of each severity category are continuously variable and that high-severity fire is a natural part of most forest fires in the West.

part of mixed- and high-severity conifer forest fire regimes.

Accordingly, we highlight the need for better information on the historical patterns and abundances of high-severity patches in different forest types. This is an important discussion because, even though our National Cohesive Wildland Fire Management Strategy (Wildland Fire Executive Council 2014) acknowledges that many fire regimes exist and that management needs to accommodate that variation and the variety of habitat such variation produces, contemporary fire management is focused heavily on the exclusion (prevention and suppression, collectively) or mitigation of severe fire. When either of those fails, management efforts seem to shift toward speeding the "recovery" of the forest after severe fire. With respect to the latter, there are repeated attempts to introduce legislation designed to expedite logging after fire (salvage logging). Although the removal of dead trees is justified near roads and structures for safety reasons, and although postfire logging can capture economic value of wood that would otherwise be lost, such logging has been shown to carry significant ecological costs (Hutto 2006, Lindenmayer and Noss 2006, Swanson et al. 2011, Lindenmayer and Cunningham 2013, DellaSala et al. 2015). The ecological benefits and necessity of severe fire (and its aftermath) has widespread implications for the flora and fauna that depend on the presence of burned forest conditions. Ecologically sound fire management includes land management designed to ensure the maintenance of ecologically appropriate mixes of fire severities within the forested landscapes of western North America while protecting homes and lives at the same time (Perry et al. 2011). An ecologically informed view of severe fire requires recognition that it is a natural component of many western conifer forests (Heinselman 1981, Arno 2000). Moreover, the severe-fire component must have been large enough and frequent enough to have favored the evolution of specialization by various plant and animal species to conditions that occur in the aftermath of severe fire. We offer the following points in an effort to better recognize and include severe fire as an integral part of fire management in mixed-conifer forest systems:

Severely burned forests create biologically unique conditions that cannot be created by other kinds of disturbances or through artificial means

Patterns in the habitat associations of plant and animal species can provide definitive evidence that severe fire plays an essential role in the ecology of mixed-conifer forests (Hutto et al. 2008). Specifically, if a plant or animal species occurs only in burned forest conditions created by severe fire events, then it cannot be using burned forest conditions merely opportunistically. Instead, the species must have evolved to depend on such conditions because it occurs rarely, if ever, in unburned habitat (Swanson et al. 2011, DellaSala et al. 2014). For example, some moss and lichen species are relatively restricted to severely burned forest conditions (Ahlgren and Ahlgren 1960), as are the fire morel mushroom (*Morchella elata*) and Bicknell's geranium (*Geranium bicknellii*) in forests throughout the West (Heinselman 1981, Pilz et al. 2004). The black-backed woodpecker (*Picoides arcticus*) is emblematic of a species that is relatively restricted to early successional conditions created by high-severity fire (Hutto 1995, Dixon and Saab 2000, Hoyt and Hannon 2002). Black-backed woodpeckers are attracted to postwildfire conditions because of the abundance of larvae of a number of wood-boring beetle species that are attracted to the fire-killed trees (Murphy and Lehnhausen 1998, Rota et al. 2015). Several of these beetle species are themselves relatively restricted to recently burned forests (Saint-Germain et al. 2004*a,b*, Boucher et al. 2012). Importantly, black-backed woodpeckers are significantly more likely to occur in the more severely burned portions of a mixed-severity fire (Hutto 2008, Latif et al. 2013). Although black-backed woodpeckers are known to occur outside severely burned forests on rare occasions, detailed study of survival and reproductive success shows that they exhibit growing populations only in forests recently burned by summer wildfires (Rota et al. 2014). The adaptations of thick bark, branch shedding, and serotiny in *Pinus* are thought to have evolved in response to a period of more intense crown fires in the mid-Cretaceous (He et al. 2012), and those adaptations also reflect the severe-fire backdrop against which pine, Douglas-fir, and larch are thought to thrive.

Many additional animal species, while not as narrowly restricted to burned forest conditions, clearly benefit from the burned forest conditions created by severe fires in mixed-conifer forests throughout the West (Hutto et al. 2015). For example, nest survival of white-headed woodpeckers is significantly higher in burned (wildfire) compared to unburned forest (Hollenbeck et al. 2011, Lorenz et al. 2015). In aquatic systems, severe fire events can rejuvenate stream habitats by causing large amounts of gravel, cobble, woody debris, and nutrients to be imported, resulting in increased production and aquatic insect emergence rates (Benda et al. 2003, Burton 2005, Malison and Baxter 2010, Ryan et al. 2011, Jackson et al. 2015). These changes can, in turn, affect food web dynamics in a way that results in higher growth rates in young trout, including young coastal cutthroat trout (*Oncorhynchus clarkii clarkii*) (Heck 2007) and rainbow trout (*Oncorhynchus mykiss*) (Rosenberger et al. 2011). Indeed, nonnative fish populations declined and native trout densities increased 3 yr after a severe fire in the Bitterroot River watershed, Montana, indicating that severe fire may help ensure ecological integrity of some western streams (Sestrich et al. 2011). In addition, native amphibians such as boreal toads (*Bufo boreas*) thrive in areas that burn severely (Dunham et al. 2007, Hossack and Corn 2007) and use severely burned areas more than expected due to chance (Hossack and Corn 2007, Guscio et al. 2008), as do some bat species (Buchalski et al. 2013).

These strong associations between organisms and severely burned forest patches suggests that many plant and animal species have evolved to rely on recurring severe wildfire events, and further indicates that severe fire events are a natural and important part of the fire regimes associated with many western mixed-conifer forest types. In other words, if one or more species occupy severely burned forests to the exclusion of other forest types (and if they do not tend to occupy forests disturbed through artificial means), then a severely burned forest would have to be considered natural, and would necessarily lie within the historical range of variation (Hutto et al. 2008). Moreover, a more intimate understanding of the biology of those plants and animals (e.g., knowledge of dispersal processes and patterns, foraging ecology, home-range sizes) can provide insight into the historical spatial scales at which severe fire operated across the broader landscape.

Fire history studies suggest that severe fire is an integral component of most fire regimes

In addition to the definitive evidence provided above, a growing body of fire history information points to the same conclusion—severe fire was historically, and is currently, an important component of many western conifer forest systems. At one end of the fire regime spectrum, conifer forests in the warmer, drier geographic areas in western North America are commonly characterized by frequent, low-severity fires that killed primarily juvenile trees historically, resulting in the maintenance of open pine forests with low densities of mature trees (Covington and Moore 1994*a,b*). Nevertheless, mixed and stand-replacement fires were possible even in these forest types after long inter-fire intervals, such as after an especially cold, wet period similar to what occurred during the Little Ice Age (Brown et al. 1999, Sherriff and Veblen 2007, Williams and Baker 2012, Odion et al. 2014, Hanson et al. 2015). At the other end of the fire regime spectrum, cooler, moister forest types, such as lodgepole pine forests, support fire regimes dominated by severe fire events (Brown and Smith 2000), although mixed- and low-severity fires are known to occur in these types as well (Barrett et al. 1991).

Between these two extremes lie the vast majority of mixed-conifer forest types in western North America. These include everything from the xeric, low-elevation, mixed ponderosa pine and Douglas-fir forest types to mesic, high-elevation, spruce-fir forest types. Unlike the forest types that are dominated by either the absence or presence of severe fire, mixed-conifer forests are best characterized by fire regimes of variable, or mixed severity (see Baker 2009: fig. 7.1), which means that the presence of sizable proportions of the three classes of fire severity characterize the fires that burn in those forest systems (Sherriff and Veblen 2006, 2007, Baker et al. 2007, Hessburg et al. 2007, Klenner et al. 2008, Perry et al. 2011, Schoennagel et al. 2011). Importantly, extreme weather (e.g., high temperature, low humidity, high wind speed) rather than quantity of woody fuels often exerts the greatest influence on fire severity and extent across that broad range of mixed-conifer forest types (Johnson et al. 2003, Schoennagel et al. 2004, Lydersen et al. 2014, Williams et al. 2015). This means that, in contrast with the situation in low-elevation or xeric-type ponderosa pine forests in some areas of the southwestern United States (Keane et al. 2008), the amount of high-severity fire in other mixed-conifer forest types is less likely to have departed significantly from historical ranges of variability, even though those forests may have experienced measurable twentieth century changes in fuels due to fire exclusion, timber harvest, and cattle grazing (e.g., Baker et al. 2007, Dillon et al. 2011, Marlon et al. 2012, Miller et al. 2012, Odion et al. 2014, Sherriff et al. 2014). We recognize the lack of relevant historical information on landscape-level distributions and spatial scales of different classes of fire severity for many forest types and regions, but severely burned forest patches have probably always occurred naturally, even in pure ponderosa pine forests of the Southwest, as Cooper (1961) and Weaver (1943) described long ago. We also know that, at least throughout the northern half of the western United States, the extent of severe-fire patches must have been both substantial enough in area and frequent enough to support those plant (e.g., lodgepole pine) and animal (e.g., wood-boring beetle and woodpecker) species that evolved to depend on severe fire itself or on the resulting severely burned forest conditions.

Maintaining ecological integrity means accommodating a broad spectrum of fire severities, including severe fire and its aftermath, in most mixed-conifer forests

We have now established two important facts: severe fire (moderate-to-high burn severity) is a natural agent of disturbance in many mixed-conifer forest types, and such fire is thought to be ecologically necessary for the presence or success of many plant and animal species. These two facts make it clear that management to maintain the ecological integrity of any ecosystem that harbors species that depend on severe fire as a disturbance agent will have to integrate severe fire and its effects into management goals. Moreover, if we better considered distribution patterns, home range sizes, movement patterns, and other animal adaptations that reflect the environment within which they evolved (e.g., Hutto et al. 2008), we could gain considerable insight into historical spatial scales under which severe fire operated as well. We are not questioning or attempting to discredit the evidence that some forest systems were historically dominated by low-severity fire; rather, we are encouraging land managers to also pay close attention to maintaining amounts and distributions of higher severity fire consistent with ecological integrity in our western mixed-conifer forests. The current science, management, and policy challenge for ecosystem managers is to estimate and incorporate amounts of low-, moderate-, and high-severity fire in a manner that maintains ecological integrity (Hessburg et al. 2007, Perry et al. 2011, Baker 2015).

While many fire ecologists understand the importance of more severe fire in forest ecosystems, politicians and the public at large have yet to reach the same understanding. Recent increases in the amount of forested area burned by wildfire over the past three decades in western North American forests (Westerling et al. 2006, Dennison et al. 2014) signaling what many believe to be the emergence of a new age of megafires (Attiwill and Binkley 2013), has created increased movement toward pre and postfire land management activities designed to reduce fire severity, mimic fire effects without the use of fire, or speed the recovery of a forest after fire. These activities may provide some societal benefits, but they can have real costs in terms of the way they negatively affect the ecological integrity of mixed-conifer forests born of mixed-severity fire. Removed from locations that pose a clear and immediate threat to human lives and property, the ecological costs associated with forest thinning may outweigh stated benefits by large margins. We highlight two types of land management (beyond fire suppression itself) that can have significant negative effects on fire-dependent species and, therefore, can interfere with our ability to maintain the ecological integrity of fire-dependent conifer forests: prefire fuel treatments and postfire salvage logging.

Prefire harvest treatments

We know a great deal about the effects of fuel treatments and restoration harvests on forest structure and vegetation recovery, but we know little about the ecological effects of such treatments on the prefire responses of most plant and animal species, and virtually nothing about postfire responses of the most fire-dependent plant and animal species after a treatment subsequently burns in a wildfire. This is because such treatments are rarely accompanied by "ecological effects monitoring," which, in contrast with implementation monitoring (evaluating whether a management activity was implemented) and effectiveness monitoring (evaluating whether the management activity achieved the stated goal), is specifically designed to address whether there are unforeseen negative ecological consequences of a management treatment (Hutto and Belote 2013).

Fuel treatments designed to restore fire-prone ecosystems should do so in the proper fire regime context; more specifically, they should produce appropriate postfire plant and animal responses when fire returns to the forest. Thus, treatments appropriate for dry forests that were historically maintained by a low-severity fire regime may be inappropriate for forests maintained by a mixed-severity fire regime. One serious negative consequence of canopy fuel reduction in forests that evolved with mixed-severity fire could be that fire-dependent species requiring high densities of large standing-dead trees created by the severe-fire component may not recruit after a subsequent fire. For example, the fire-dependent black-backed woodpecker was found to be even less abundant in mixed-conifer forests that were thinned before fire than in the same forest types logged after fire, even though the two pathways support similar standing dead tree densities. This is probably because birds rarely colonize thinned forests that burn, but they still make the best of a bad situation when trees are removed after they have already colonized a densely stocked, severely burned forest (Hutto 2008). Recent research on postfire soil conditions shows that soil C and N response following wildfire also depends on whether there have been fuel treatments, so the assessment of fuel treatment effects needs to include postfire response and not simply postharvest response (Homann et al. 2015). It has been suggested (e.g., Franklin and Johnson 2014) that variable-retention harvests could be designed to emulate early-seral conditions following natural disturbance events in forests born of mixed-severity fire, thereby avoiding the negative consequences associated with other tree harvesting methods. Unfortunately, that strategy is unlikely to satisfy the needs of those fire-dependent animal species that require high densities of fire-killed trees immediately following severe fire (Schieck and Song 2006, Hutto 2008, Reidy et al. 2014).

Postfire salvage logging

Salvage logging after fire is intended to recover economic value of timber that would otherwise be lost, to ensure human safety, and to reduce the risk of future fires. Unfortunately, salvage harvesting activities undermine the ecosystem benefits associated with fire (Lindenmayer et al. 2004, Lindenmayer and Noss 2006, Swanson et al. 2011). For example, postfire salvage logging removes dead, dying, or weakened trees, but those are precisely the resources that provide nest sites and an abundance of food in the form of beetle larvae and bark surface insects (Hutto and Gallo 2006, Koivula and Schmiegelow 2007, Saab et al. 2007, 2009, Cahall and Hayes 2009). No fire-dependent bird species has ever been shown to benefit from salvage logging (Hutto 2006, Hanson and North 2008). The ecological effects of salvage logging on aquatic ecosystems are also largely negative (Karr et al. 2004). In fact, the demonstrated negative ecological effects associated with postfire salvage logging are probably the most consistent and dramatic of any wildlife management effects ever documented for any kind of forest management activity (Hutto 2006). Therefore, because the National Forest Management Act and other legal mandates require public land managers to maintain the integrity of the larger ecological system, burned forests should perhaps be given special consideration compared with green-tree forests. Specifically, they could receive a low priority ranking when it comes to timber harvest decisions (with the obvious exception of small harvests associated with roads and other areas where safety or infrastructure are legitimate concerns). Timber can be harvested from many green-tree forests in a manner that imposes relatively little ecological cost in comparison with the costs associated with logging in burned forest (Lindenmayer and Cunningham 2013).

How do we move toward a more ecologically informed view of forest fires?

The ecological costs associated with some of the more commonly employed pre and postfire management activities in the western United States probably increase substantially as one moves from the low-elevation or xeric ponderosa pine or woodland forest types, where trees were widely spaced and severe fire historically played a spatially restricted role, to the broad array of more densely stocked mixed-conifer forest types, where severe fire historically played a major role. Therefore, a thorough understanding of the historical fire regime associated with any particular vegetation type or land area (as determined from multiple lines of evidence concerning regionally specific fire history) is critically important for land managers who concern themselves with the issues of wildfire risk, ecological restoration, or maintenance of the diversity of native species (Schoennagel and Nelson 2011). More specifically, quantification of appropriate fire rotations and proportions of low-, moderate-, and high-severity fire for any given forest landscape is critical for enlightened land management. For example, in some xeric ponderosa pine forest types, ecosystem restoration activities designed to decrease the severity of wildfire may be ecologically appropriate. The same management activities are not likely to be ecologically appropriate in many mixed-conifer forests, however, because key indicator species evolved to depend on significant amounts of severe fire in those forest types (Schoennagel et al. 2004, Hutto 2008, Klenner et al. 2008, Baker 2012, 2015, Williams and Baker 2012, Odion et al. 2014).

Land and fire managers are now facing future fires that many hypothesize will become larger and contain larger proportions of more severely burned patches under warming climate conditions (Rocca et al. 2014). Problems associated with climate change, however, must be solved through efforts directed toward the causes of climate change and not toward the symptoms of climate change. Any perceived problem with future changes in fire behavior cannot be solved by redoubling our effort to treat this particular climate change symptom by installing widespread fuel treatments that do nothing to stop the warming trend, and do little to reduce the extent or severity of weather-driven fires (Gedalof et al. 2005). Therefore, fuel management efforts to reduce undesirable effects of wildfires outside the xeric ponderosa pine forest types could be more strategically directed toward creating fire-safe communities (Calkin et al. 2014, Kennedy and Johnson 2014). A management emphasis directed toward altering conditions in and immediately adjacent to human communities is very different from an emphasis directed toward treating massive amounts of fuel on more remote public lands. Fuel treatment efforts more distant from human communities may carry the negative ecological consequences we outlined earlier and do little to stop or mitigate the effects of fires that are increasingly weather driven (Rhodes and Baker 2008, Franklin et al. 2014, Moritz et al. 2014, Odion et al. 2014).

Public land managers face significant challenges balancing the threats posed by severe fire with legal mandates to conserve wildlife habitat for plant and animal species that are positively associated with recently burned forests. Nevertheless, land managers who wish to maintain biodiversity must find a way to embrace a fire-use plan that allows for the presence of all fire severities in places where a historical mixed-severity fire regime creates conditions needed by native species while protecting homes and lives at the same time. This balancing act can be best performed by managing fire along a continuum that spans from aggressive prevention and suppression near designated human settlement areas to active "ecological fire management" (Ingalsbee 2015) in places farther removed from such areas. This could not only save considerable dollars in fire-fighting by restricting such activity to near settlements (Ingalsbee and Raja 2015), but it would serve to retain (in the absence of salvage logging, of course) the ecologically important disturbance process over most of our public land while at the same time reducing the potential for firefighter fatalities (Moritz et al. 2014). Severe fire is not ecologically appropriate everywhere, of course, but the potential ecological costs associated with prefire fuels reduction, fire suppression, and postfire harvest activity in forests born of mixed-severity fire need to considered much more seriously if we want to maintain those species and processes that occur only where dense, mature forests are periodically allowed to burn severely, as they have for millennia.

Another integral part of moving toward an ecologically informed perspective of forest fire involves getting the public, politicians, and policy-makers to better recognize and appreciate the critical role that severe fire plays in many forest systems. This has been difficult, and this difficulty has been exacerbated by public messages about severe fire that are uniformly negative. Progress toward allowing fires to burn is difficult unless the public begins to receive a message that differs markedly from the message that Smokey the Bear is sending them now. Fires in our wildlands are fundamentally natural and beneficial, so we must learn to live in a way that allows naturally occurring fires, including severe fires, to burn while minimizing risk to human property and lives (Calkin et al. 2014). That is a vastly different message from one that says severe fires are fundamentally bad and that we have to do everything in our power to prevent and suppress them, or from one that says severely burned forests are places where we should expedite efforts to capture residual economic value through "salvage" logging. We challenge ecologists and managers to pay greater attention to the degree of variation in fire regimes within mixed-conifer forests and to recognize that prefire thinning and postfire "restoration" activities may not always be compatible with maintenance of the ecological integrity of conifer forests that depend on complex mixed-severity fire disturbance.

Acknowledgments

The ideas presented here emerged from a special session that each of us participated in at the 2014 Large Wildland Fires Conference held in Missoula, MT; all authors participated in writing and re-writing drafts of the manuscript. We thank the organizers for the opportunity to pull these ideas together, and we thank anonymous reviewers for numerous helpful suggestions.

ABSTRACT

The use of fire as a land management tool is well recognized for its ecological benefits in many natural systems. To continue to use fire while complying with air quality regulations, land managers are often tasked with modeling emissions from fire during the planning process. To populate such models, the Landscape Fire and Resource Management Planning Tools (LANDFIRE) program has developed raster layers representing vegetation and fuels throughout the United States; however, there are limited studies available comparing LANDFIRE spatially distributed fuel loading data with measured fuel loading data. This study helps address that knowledge gap by evaluating two LANDFIRE fuel loading raster options—Fuels Characteristic Classification System (LANDFIRE-FCCS) and Fuel Loading Model (LANDFIRE-FLM) layers—with measured fuel loadings for a 20 000 ha mixed

RESUMEN

El uso del fuego como herramienta de manejo de tierras es bien reconocido por sus beneficios ecológicos en varios ecosistemas naturales. Para continuar con el uso del fuego y a su vez cumplir con las regulaciones referidas a la calidad del aire, los gestores de tierras deben frecuentemente cumplir con tareas de modelado de emisiones durante el proceso de planificación de las quemas. Para alimentar tales modelos, el programa denominado *Landscape Fire and Resource Management Planning Tools* (LANDFIRE) ha desarrollado capas raster, que representan vegetación y combustibles a lo largo de todos los EEUU; desde luego, son limitados los estudios disponibles que puedan comparar los datos de carga de combustibles espacialmente distribuidos derivados del LANDFIRE, con datos similares producto de mediciones de carga de combustible en el terreno. Este estudio ayuda a dilucidar este vacío en el conocimiento mediante la evaluación de carga de combustible usando dos opciones del programa LANDFIRE—el *Fuels Characteristic Classification System* (LANDFIRE-FCCS) y el *Fuel Loading Model* (LANDFIRE-FLM) *layers*—

conifer study area in northern Idaho, USA. Fuel loadings are compared, and then placed into two emissions models—the First Order Fire Effects Model (FOFEM) and Consume—for a subsequent comparison of consumption and emissions results. The LANDFIRE-FCCS layer showed 200%* higher duff loadings relative to measured loadings. These led to 23% higher total mean total fuel consumption and emissions when modeled in FOFEM. The LANDFIRE-FLM layer showed lower loadings for total surface fuels relative to measured data, especially in the case of coarse woody debris, which in turn led to 51% lower mean total consumption and emissions when modeled in FOFEM. When the comparison was repeated using Consume model outputs, LANDFIRE-FLM consumption was 59% lower relative to that on the measured plots, with 58% lower modeled emissions. Although both LANDFIRE and measured fuel loadings fell within the ranges observed by other researchers in US mixed conifer ecosystems, variation within the fuel loadings for all sources was high, and the differences in fuel loadings led to significant differences in consumption and emissions depending upon the data and model chosen. The results of this case study are consistent with those of other researchers, and indicate that supplementing LANDFIRE-represented data with locally measured data, especially for duff and coarse woody debris, will produce more accurate emissions results relative to using unaltered LANDFIRE-FCCS or LANDFIRE-FLM fuel loadings. Accurate emissions models will aid

comparados con la medición de la carga para 20 000 ha de un área de bosques mixtos de coníferas en el norte de Idaho, EEUU. Las cargas de combustibles fueron comparadas, y luego ubicadas dentro de dos modelos—el *First Order Fire Effects Model* (FOFEM) y el *Consume*—para su subsecuente comparación de los resultados del consumo de combustibles y sus emisiones. El LANDFIRE-FCCS mostró una estimación 200%* superior en la carga del mantillo comparado con la carga medida a campo. Esto llevó a un valor 23% más alto en la media total de consumo y emisiones del combustible cuando fue modelado mediante el modelo FOFEM. El modelo LANDFIRE-FLM layer mostró menores cargas para combustibles de superficie relativo a datos medidos a campo, especialmente en el caso de restos de combustible leñoso grueso (*coarse woody debris*), que a su vez llevó a un 51% menos en el consumo y emisiones promedio cuando fueron modeladas por el modelo FOFEM. Cuando la comparación fue repetida usado el *Consume model outputs*, el consumo estimado por el LANDFIRE-FLM fue un 59% menor en relación a lo determinado en las parcelas medidas, con un 58% menos que las emisiones modeladas. Aunque ambos modelos de LANDFIRE y las cargas efectivamente medidas se ubican dentro de los rangos observados por otros investigadores en los ecosistemas mixtos de coníferas de los EEUU, la variación dentro de las cargas de combustible determinadas por las distintas fuentes fue alta, y las diferencias en carga de combustible llevan a diferencias significativas en consumo y emisiones, dependiendo éstos del modelo elegido. Los resultados de este estudio de caso son consistentes con aquellos obtenidos por otros investigadores, e indican que suplementando datos de LANDFIRE con datos locales obtenidos de mediciones a campo, especialmente para el mantillo y restos de combustible leñoso grueso, producirá resultados de consumo y emisiones más precisos que aquellos que usan solamente datos de carga provistos por LANDFIRE-FCCS o LANDFIRE-FLM. Los modelos de emisiones preci-

INTRODUCTION

The use of fire as a land management tool is widely recognized for its ecological benefits, and as a historic disturbance that has driven succession across many ecosystems (Agee 1996, Hardy and Arno 1996, Rothman 2005). While fire science and policy has advanced in the last 50 years to better allow for the use of fire in managing wildlands (van Wagtendonk 2007), increasingly stringent air quality regulations (US EPA 1990, Hardy *et al.* 2001, US EPA 2015,) and an increased awareness of the health impacts from smoke (Liu *et al.* 2015) can make the use of fire as a management tool difficult. In a recent United States survey, prescribed fire practitioners expressed that smoke and air quality issues are the third greatest impediment to prescribed burning, following low work capacity and unfavorable weather conditions (Melvin 2012). To continue using fire as a management tool, land managers must plan to meet management objectives, while also limiting the impact of smoke on public health and keeping smoke levels within regulatory thresholds (NWCG 2014). Such planning may often require the use of models to determine the quantity of emissions generated by fire; these models require many pieces of information, including expected fire size, fuel loading characteristics, and fuel consumption. Of these, fuel loading has been identified as the most critical step in obtaining accurate smoke predictions (Drury *et al.* 2014). Unfortunately, in many areas there may be little or no measured data on fuel loading; this creates a major difficulty in estimating fuel consumed and emissions produced.

To address the lack of fuel loading information in planning, geospatial Fire Effects Fuel Model (FEFM) layers developed by the Landscape Fire and Resource Management Planning Tools (LANDFIRE) program are often used. LANDFIRE data layers were developed for the contiguous United States, Alaska, and Hawaii to provide consistent geospatial data describing the vegetation type, structure, fuel loading, and disturbances, regardless of land ownership boundaries (Rollins 2009). LANDFIRE is principally intended to inform management and planning decisions made by land management agencies in the United States. It is also the only resource available that provides the geospatial information outlined above across as wide an area as the continental US. To populate models for smoke production, LANDFIRE FEFMs describe fuel loading for duff, litter, woody fuels from timelag size classes ranging from one hour (≤0.6 cm) to 1000 hours (≥7.62 cm), and live herb and shrub loading. Currently, there are two FEFM choices available through LANDFIRE: one represents fuel loading based on the Fuel Loading Model (FLM) categories developed by Lutes *et al.* (2009), and the other based on Fuels Characteristics Classification System (FCCS) categories developed by Ottmar *et al.* (2007). Both methods are derived from extensive measured datasets; however, FCCS is stratified to represent fuel loading by vegetation type (Ottmar *et al.* 2007), while FLM is stratified to represent fuel loadings by their potential fire effects (Lutes *et al.* 2009). The two LANDFIRE FEFMs are different not only in how they stratify fuels, but also in their reported fuel loadings.

There have been few studies that detail the differences between these two LANDFIRE FEFMs. One study evaluated their mapping performance across the western United States (Keane *et al.* 2013), and another compared their loadings and resulting emissions as part of a broader comparison of factors affecting smoke predictions in Washington, USA (Drury *et al.* 2014). When Keane *et al.* (2013) compared fuel loading and mapping accuracy of FCCS and FLM LANDFIRE layers throughout the western United States to data from the Forest Inventory and Analysis (FIA) program, they found poor correlations between FIA and LANDFIRE represented loadings, mainly due to the high variability in fuel loadings. Drury *et al.* (2014) compared FLM and FCCS FEFM data with other local datasets and found the landscape fuel loadings to range from 2.7 million Mg to 8.8 million Mg for their research area in Washington, USA, depending on which fuel loading dataset they used.

Studies such as these are extremely valuable for documenting the complexity and variation within fuel loading data, and identifying the importance and challenges of applying FEFM fuels data to model emissions. Our study builds on the few evaluations of LANDFIRE FEFMs to date by comparing FEFM surface fuel loading with measured fuel loadings, and using these loadings in two popular consumption and emissions models—the First Order Fire Effects Model (FOFEM) and Consume—to compare the resulting differences in fuel consumption and emissions production, while holding the site and environmental conditions constant. This provides insight into the degree of fuel loading differences possible at smaller scales relative to the national or sub-regional scales that LANDFIRE was developed to represent. Yet this 20 000 ha area is large enough to fall within the range of fire management units that land managers are tasked to manage (USDI NPS 2005, USDA FS 2008). We compared duff, litter, herb, shrub, and woody fuel loadings measured in forest inventory plots to those shown on both LANDFIRE Fuel Loading Models (LANDFIRE-FLM) and LANDFIRE Fuels Characterization Classification System (LANDFIRE-FCCS) maps. Subsequent differences in modeled consumption and emissions using FOFEM and Consume are reported.

METHODS

Study Area

To evaluate potential differences in predicted fuel loadings and fire effects, we selected a 20 000 ha study area centered on Moscow Mountain in Latah County, Idaho, USA (Figure 1). The mountain lies in the Palouse Range of northern Idaho, with elevations ranging from 770 m to 1516 m. Moscow Mountain is dominated by mixed conifer forest tree species including ponderosa pine (*Pinus ponderosa* C. Lawson var. *scopulorum* Engelm.), Douglas-fir (*Pseudotsuga menziesii* [Mirb.] Franco var. *glauca* [Beissn.] Franco), grand fir (*Abies grandis* [Douglas ex D. Don] Lindl.), western red cedar (*Thuja plicata* Donn ex D. Don), western hemlock (*Tsuga heterophylla* [Raf.] Sarg.), and western larch (*Larix occidentalis* Nutt.). Ponderosa pine and Douglas-fir habitat types occur on the xeric southern and western aspects, grand fir and cedar-hemlock habitat types occur on the mesic northern and eastern aspects (Cooper *et al.* 1991). The majority of the land is owned by private timber companies, private non-commercial landowners, and public land holdings. Recent disturbances recorded between 2003 and 2009 were predominantly the result of forest man-

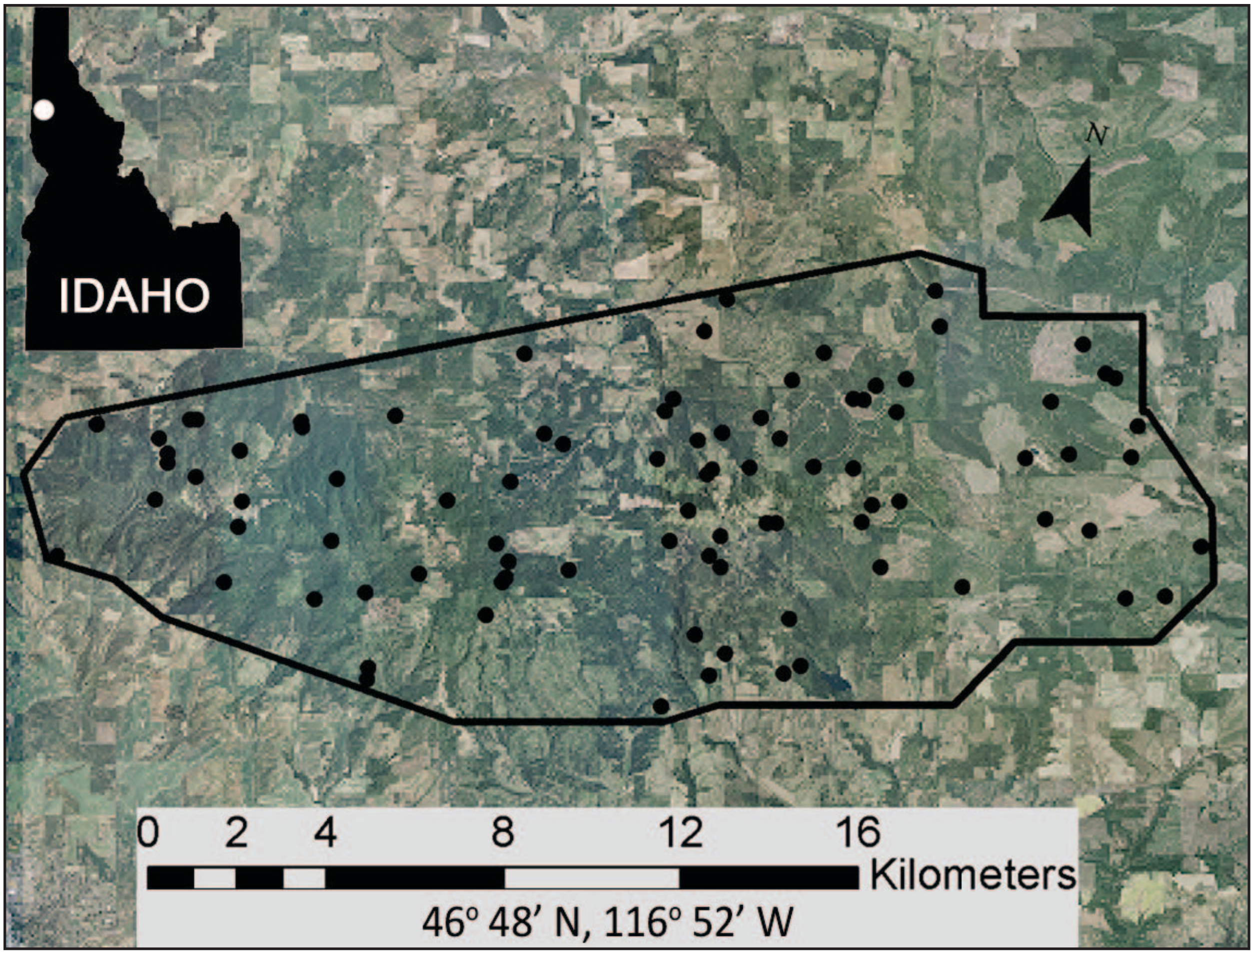

Figure 1. 2009 orthoimagery of the Moscow Mountain, Idaho, USA, study area (outlined) from the United States Geological Survey. The white dot in the inset is the study area. Plot locations are indicated with black dots.

agement practices including thinning, timber harvesting, and prescribed burning (Hudak *et al.* 2012). These activities have resulted in a forest with varying stand ages and structures that occur over a variety of biophysical settings (Falkowski *et al.* 2009, Martinuzzi *et al.* 2009, Hudak *et al.* 2012).

Plot Fuel Loadings

Plot data used in this study were collected in 2009, with information on plot placement and methodologies described in detail in Hudak *et al.* (2012). Following a stratified random sampling design of the study area, 0.04 ha fixed-radius field plots were placed randomly within strata based on elevation, slope, aspect, and percent forest cover. Plots that randomly fell within agricultural areas were subsequently excluded, leaving 87 forested plots for this analysis. Within each plot, duff; litter; coarse woody debris (CWD) in the ≥1000 hour (≥7.62 cm) size class; and fine woody debris in one hour (<0.635 cm), ten hour (0.635 cm to 2.54 cm), and 100 hour (2.54 cm to 7.62 cm) size classes were measured and loading was determined as described by Hudak *et al.* (2009), briefly summarized as follows: fuel loading was determined using two parallel 15 m Brown's transects (Brown 1974) centered 2.5 m upslope and downslope from plot center. On each transect, one hour and ten hour fuels were tallied over a 1.8 m segment, 100 h fuels over a 4.6 m segment, and 1000 h fuels over the entire length of both transects. Shrub and herbaceous cover were estimated ocularly and translated to loadings using equations from Brown (1981) and Smith and Brand (1983). Duff and litter depths were measured once at a set distance along each transect (Brown 1981), and loading was derived from relationships presented in Brown *et al.* (1982) with bulk densities from Woodall and Monleon (2008).

LANDFIRE Fire Effects Fuel Model Loadings

LANDFIRE FEFM map layers are available for both FCCS and FLM fuel classification systems. The FCCS system is composed of fuel loading data organized by vegetation type; each vegetation type is represented by loadings derived from field data collected from that vegetation type (Ottmar *et al.* 2007). FLM fuel loadings are the result of several field-collected datasets, which are grouped into statistically distinct groups based on fuel loading and modeled fire effects (i.e., emissions and soil heating; Lutes *et al.* 2009). In-depth comparisons of these approaches have been addressed by Keane (2013).

For this study, we compared LANDFIRE Refresh 2008 FEFMs to measured fuel loadings. LANDFIRE-FCCS and LANDFIRE-FLM layers were generated using different methodologies. LANDFIRE-FCCS layers were derived by matching FCCS fuelbeds to LANDFIRE vegetation communities (Comer *et al.* 2003) and vegetation type (McKenzie *et al.* 2012, LANDFIRE Team 2014*a*). LANDFIRE-FLMs were derived by a series of database queries that matched LANDFIRE data to the appropriate FLMs (Hann *et al.* 2012). More specifically, Forest Inventory and Analysis (FIA) data (Woudenberg *et al.* 2010) were keyed to FLMs (Lutes *et al.* 2009) and these FLMs were systematically matched to LANDFIRE vegetation types and cover. We should note that the scope of our study focuses on the surface fuel loadings represented in LANDFIRE map layers, not the FCCS and FLM fuel classification systems that the layers are intended to represent.

Generating Emissions within FOFEM and Consume

Consumption and emissions were generated using two common fire effects models: Consume version 4.2 (FERA Team 2014) and the Fire Order Fire Effects Model (FOFEM) version 6.0 (Lutes 2012). Consume calculates consumption and emissions based on empirical algorithms from many studies (Prichard *et al.* 2005). The FOFEM model generates consumption based on equations from the BURNUP model (Albini and Reinhardt 1997) and emission factors from Ward *et al.* (1993). Evaluating results in both models is important as FOFEM and Consume are both commonly used in fire management and are integrated into planning tools such as the Interagency Fuels Treatment Decision Support System (IFTDSS 2015). Consume is also integrated into the BlueSky Framework that is used for emissions calculations (AirFire 2015). For this study, we included the major compounds emitted by wildland fire that could be of concern for reasons of human health effects, regulatory impacts, or greenhouse gas emissions: carbon dioxide (CO_2), carbon monoxide (CO), methane (CH_4), and particulate matter 2.5 μm and 10 μm ($PM_{2.5}$ and PM_{10}). Nitrogen oxides (NO_x) and sulfur dioxide (SO_2) were also modeled using only FOFEM, and non-methane hydrocarbons (NMHC) were modeled using only Consume as these options are specific to each model. To parameterize these models we used the values in Table 1 to simulate summer fire conditions under which past fires in the region have ignited (McDonough 2003).

Table 1. Environmental parameters used to populate FOFEM and Consume under default 'Low' moisture conditions to simulate an early summer fire.

Parameter	Input
Moistures	
Duff	40%
10 hour	10%
CWD	15%
Soil	10%
Fuel type	Natural
Region	Interior West
Season	Summer

Statistical Comparison of Fuel Loadings

All analyses were conducted using R Statistical Software (R-Project 2013). We initially tested fuel loading differences using Bartlett's test for equal variance (Bartlett 1937). This indicated that the data did not meet the assumption of homoscedasticity required for parametric regression analysis. Therefore, we used non-parametric statistical methods. Analysis of variance was chosen and performed using the Anova test from the "car" package (Fox *et al.* 2014) as this version implemented the test using heteroscedasticity-corrected coefficient covariance matrices. If a significant difference was detected, further analysis was conducted with the Dunnett-Tukey-Kramer pairwise multiple comparison test adjusted for unequal variances and unequal sample sizes (Dunnet 1980) using the DTK package (Lau 2013) at the alpha = 0.05 significance level. This method was used to compare fuel loadings, consumption, and emissions. To examine the influence of different fuels on the total emissions produced, we used Hoffman and Gardner's Importance Index, a ratio of variances between total emissions generated and each individual fuel component (Hoffman and Gardner 1983 , Hamby 1994). Values close to one indicate higher significance than values closer to zero.

RESULTS

Fuel Loadings

In comparing LANDFIRE fuel loadings with measured fuel loadings, all fuel components differed at the alpha = 0.05 significance level with the exception of shrubs (Table 2, Figure 2). LANDFIRE-FCCS loadings over-represented duff and herbs; under-represented litter, 10 h, and 100 h fuels; and did not differ for 1 h fuels or CWD. LANDFIRE-FLM under-represented duff, litter, fine (1 h, 10 h, and 100 h), and CWD fuel loadings; over-represented herb loadings; but duff loading did not

Table 2. Mean fuel loads (Mg ha^{-1} and SD in parentheses) on measured plots and as modeled by LANDFIRE-FCCS and LANDFIRE-FLM. Asterisks indicate statistically significant difference relative to measured loading data at the $P < 0.05$ significance level.

	Mean plot loading		
Fuel	**Measured**	**LANDFIRE-FCCS**	**LANDFIRE-FLM**
Duff	10.55 (10.20)	31.89 (17.80)*	7.76 (12.19)
Litter	5.86 (4.13)	4.199 (1.37)*	3.66 (3.40)*
1 h	0.65 (0.47)	0.81 (0.46)	0.50 (0.32)*
10 h	2.57 (2.19)	1.85 (1.11)*	1.65 (1.13)*
100 h	4.98 (5.20)	2.47 (3.41)*	1.94 (1.66)*
CWD	20.087 (23.33)	18.45 (16.38)	2.75 (4.04)*

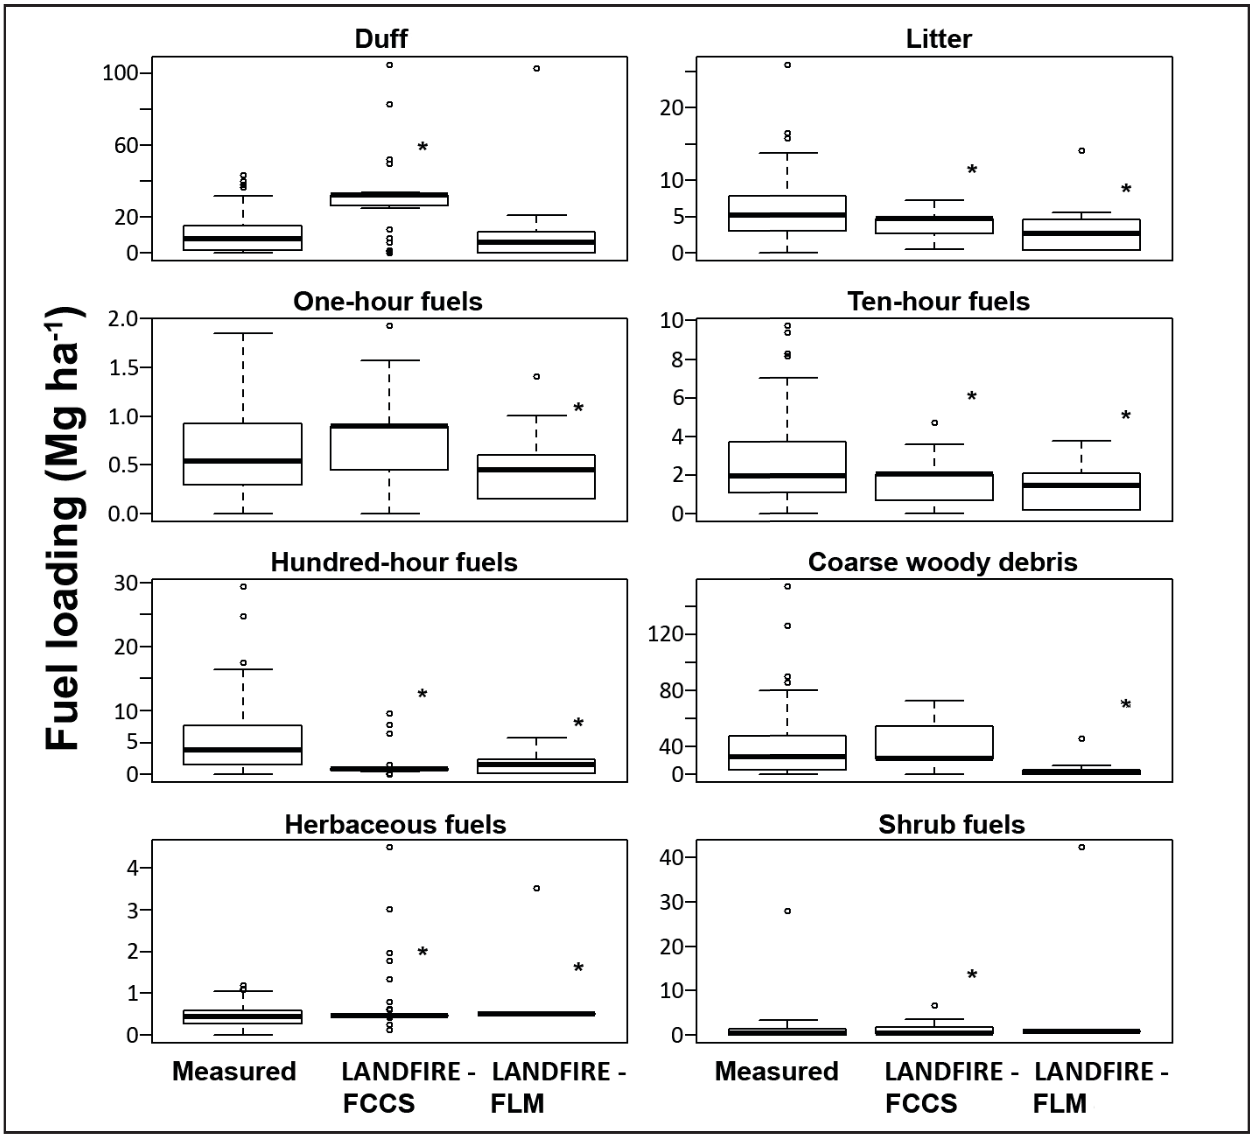

Figure 2. Differences in fuel loading for measured plots, LANDFIRE-FLM, and LANDFIRE-FCCS products. Bold horizontal lines indicate median values, asterisks represent significant differences relative to measured loadings. Circles indicate outliers, and whiskers indicate the region between the first and third quartiles.

differ. Duff and CWD fuel components showed the most pronounced difference in loadings, with LANDFIRE-FCCS duff loadings 200 % higher than measured loadings, and 300 % higher than LANDFIRE-FLM loadings. LANDFIRE-FLM CWD loading was 9 times lower than measured or LANDFIRE-FCCS loadings. When comparing LANDFIRE FEFMs to each other, only duff, CWD, and 1 h fuel loadings differed, with LANDFIRE-FCCS having the greater loadings.

Modeled Consumption and Emissions in FOFEM

The statistical relationships for fuel consumption mirrored those for fuel loading (Figures 2 and 3, Tables 2 and 3). Relative to measured consumption, the mean total surface consumption from LANDFIRE-FCCS was 23 % higher, and LANDFIRE-FLM was 51 % lower. It is apparent that the high LANDFIRE-FCCS duff loading led to the higher

overall consumption, and that the low CWD loading in the LANDFIRE-FLM contributed to less consumption. This in turn had a direct effect on the emissions modeled. All modeled emissions, with the exception of NO_x, were significantly higher when modeled using LANDFIRE-FCCS loadings, and lower when using LANDFIRE-FLM loadings, while emissions derived from measured fuel loadings fell in between (Table 4, Figure 4).

The relative importance of CWD and duff to total emissions was reaffirmed and quantified using the importance index (Table 5). Duff and CWD stood out as the primary con-

tributors to total emissions in all cases, with the exception of LANDFIRE-FLM data, in which duff and shrub loadings were the primary contributors. Although shrub loadings did not statistically different in our study, shrub loadings tended to be higher in LANDFIRE-FLMs compared to other sources.

Modeled Consumption and Emissions in Consume

With the exception of duff, the relationships between fuel loading and modeled consumption when using Consume remained the same as with FOFEM; modeled duff consumption was much lower when using Consume (Table 3). Duff consumption using LANDFIRE-FCCS loadings did not significantly differ from consumption generated from measured loadings. Because of this, the overall modeled fuel consumption from LANDFIRE-FCCS did not significantly differ from the fuel consumption generated by measured loadings. However, the modeled consumption from LANDFIRE-FLM was significantly lower than consumption from measured loadings, with mean total surface fuel consumption 59% less than that derived from measured fuel loadings.

The importance index for the consumption and total emissions in Consume was similar to the FOFEM emissions importance index (Table 5). Duff consumption was still an important component with regard to emissions production, even though it did not statistically differ between measured and modeled fuel datasets when modeled with Consume. When emissions were evaluated, the LANDFIRE-FLM generated emissions were significantly lower than those generated using measured fuel loadings. Emissions generated using LANDFIRE-FCCS and measured fuel loadings did not differ from each other (Table 4).

DISCUSSION

Measured Versus Modeled Fuel Loading

Duff and CWD led to the most significant differences in modeled consumption and emissions. LANDFIRE-FLMs contained higher shrub loadings, although this number did not result in a statistically significant difference, nor was it great enough to influence the total surface fuel loading when consumption and emissions were modeled. While the cause for these LANDFIRE-FLM shrub values to be so much higher is not known, the FLM system itself was developed with very little available shrub data (Lutes *et al.* 2009). This likely influenced which FLMs were available to assign

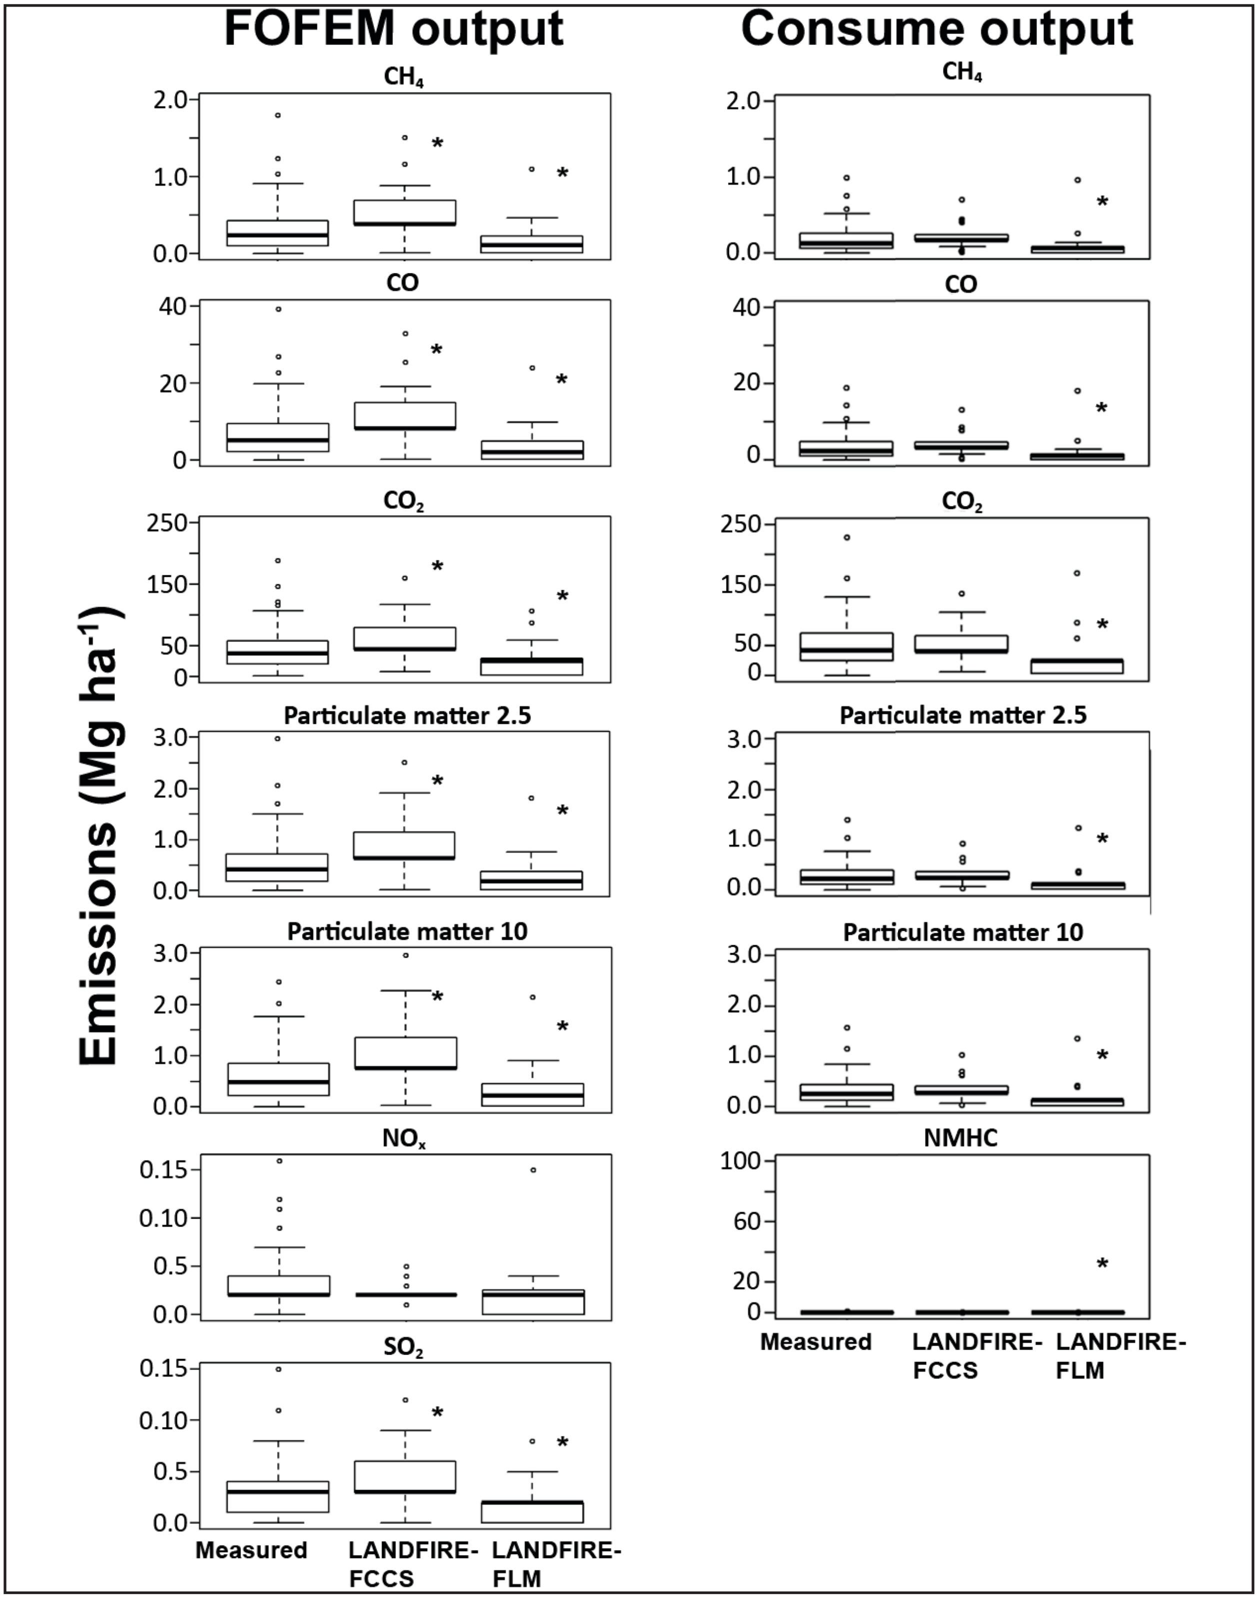

Figure 4. Differences in modeled emissions for measured, LANDFIRE-FLM, and LANDFIRE-FCCS fuel loadings. Bold horizontal lines indicate median values, asterisks represent significant differences relative to results derived from measured loadings.

Table 5. Hoffman and Gardner Importance Index for each FEFM and each fuel type shows that the fuel of relative importance to the total emissions produced varied depending by FEFM. Emissions from measured data and FCCS fuelbeds were most influenced by CWD and duff, and FLM by duff and shrubs, respectively. Highest values are indicated in bold.

to LANDFIRE maps when the LANDFIRE-FLM was created. Because the scope of this study focused on a mixed conifer ecosystem, our shrub data were somewhat limited and probably provided little insight in shrub-dominated ecosystems where shrubs are a large fuel component. Further investigation of these LANDFIRE layers in shrub-dominated systems and further fuel loading data from shrub ecosystems would be beneficial to further refining FLMs and the resulting LANDFIRE-FLM data for shrub ecosystems.

When comparing each fuel component for measured and LANDFIRE-represented loadings with those of other mixed conifer systems, all three of our fuel loading sets fell within the ranges observed by other researchers (Table 6). Focusing on duff and coarse woody debris, we found LANDFIRE-FCCS mean duff loading exceeded our measured values, but more closely resembled the ranges found in other mixed conifer forests. Thus, it is possible that our study area may have had less duff loading than other mixed conifer forests. When evaluating mean CWD loadings, we found the wide range noted in other studies, from 0.5 Mg ha^{-1} to 37 Mg ha^{-1}; LANDFIRE-FLM mean CWD loadings were at the low end of this range averaging 0.53 Mg ha^{-1}, while our measured data and LANDFIRE-FCCS were 10.6 Mg ha^{-1} and 8.6 Mg ha^{-1}, respectively.

Our results support a broader evaluation of the importance of various steps in the emissions modeling process in which Drury *et al.* (2014) compared LANDFIRE-represented loadings to a custom loading map based on measured data. Like our results, their duff loading was higher for LANDFIRE-FCCS relative to loadings represented using measured data, while in our study the LANDFIRE-FCCS total loadings were greater. Drury *et al.* found a wide range in possible fuel loadings depending upon the method chosen, as did we, and concluded that custom fuel loading layers derived from measured data produced the most reliable emissions estimates. Of the two LANDFIRE fuel layers, Drury *et al.* found the LANDFIRE-FCCS layer produced results closer to the custom loading layers. We found this to be true in our study when modeling emissions with Consume, but still found LANDFIRE-FCCS to produce higher emissions values when modeled using FOFEM.

In another study that compared classification, mapping accuracy, and fuel loadings of LANDFIRE-FCCS and LANDFIRE-FLM to Forest Inventory and Analysis (FIA) plot data across the western US, Keane *et al.* (2013) found poor performance in both LAND-

FIRE-represented FEFMs. LANDFIRE-FLM tended to under-predict loadings while LANDFIRE-FCCS tended toward over prediction. However, LANDFIRE-FLM loadings had lower root mean squared errors (Keane *et al.* 2013). Our findings here support the work of Keane *et al.* (2013) and Drury *et al.* (2014) in describing the tendency of LANDFIRE-FCCS to have higher loadings relative to LANDFIRE-FLMs.

Modeled Consumption and Emissions Using FOFEM

Relative differences in consumption values when modeled with FOFEM mirrored those of the loading values. High LANDFIRE-FCCS duff and low LANDFIRE-FLM CWD loading and consumption contributed to the total modeled emissions being highest when using LANDFIRE-FCCS inputs, and lowest when using LANDFIRE-FLM inputs. In examining the fuel loading data (Table 2), there is high variance in all fuel loading categories. This supports the work by Keane *et al.* (2013), who noted the high variance inherent in all categories of fuel loading, and the difficulties caused by spatial variation when trying to represent fuel loadings across large landscapes. Consumption followed the pattern of the total fuel loading values for the landscape, with LANDFIRE-FCCS being the highest, FLM being the lowest, and measured values in the middle. This in turn produced higher emissions from LANDFIRE-FCCS and lower emissions from LANDFIRE-FLM, highlighting the differences in emissions outcomes depending upon the choices made to represent fuel loadings.

Modeled Consumption and Emissions Using Consume

In comparing consumption and emissions from Consume, the choice of model has an effect on emissions generated. In this study, there were similar trends in modeled consumption with both fire effects models, but the lower duff consumption in Consume, relative to FOFEM, led to emissions outputs in which LANDFIRE-FCCS derived emissions did not differ from those derived from measured loadings. This difference in duff consumption is due to the fact that Consume and FOFEM calculate the consumption of duff using different equations, derived from different data sets (Reinhardt 2003, Prichard *et al*. 2005).

Research Implications

In modeling emissions, fuel loadings have been identified as the most crucial variables (Drury *et al.* 2014), yet they represent one of the greatest uncertainties in modeling emissions (French *et al.* 2011). In a detailed discussion on the topic, Keane *et al.* (2013) identified several factors creating difficulties in quantifying fuel loadings. These include lack of data to develop thorough loading maps; the use of classification systems that were developed from discrete plot locations but then applied to large, national-scale areas; and the inherent difficulty of classifying fuels into categories such as hourly size classes and duff, when each of these size classes may have different degrees of variation at different spatial scales (Keane *et al.* 2012, 2013). If existing fuel loading classification maps are to be improved, more data are necessary. The results of our study indicate that data on CWD and duff should be priorities, due to the relative importance of these fuels to overall emissions in mixed conifer forests (Table 5). While consumption didn't statistically differ for the specific case of shrubs, shrub loading accounted for a great deal of variability in emissions from LANDFIRE-FLMs (Table 5), a classification that was developed with little available shrub data (Lutes *et al.* 2009). For the case of LANDFIRE-FLMs, having additional data on shrub loadings would be beneficial.

Despite being represented at a 30 m resolution, LANDFIRE data layers are intended to be used at larger, sub-regional to national scales (LANDFIRE Team 2014*b*). Data from fuel loading maps may work for finer scales; however, there will likely be greater need to supplement that data with local knowledge. Based on our findings in a 20 000 ha area, using measured data, especially for duff and CWD loadings, is preferable relative to unaltered LANDFIRE layers. However, we understand that measured data are often unavailable, may be incomplete, or limited in availability.

Management Implications

If monitoring resources are available, emission estimates will be improved by having more information on duff loading, as differences in duff loading lead to the greatest differences in emissions, followed by CWD. For coarse woody debris, the planar intercept sampling methods have been most commonly used in forests such as in this study, although the Photoload (Keane and Dickinson 2007) method has also performed well (Sikkink and Keane 2008). Duff sampling is often performed via sampling points along a planar intercept to gather both loading and depth (Brown 1974). The fuel photoseries guides available for many ecosystems provide estimates of duff loading (Ottmar *et al.* 2003), but there are few studies comparing their performance relative to the traditional method. If measured data are not available, one could model with both the LANDFIRE-FLM and LANDFIRE-FCCS derived fuel loadings, and then average the two sets of results.

The use of systems such as the Wildland Fire Decision Support System (WFDSS) and the Interagency Fuels Treatment Decision Support System (IFTDSS) also hold potential for obtaining measured fuel loading information (IFTDSS 2015, WFDSS 2015). These systems provide online access to several models to represent fire behavior and effects (including emissions), but they also provide an easy platform from which data can be shared from user to user. In the future, it would be ideal to see a searchable database of user-provided fuel loadings within these decision support systems, similar to the searchable data available through the Fire Research and Management Exchange System (FRAMES) Resource Catalog (FRAMES 2015).

This study has characterized the potential differences in LANDFIRE-represented fuel loadings in a mixed conifer case study area, and their impact on the emissions modeling. While using measured data provides the most reliable outcome, either by itself or to help supplement the LANDFIRE data, this is not always possible. Web-based systems can aid in finding and sharing data; however, a search for the keywords "duff" and "coarse woody debris" in FRAMES returned 34 and 3 results, respectively. While online systems can be powerful sources of information, there is clearly a need for additional data with which tools such as the LANDFIRE map layers could be strengthened. In the interim, information on the relative differences in fuel loadings from LANDFIRE-represented data may be useful to managers who are tasked with quantifying emissions for fire management planning. Using all of these resources will aid in generating more accurate emissions estimates in a climate where regulatory pressure and the need to accurately represent potential emissions from fire are increasing.

ACKNOWLEDGEMENTS

The authors would like to thank the National Wildfire Coordinating Group's Fuels Committee for providing funding to the National Interagency Fuels Technology Transfer, which made this research possible. Additional thanks go to the USDA Forest Service for providing measured fuel loading, and to forestry technician P. Fekety for data preparation.

CONSERVATION

A global map of roadless areas and their conservation status

Pierre L. Ibisch,[1,2]* Monika T. Hoffmann,[1] Stefan Kreft,[1,2] Guy Pe'er,[2,3,4] Vassiliki Kati,[2,5] Lisa Biber-Freudenberger,[1,6] Dominick A. DellaSala,[7,8] Mariana M. Vale,[9,10] Peter R. Hobson,[1,2,11] Nuria Selva[12]*

Roads fragment landscapes and trigger human colonization and degradation of ecosystems, to the detriment of biodiversity and ecosystem functions. The planet's remaining large and ecologically important tracts of roadless areas sustain key refugia for biodiversity and provide globally relevant ecosystem services. Applying a 1-kilometer buffer to all roads, we present a global map of roadless areas and an assessment of their status, quality, and extent of coverage by protected areas. About 80% of Earth's terrestrial surface remains roadless, but this area is fragmented into ~600,000 patches, more than half of which are <1 square kilometer and only 7% of which are larger than 100 square kilometers. Global protection of ecologically valuable roadless areas is inadequate. International recognition and protection of roadless areas is urgently needed to halt their continued loss.

The impact of roads on the surrounding landscape extends far beyond the roads themselves. Direct and indirect environmental impacts include deforestation and fragmentation, chemical pollution, noise disturbance, increased wildlife mortality due to car collisions, changes in population gene flow, and facilitation of biological invasions (*1*–*4*). In addition, roads facilitate "contagious development," in that they provide access to previously remote areas, thus opening them up for more roads, land-use changes, associated resource extraction, and human-caused disturbances of biodiversity (*3*, *4*). With the length of roads projected to increase by >60% globally from 2010 to 2050 (*5*), there is an urgent need for the development of a comprehensive global strategy for road development if continued biodiversity loss is to be abated (*6*). To help mitigate the detrimental effects of roads, their construction should be concentrated as much as possible in areas of relatively low "environmental values" (*7*). Likewise, prioritizing the protection of remaining roadless areas that are regarded as important for biodiversity and ecosystem functionality requires an assessment of their extent, distribution, and ecological quality.

Such global assessments have been constrained by deficient spatial data on global road networks. Importantly, recent publicly available and rapidly improving data sets have been generated by crowd-sourcing and citizen science. We demonstrate their potential through OpenStreetMap, a project with an open-access, grassroots approach to mapping and updating free global geographic data, with a focus on roads. The available global road data sets, OpenStreetMap and gROADS, vary in length, location, and type of roads; the former is the data set with the largest length of roads (36 million km in 2013) that is not restricted to specific road types (table S1). OpenStreetMap is more complete than gROADS, which has been used for other global assessments (*7*), but in certain regions, it contains fewer roads than subglobal or local road data sets [see the example of Center for International Forestry Research data for Sabah, Malaysia (*8*); table S1]. Given the pace of road construction and data limitations, our results overestimate the actual extent of global roadless areas.

The spatial extent of road impacts is specific to the impact in question and to each particular road and its traffic volume, as well as to taxa, habitat, landscape, and terrain features. Moreover, for a given road impact, its area of ecological influence is asymmetrical along the road and can vary among seasons, between night and day, according to weather conditions, and over longer time periods. We conducted a comprehensive literature review of 282 publications dealing with "road-effects zones" or including the distance to roads as a covariate, of which 58 assessed the spatial influence of the road (table S2). All investigated road impacts were documented within a distance of

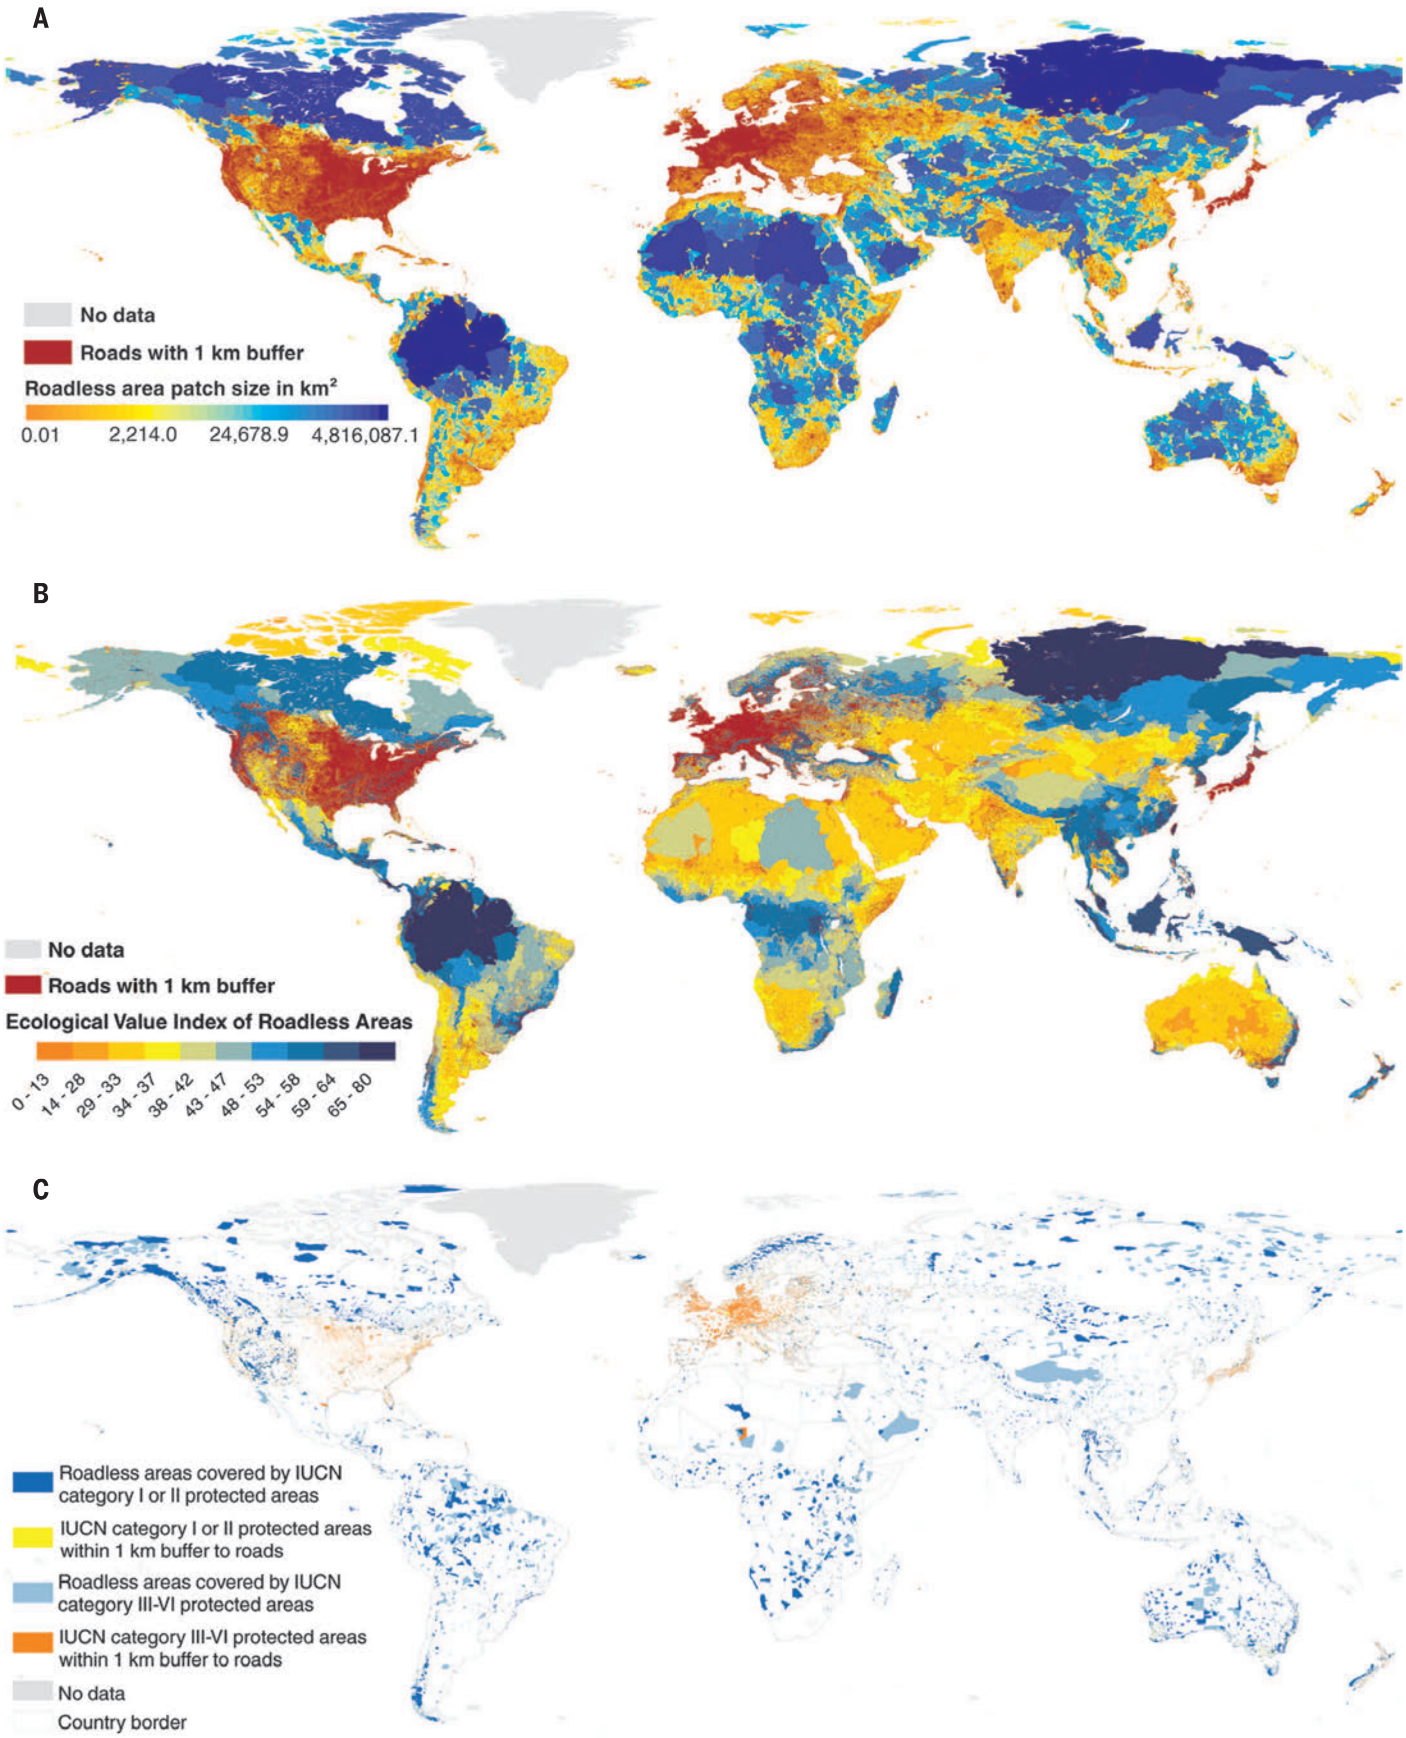

Fig. 1. The global distribution of roadless areas, based on a 1-km buffer around all roads. The distribution is depicted according to (**A**) size classes, (**B**) the ecological value index of roadless areas (EVIRA; based on patch size, connectivity, and ecosystem functionality), and (**C**) representation in protected areas (*8*).

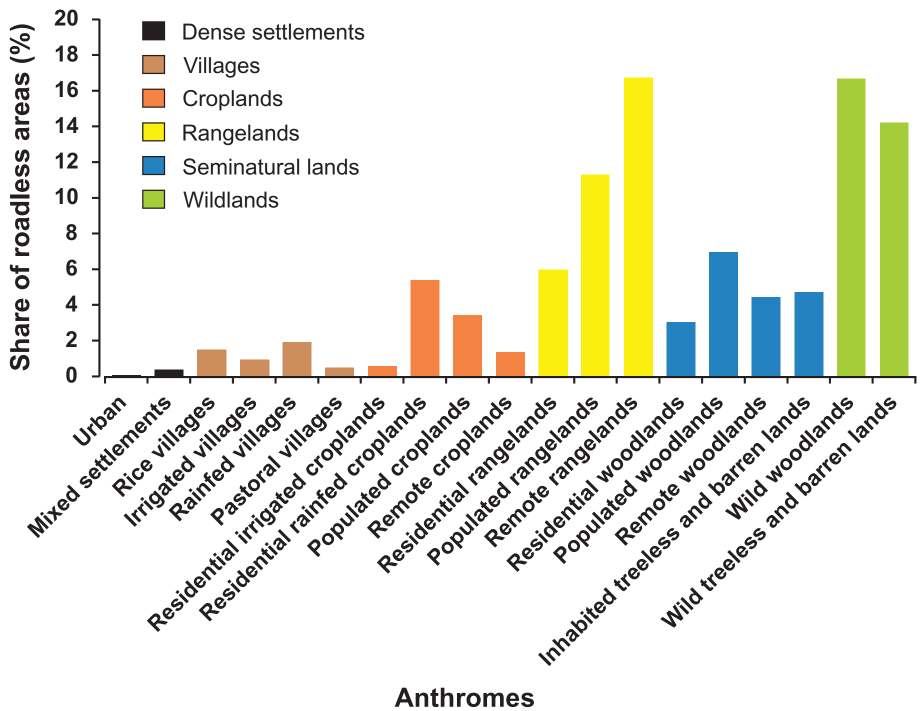

Fig. 2. Extent of roadless areas (1-km buffer) across anthromes. The majority of the world's roadless areas are in remote and unmodified landscapes, but they also occur in anthropogenically modified landscapes. The so-called anthromes were mapped according to (*10*).

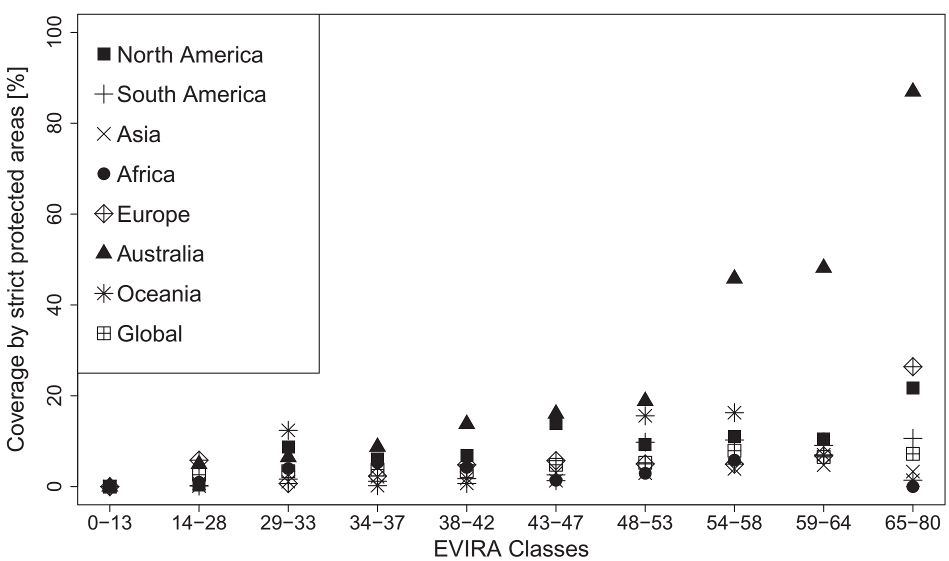

Fig. 3. Coverage of roadless areas by strictly protected areas (IUCN categories I and II) compared with global and continental EVIRA values. If priority were given to protecting roadless areas with high ecological functionality, we should see a positive correlation, with higher coverage associated with higher EVIRA values.

1 km from the road, 39% reached out to 2 km from the road, and only 14% extended out to 5 km from the road (fig. S1). Because the 1-km buffer along each side of the road represents the zone with the highest level and variety of road impacts, we defined roadless areas as those land units that are at least 1 km away from all roads and, therefore, less influenced by road effects. We compared results from using this criterion with the outcomes from using an alternative 5-km buffer (see fig. S2 and table S3). We excluded all large water bodies, as well as Greenland and Antarctica, which are mostly covered by ice, from the analyses.

Roadless areas with a 1-km buffer to the nearest road cover about 80% of Earth's terrestrial surface (~105 million km^2). However, these roadless areas are dissected into almost 600,000 patches. More than half of the patches are <1 km^2; 80% are <5 km^2; and only 7% are >100 km^2 (table S4 and fig. S3). If the buffer is extended to 5 km, there is a substantial reduction in roadless areas to about 57% of the world's terrestrial surface (~75 million km^2), dissected into 50,000 patches (fig. S2 and table S3). The occurrence, distribution, and size of roadless areas differ considerably among continents (Fig. 1A and fig. S4). For instance, the mean size of roadless patches (1-km buffer) is 48 km^2 in Europe, compared with >500 km^2 in Africa. Because of comparatively large gaps in available spatial data on roads in many segments of the tropics, the number and size of roadless areas are overestimated and should be treated with caution (e.g., Borneo; table S1).

All identified roadless areas were assessed for a set of ecological properties that were selected to reflect their relative importance to biodiversity, ecological functions, and ecosystem resilience: patch size, connectivity, and ecosystem functionality (*9*) (table S5). We normalized these three indicators to between 0 and 100 to calculate an additive and unitless index of the ecological value of each roadless area identified (termed the ecological value index of roadless areas, or EVIRA) [Fig. 1B and fig. S5; the specific rationale and technicalities of the chosen indicators are described in table S5 (*8*)]. The EVIRA values range from 0 to 80. A sensitivity analysis shows that ecosystem functionality and patch size are the best single indicators for the final index values (table S6 and figs. S6 to S8). Areas with relatively high index values tend to have a lower coefficient of variation (fig. S9).

We used the International Union for Conservation of Nature (IUCN) and UN Environment Programme–World Conservation Monitoring Centre data set of global protected areas to determine the extent of roadless areas that are protected (*8*) (Fig. 1C). The roadless areas distribution across human-dominated landscapes was determined following the classification of so-called anthromes, defined as biomes shaped by human land use and infrastructure (*10*) (Fig. 2 and table S7).

When examining the density of roads within different biomes, large discrepancies in distribution are apparent. The tundra and rock and ice-covered biomes are nearly entirely roadless, whereas temperate broadleaf and mixed forests have the lowest share of roadless areas (41%; figs. S9 and S10). Boreal forests of North America and Eurasia still retain large tracts of roadless areas (figs. S10 and S11). In the tropics, large roadless landscapes (>1000 km^2) remain in Africa, South America, and Southeast Asia, with the Amazon having the single largest roadless segment. In relation to the anthromes (*10*), about two-thirds of the world's roadless areas can be described as remote and unmodified landscapes [26% uninhabited or sparsely inhabited treeless and barren lands; 21% natural and remote seminatural woodlands, with 17% wild woodlands therein (*8*); Fig. 2 and table S7]. The remaining one-third consists of rangelands, indicating that roadless areas can also occur in anthropogenically modified landscapes.

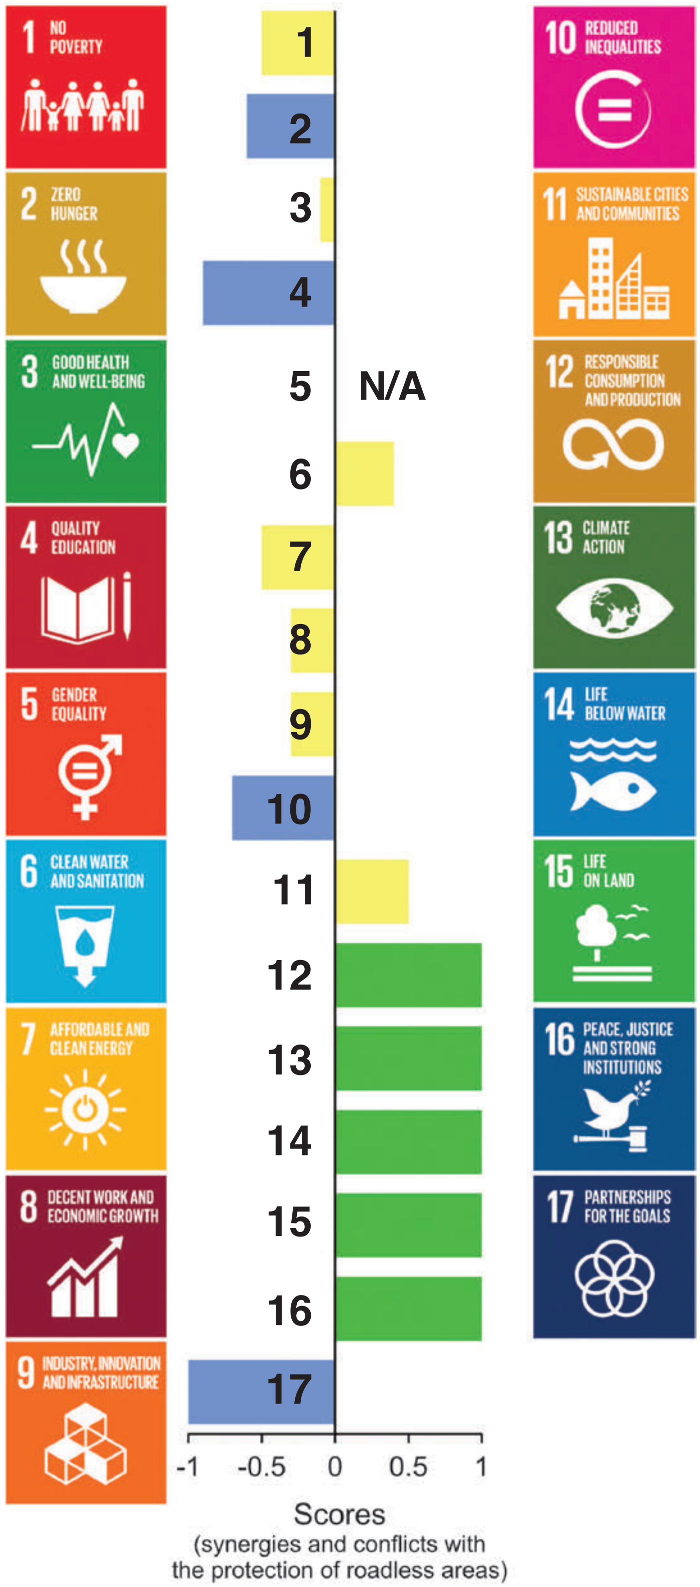

Fig. 4. Synergies and conflicts between conservation of roadless areas and the United Nations' Sustainable Development Goals. Scores <–0.5 (blue bars) indicate that conflicts with the goal prevail; scores between –0.5 and 0.5 (yellow) indicate a mixture of synergies and conflicts with the goal; and scores >0.5 (green) indicate prevailing synergies with the goal [for details, see table S11 (*8*)]. The scores reflect substantial imminent conflicts between various Sustainable Development Goals and conservation of roadless areas (table S11).

About one-third of the world's roadless areas have low EVIRA values. Patches with relatively low EVIRA values (ranging from 0 to 37; namely, <50% of the maximum value) account for 35% of the overall roadless area distribution, because most are small, fragmented, isolated, or otherwise heavily disturbed by humans. Some large tracts of roadless areas, such as arid lands in northern Africa or central Asia, occur in areas of sparse vegetation and low biodiversity and, thus, have low index values for ecosystem functionality (*9*) (Fig. 1B). High EVIRA values occur both in tropical and boreal forests. The relative conservation value of roadless areas is context-dependent. Comparatively small or moderately disturbed roadless areas have higher conservation importance in heavily roaded environments, such as most of Europe, the conterminous United States, and southern Canada.

Although the world's protected areas cover 14.2% of the terrestrial surface, only 9.3% of the overall expanse of roadless areas is within protected areas (all IUCN categories; Fig. 1C and table S8). There is no major difference in the coverage of roadless areas by strictly protected areas (IUCN categories I and II) versus the coverage of the overall landscape by strictly protected areas (3.8% roadless versus 4.2% overall). Only in North America, Australia, and Oceania are more than 6% of roadless areas under strict protection (table S8). If conservation efforts were to prioritize functional, ecologically important roadless areas, we would find a positive relation between strict protection coverage and EVIRA values of roadless areas. However, with the exception of Australia, this is not the case (Fig. 3 and table S9). Asia and Africa have particularly low protection coverage for roadless areas with high EVIRA values. For instance, we found gaps in the Asian tropical southeast, as well as in boreal biomes.

The recent Global Biodiversity Outlook (*11*) gives a bleak account of the progress made toward reaching the United Nations' biodiversity agenda as specified in the 20 Aichi Targets of the Convention on Biological Diversity (*12*). Governments have failed on several accounts to keep their use of natural resources well within safe ecological limits (target 4); to halt or at least halve the rate of habitat loss and substantially reduce the degradation and fragmentation of natural habitats (target 5); and to appropriately protect areas of particular importance for biodiversity and ecosystem services (target 11). To achieve global biodiversity targets, policies must explicitly acknowledge the factors underlying prior failures (*13*). Despite increasing scientific evidence for the negative impacts of roads on ecosystems, the current global conservation policy framework has largely ignored road impacts and road expansion. Furthermore, key policies on road infrastructure and development, such as the Cohesion Policy of the European Union, fail to take into account biodiversity.

In the much wider context of the United Nations' Sustainable Development Goals, conflicting interests can be seen between goals intended to safeguard biodiversity and those promoting economic development (*14*). We analyzed how roadless areas relate to the global conservation and sustainability agendas. As a transparent synthesis, we calculated simple scores of conflicts versus synergies of Sustainable Development Goals and Aichi Targets with the conservation of roadless areas (tables S10 and S11). Roads are explicitly mentioned in the Sustainable Development Goals only for their contribution to economic growth (goal 8), promoting further expansion into remote rural areas, and consideration is given neither to the environmental nor the social costs of road development. The resulting scores reflect substantial imminent conflicts (Fig. 4 and table S10); only in five Sustainable Development Goals do synergies with conservation of roadless

areas prevail, and four Sustainable Development Goals are predominantly in conflict with conservation of roadless areas. Maybe even more surprisingly, several of the Aichi Targets are ambivalent with respect to conserving roadless areas, rather than being in synergy entirely [six conflicting versus 11 synergistic targets (*8*); table S11].

There is an urgent need for a global strategy for the effective conservation, restoration, and monitoring of roadless areas and the ecosystems that they encompass. Governments should be encouraged to incorporate the protection of extensive roadless areas into relevant policies and other legal mechanisms, reexamine where road development conflicts with the protection of roadless areas, and avoid unnecessary and ecologically disastrous roads entirely. In addition, governments should consider road closure where doing so can promote the restoration of wildlife habitats and ecosystem functionality (*4*). Our global map of roadless areas represents a first step in this direction. During planning and evaluation of road projects, financial institutions, transport agencies, environmental nongovernmental organizations, and the engaged public should consider the identified roadless areas.

The conservation of roadless areas can be a key element in accomplishing the United Nations' Sustainable Development Goals. The extent and protection status of valuable roadless areas can serve as effective indicators to address several Sustainable Development Goals, particularly goal 15 ("Protect, restore and promote sustainable use of terrestrial ecosystems, sustainably manage forests, combat desertification, and halt and reverse land degradation and halt biodiversity loss") and goal 9 ("Build resilient infrastructure, promote inclusive and sustainable industrialization and foster innovation"). Enshrined in the protection of roadless areas should be the objective to seek and develop alternative socioeconomic models that do not rely so heavily on road infrastructure. Similarly, governments should consider how roadless areas can support the Aichi Targets (see tables S10 and S11). For instance, the target of expanding protected areas to cover 17% of the world's terrestrial surface could include a representative proportion of roadless areas.

Although we acknowledge that access to transportation is a fundamental element of human well-being, impacts of road infrastructure require a fully integrated environmental and social cost-benefits approach (*15*). Still, under current conditions and policies, limiting road expansion into roadless areas may prove to be the most cost-effective and straightforward way of achieving strategically important global biodiversity and sustainability goals.

PLANT PATHOLOGY

Regulation of sugar transporter activity for antibacterial defense in *Arabidopsis*

Kohji Yamada,[1,2]* Yusuke Saijo,[3,4] Hirofumi Nakagami,[5]† Yoshitaka Takano[1]*

Microbial pathogens strategically acquire metabolites from their hosts during infection. Here we show that the host can intervene to prevent such metabolite loss to pathogens. Phosphorylation-dependent regulation of sugar transport protein 13 (STP13) is required for antibacterial defense in the plant *Arabidopsis thaliana*. STP13 physically associates with the flagellin receptor flagellin-sensitive 2 (FLS2) and its co-receptor BRASSINOSTEROID INSENSITIVE 1–associated receptor kinase 1 (BAK1). BAK1 phosphorylates STP13 at threonine 485, which enhances its monosaccharide uptake activity to compete with bacteria for extracellular sugars. Limiting the availability of extracellular sugar deprives bacteria of an energy source and restricts virulence factor delivery. Our results reveal that control of sugar uptake, managed by regulation of a host sugar transporter, is a defense strategy deployed against microbial infection. Competition for sugar thus shapes host-pathogen interactions.

Plants assimilate carbon into sugar by photosynthesis, and a broad spectrum of plant-interacting microbes exploit these host sugars (*1*, *2*). In *Arabidopsis*, pathogenic bacterial infection causes the leakage of sugars to the extracellular spaces (the apoplast) (*3*), a major site of colonization by plant-infecting bacteria. Although leakage may be a consequence of membrane disintegration during pathogen infection, some bacterial pathogens promote sugar efflux to the apoplast by manipulating host plant sugar transporters (*4*, *5*). Interference with sugar absorption by bacterial and fungal pathogens reduces their virulence, highlighting a general

A global map of roadless areas and their conservation status

Editor's Summary

Too many roads

Roads have done much to help humanity spread across the planet and maintain global movement and trade. However, roads also damage wild areas and rapidly contribute to habitat degradation and species loss. Ibisch *et al*. cataloged the world's roads. Though most of the world is not covered by roads, it is fragmented by them, with only 7% of land patches created by roads being greater than 100 km ^{2}. Furthermore, environmental protection of roadless areas is insufficient, which could lead to further degradation of the world's remaining wildernesses.

F. Policy analyses: synergies and conflicts between conservation of roadless areas and conservation and sustainability agendas

A. Definition of roadless areas

We reviewed 282 scientific papers, out of which 58 publications provided information on the spatial influence of various road impacts and/or on the road-effect zone (Table S2). All studied impacts were documented within a distance of 1 km from the road, 39% were observed in the 1-2 km zone, and only 14% extended out to 5 km. Road effects that go beyond 50 km and to even 100 km are rarely documented; they refer to deforestation in relation to distance to main roads, not including other minor roads and paths that are necessary for forest clearings (Table S2). The 1-km buffer would therefore rather underestimate than overestimate the extension of areas impacted by roads. Still it represents a reasonable approach to excluding with high certainty those areas that are significantly affected by roads. We consider 1 km as the minimum value for road-effect zones at a global scale, taking into account landscape heterogeneity, as well as the wide range of road impacts across biomes and road categories. Consequently, we defined roadless areas as terrestrial areas not dissected by roads and low impacted by road effects (which are at least 1 km away from the nearest road).

B. Dataset and data accuracy

We used a data set of OpenStreetMap (11/2013) to create a global map of roadless areas. This data set is updated on a daily basis and can be freely downloaded. We purchased a pre-processed data set provided by Geofabrik (http://www.geofabrik.de/de/). The pre-processing did not change the road data, but instead provided a filtered data set that contained only road layers in shapefile format. OpenStreetMap is a volunteered geographic information project founded in Britain in 2004 *(16)*. It is one of the most cited, analyzed and commonly used platforms of this type and became one of the best alternative sources for geodata *(17, 18)*. The aim of OpenStreetMap is to produce and distribute free global geographic data *(19)*. The OpenStreetMap data set used in this research provides six main road categories. Examples of 'major roads' can be motorways and freeways (*category one*); 'minor roads' are categorized as small local roads, residential roads, etc. (*category two*). *Category three* is represented by 'highway links' (sliproads/ramps) that connect roads with each other. Service roads or roads for agricultural use are considered as 'very small roads' under *category four*. *Category five* is called 'path' and mainly used for horse riding and cycling, but also for small or off-road vehicles. *Category six* roads are 'unknown' types of roads. As all road categories have ecological impacts (Table S2), we included all of them in the analyses.

The CIA World Factbook estimated the road length to be 64-million km in 2013 *(20)*. The OpenStreetMap data set (2013) used in this research consists of 36-million km of roads. In contrast, the Global Roads Open Access Data Set (gROADS), published in 2013, contains 9.1-million km of roads (CIESIN 2013). The gROADS data set has been used in global studies on road impacts, in spite of containing less data than OpenStreetMap (e.g. *(7)*).

OpenStreetMap relies on the willingness of volunteers, both to contribute entries and to edit them for errors *(21)*. Therefore, the data are a crowd-sourced product with unknown data quality standards. However, a quality assessment of the OpenStreetMap data, including spatial data quality, evolution of street network, polygon geometry, comparison of user activity, development, positional accuracy, and completeness is available for different regions *(17, 22-28)*. Gröchenig et al. (2014) conducted a global evaluation of the mapping progress of OpenStreetMap history between 2006 and 2013 *(29)*. Their results state that external and internal factors significantly influence the mapping progress. Some of these factors are regional activity of the mapping community, data imports, and environmental disasters or other unforeseen events *(29)*. Demographic characteristics affect the mapping progress, and the quality of the data can vary significantly among countries (*17, 29)*.

A high number of road assessments were conducted in Europe *(30-34)*. Often, commercial or administrative data sets are used to compare and evaluate OpenStreetMap *(17)*. A study published in 2010 assessed the quality of OpenStreetMap for Germany *(32)*. Among its findings, the total length of roads was calculated as 1,204,213.69 km, whereas the road length data made available by TeleAtlas (an enterprise that provides digital maps, user content navigation, and location-based services) was 1,272,681.77 km. TeleAtlas focuses more on roads suitable for cars, whereas OpenStreetMap includes all road types *(32)*. In the case of the Brazilian Amazon it has been found that the road data from the Brazilian Institute for Geography and Statistics (IBGE) are more complete, including ca. 157,000 km of roads in contrast to ca. 114,000 km in our OpenStreetMap data set.

In areas of the tropics where land conversion is advanced, the road network may not be well reflected by OpenStreetMap. An extreme example of missing roads in the OpenStreetMap data set is Borneo. We carried out a comparative analysis of roads in the Sabah region, Malaysia, in northern Borneo. In areas considered to be roadless, closer inspection on the ground (in 2015) revealed extensive networks of vehicle tracks, for instance, throughout oil palm plantations. A similar result was found in forested areas impacted by logging roads. Indeed, cumulative data (1970-2010) compiled by the Center for International Forestry Research (CIFOR) indicate that there would be 37,498 km of logging roads in the region of Sabah alone. The 2013 OpenStreetMap data set (for Sabah created since 2009) used in this study comprises just 4,880 km, which is still more than the 2,937 km included in the road data set gROADS (1980-2010) that was the basis for other global road assessments (CIESIN 2013, *7*). Applying a 1-km buffer to each of the three road data sets for Sabah demonstrates that roadless areas are underestimated by the OpenStreetMap and the gROADS data set (Table S1). According to the gROADS data set (CIESIN 2013), 92% of Sabah is roadless. The OpenStreetMap data set shows that 91% of Sabah is roadless. In contrast, buffering the logging roads (CIFOR) reveals that only 40% of Sabah remains roadless. However, on the other hand, the CIFOR data set seems to overestimate existing logging roads. The CIFOR logging roads were mapped in four time intervals (1970, 1990, 2000 and 2010) by visual interpretation of satellite imagery. Analyzing the CIFOR logging roads with current Google Earth satellite images suggests that numerous roads have been overgrown by forest. The amount of logging roads that were either non-existent in 2010 or were <10 m wide (therefore not included in the CIFOR analysis) is high *(35)*. This simple exercise highlights the methodological problems to be overcome in future mapping. The three data sets can only be compared to a limited extent, since the roads have been mapped in different ways, time intervals and for different purposes. The gROADS data set (CIESIN 2013) focuses on roads between settlements. For Malaysia, gROADS is based on the Vector Smart Map Level 0 data. The CIFOR road data set does not include any other road category besides logging roads. In general, the three different road data sets (OpenStreetMap, gROADS, CIFOR) vary in length, location and type of roads, with OpenStreetMap being the data set with the largest length of roads at a global scale, and not limited to one type of roads (Table S1).

C. Data processing - Mapping of roadless areas and general processing

The global road data set was analyzed and processed for each continent, except for Antarctica and Greenland. All roads were buffered on both sides with a geodesic buffer of 1 km. Due to a very high number of vertices, all buffered roads were generalized with a "maximum offset tolerance" of 30 m, using the "Douglas-Peucker simplification algorithm" *(36)*. All analyses were conducted with ArcGIS 10.2. A road model tool was created with the ArcGIS model builder to facilitate the process. For the purpose of comparison, an alternative map of roadless areas was developed with a 5-km buffer to all roads (Fig. S2).

For area calculations, roadless areas were projected with the World Cylindrical Equal Area Projection. Spatial calculations and maps were made with ArcGIS Version 10.2. Protected area coverage of roadless areas was calculated based on IUCN categories of protected areas, including (a) IUCN categories Ia, Ib and II, and (b) other protected areas classified as IUCN categories III to VI (IUCN & UNEP-WCMC 2015). Protected area data sets for each country were downloaded and processed singularly instead of using the global protected area file due to inconsistencies in the global data set.

D. Data processing - Ecological Value Index of Roadless Areas (EVIRA)

There are manifold and partially contrasting approaches for defining the conservation values of given areas. Attempts at conservation priority setting have been classified as reactive and proactive *(37)*, some approaches focus on patterns rather than processes; however, in times of rapid environmental change, there are good arguments for especially targeting ecological functionality and biological viability *(9, 38)*. Therefore, we chose a functional priority-setting approach that is not based on merely anthropocentric values, such as use value or aesthetics, but comprises indicators that are defined in line with principles of modern ecosystem theory. In this context, we especially consider the capability of ecosystems to self-order and regulate abiotic and biotic conditions, which is greatly based on the capacity of uptaking and storing eco-exergy *(39, 40)*. Specifically, exergy has been used for analyzing and indicating ecosystem health *(41-46)*. As key attributes of ecosystem growth and development, Jørgensen (2006) *(42)* and Jørgensen et al. (2000) *(43)* proposed biomass, information and network as main growth forms of ecosystems.

To assess the conservation value of roadless areas, a corresponding additive index (Ecological Value Index of Roadless Areas, EVIRA) was created. Three indicators were chosen (for individual and more specific rationale of indicators see Table S5):

(1) Roadless area patch size: A larger roadless area patch size indicates less human disturbance, lower edge effects, higher populations of road-sensitive species, as well as higher ecological integrity and self-regulating capacity.

(2) Thiessen connectivity into all directions for roadless area patches: We describe connectivity (and degree of isolation), as the ratio between the size of a roadless area patch and its surrounding Thiessen polygon. A Thiessen (or Voronoi) polygon describes the area around a sample point or area where any position taken from inside the polygon is closer to the sample point/area than to any of the other sample points/areas *(47)*. To create Thiessen polygons Euclidean distance was calculated with the formula:

$$d(x,y) = \sqrt{\sum_{i=1}^{n}(x_i - y_i)^2}$$

The larger the Thiessen connectivity value, the closer neighboring roadless patches can be found. This is important for the integrity of landscape-scale processes (e.g., genetic exchange of metapopulations and endemics with narrow geographic ranges confined to roadless areas).

(3) Ecosystem Functionality Index *(9)*: This weighted, additive dimensionless index comprises vegetation density, tree height, carbon storage, species richness of vascular plants, plant functional richness and slope. Functionality is defined as "the state of ecosystems, characterized by inherent structures,

> ecological functions and dynamics, that provide ecosystems with both, the necessary efficiency and resilience to develop without abrupt change of system properties and geographical distribution, and allows for flexible response to external changes" *(9)*.

All indicators (Roadless area patch size, Thiessen connectivity, Ecosystem Functionality Index) were rasterized and adjusted in resolution and projection. A resolution of 0.002 (equally to 0.2 km) was chosen. ArcGIS 10.2 was used for projection, resolution and rasterization. All indicators were normalized between 0 and 100 and a weighted additive index was calculated using the software Insensa-GIS *(48)*. Thiessen connectivity into all directions and roadless areas patch size were weighted with 25%, whereas ecosystem functionality was weighted with 50%.

E. <u>Sensitivity analysis for the Ecological Value Index of Roadless Areas (EVIRA)</u>

Index construction always involves steps such as indicator selection and weighting. In order to transparently highlight the sensitivity of EVIRA to changes in these steps, we performed a statistical sensitivity analysis. Three different index versions were produced using jackknifing, ten of them using random weight variation within defined borders (connectivity into all directions and roadless area patch size 10-50%; ecosystem functionality index 30-70%) and one using equal weighting. Within the jackknifing procedure, three versions were created where each indicator was removed iteratively from the index calculation procedure. Overall 14 different index versions were created to perform the sensitivity analysis.

Pearson and Spearman rank correlation coefficients were calculated for the three indicators and EVIRA (Table S6). Significant and highly positive Spearman rank and Pearson correlation coefficients were found between the Ecosystem Functionality Index (EFI) (*9*) and EVIRA (Spearman r= 0.818; p<0.0001; Pearson r= 0.881; p<0.0001; Table S6). This is likely to be a consequence of the original weighting scheme of EVIRA, where EFI was given a weight double as high as the two other indicators. A high positive and significant Spearman rank correlation was also detected for roadless area patch size and EVIRA (Spearman r= 0.768; p<0.0001; Table S6). Therefore, EFI and roadless area patch size are the best single indicators for the final index output.

Mean values over all 14 index variations are shown in figure S6 with the highest values represented in blue and low values shown in orange. Similar to the original EVIRA, highest mean values are recorded for the Amazon, followed by the tundra and taiga of the northern and eastern lowlands of Siberia, as well as south-east Asian tropical rain forests.

The coefficient of variation was calculated over all 14 index variations to evaluate the variability of EVIRA (Fig. S9). Most parts of Australia show high levels of variation, as well as parts of Africa and central- and southwest Asia. The overall pattern is that regions with relatively high index values tend to have a lower coefficient of variation, whereas areas with high levels of variation tend to occur in regions with low index values. This results in a high confidence in the prediction of the ecological value, especially of those areas with high EVIRA values. A negative correlation coefficient between EVIRA and the coefficient of variation was detected (Spearman rank correlation: -0.97; Pearson correlation: -0.94). The volatility highlights the areas which were most frequently assigned a high index value (>70% of the maximum value) within the 14 different index variations

(Fig. S7). Very high readings were found for the sites with highest roadless area patch size as well as parts of Southeast Asia.

The proportion of area that changes its index value by less than 25%; between 25-50%; between 50-75%; and more than 75%, was explored for the equal weight method, and the three different index versions created by the jackknifing procedure (Fig. S8). Indicator selection seems to have a stronger effect on the output than the weighting scheme. More than half of the area changes its index value between 50 to 75% when connectivity into all directions was removed from the index, and 19% of the areas changed its index value by more than 75%. The exclusion of EFI showed that more than 60% of the area changed its index value between 25 and 50%. The removal of roadless area patch size (18% change in category 25-50%) and applying an equal weighting scheme (5% change in category 25-50%) did not change the index output significantly.

F. <u>Policy analyses: synergies and conflicts between conservation of roadless areas and conservation and sustainability agendas</u>

The "Aichi Biodiversity Targets" of the Convention on Biological Diversity (CBD) are part of the "Strategic Plan for Biodiversity 2011-2020" *(12)*. They circumscribe the United Nations' central agenda for the conservation of the Earth's diversity of life. They were adopted in October 2010 and comprise 20 targets that are grouped into five Strategic Goals. Seventeen "Sustainable Development Goals" (SDGs) have been defined within "Transforming our world: the 2030 Agenda for Sustainable Development" of the United Nations *(14)*, adopted in September 2015. They replace eight "Millennium Development

Goals" that were pursued from year 2000 to 2015 *(49)*. The SDGs are associated with 169 targets. Work on underlying indicators is ongoing; nevertheless, the latest report can provide direction for the interpretation of the goals and their respective targets *(50)*.

Specifically, our analyses of the global sustainability agendas aim at identifying potential synergies, conflicts and ambivalences between roadless areas conservation and the achievement of conservation and sustainability goals in the policy framework of the United Nations. In addition, these analyses indicate imminent conflicts among goals within the respective policy frameworks, particularly those concerning the global sustainability agenda. Furthermore, a considerable number of conservation and sustainability targets also were found to be ambivalent.

The calculation of conflict-synergy scores for the SDGs (Table S10) and the Aichi Strategic Goals (Table S11) is based on a simple index composed of individual scores attributed to all corresponding targets to which roadless areas are in some way applicable. We excluded the targets related to governance in general (marked by a combination of number and letter, e.g. "13.a") from the analysis, thus reducing the number from 169 to 126. The individual scores for targets can have three discrete values:

- -1 (indicated by blue color): conservation of roadless areas is in conflict with the achievement of the target;
- 0 (yellow): conservation of roadless areas has an ambivalent relationship with the achievement of the target; and

- 1 (green): conservation of roadless areas is in synergy with the achievement of the target.

Roadless areas do not relate to a number of targets; these targets are therefore excluded from the analysis (indicated by grey color). The conflict-synergy score for a goal is calculated as the mean of all values for corresponding targets. The scores can, thus, vary between -1 and +1. They are classified as follows:

- <-0.5 (indicated by blue color): conflicts with goal prevail;
- -0.5 to 0.5 (yellow): mixture of synergies and conflicts with goal; and
- >0.5 (green): synergies with goal prevail.

The conflict-synergy scores for goals are also visualized by the colors in the large boxes of Tables S10 and S11.

SUPPLEMENTARY FIGURES (S1-S11)

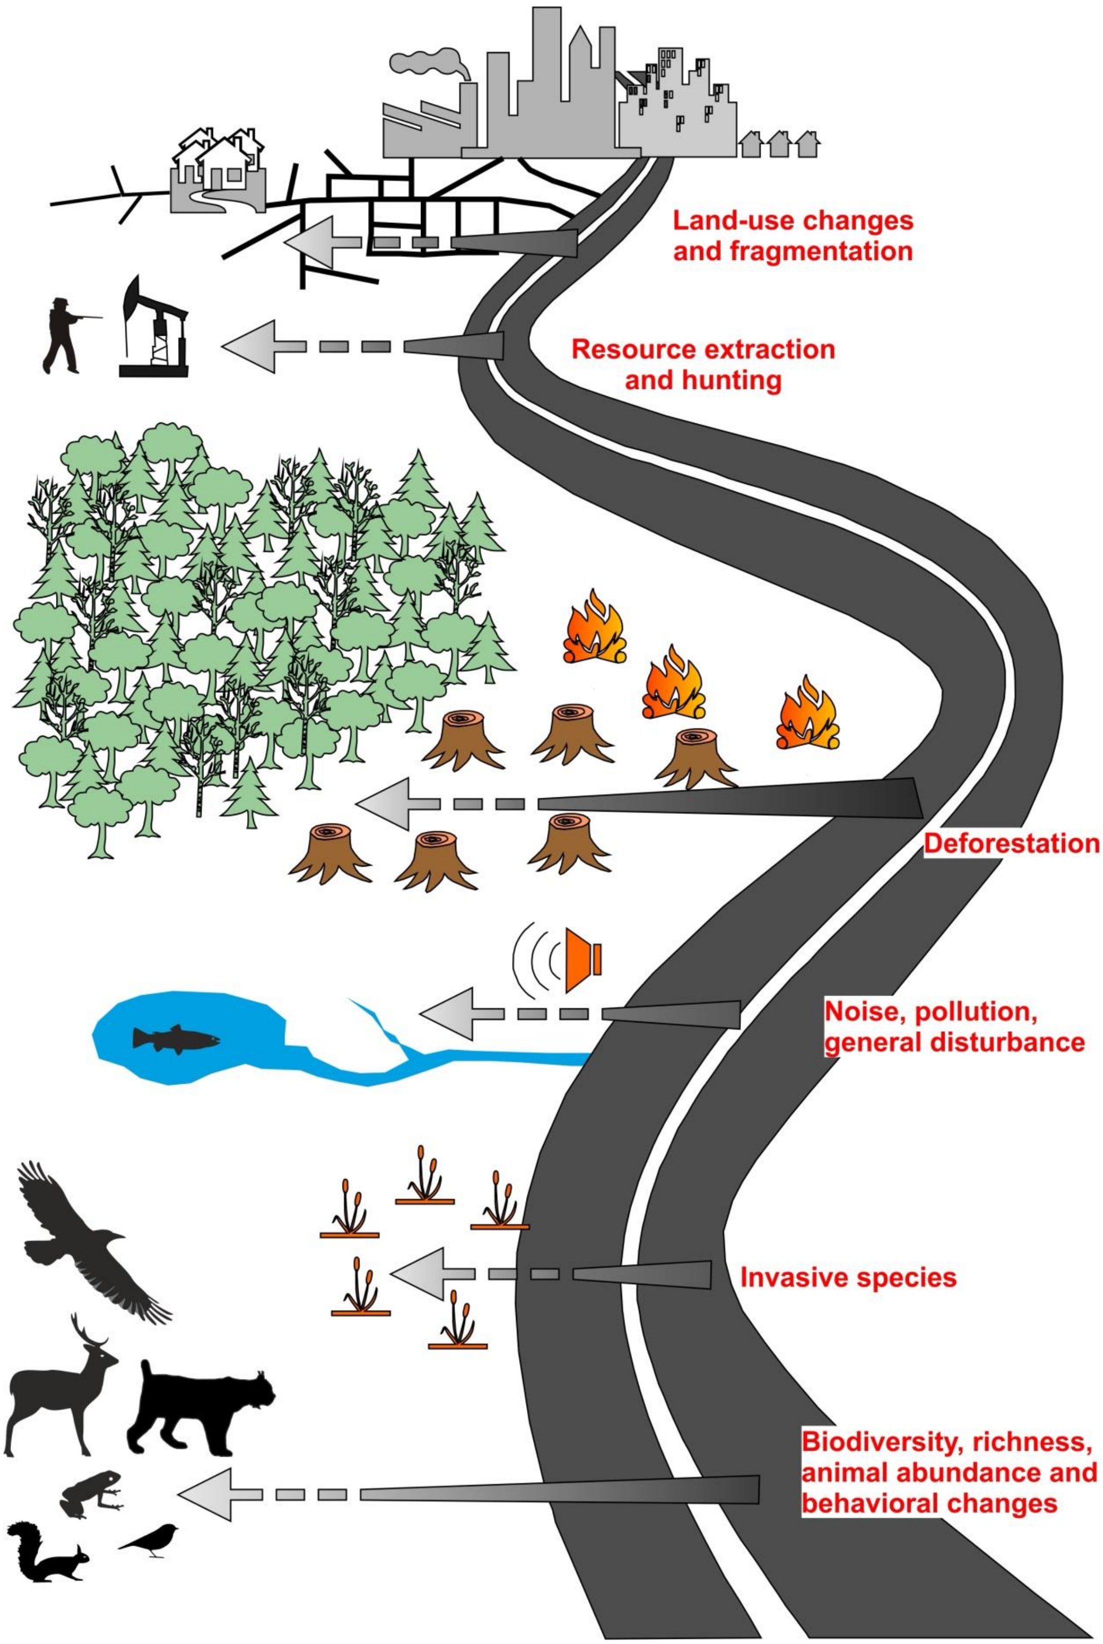

Fig. S1. Schematic representation of different categories of road impacts on biodiversity. These impacts decrease with the distance from the road. Road effects generally attenuate beyond one kilometer distance from the road (see literature review in table S2). One kilometer was therefore selected as a buffer to identify roadless areas as those areas relatively free from road disturbances.

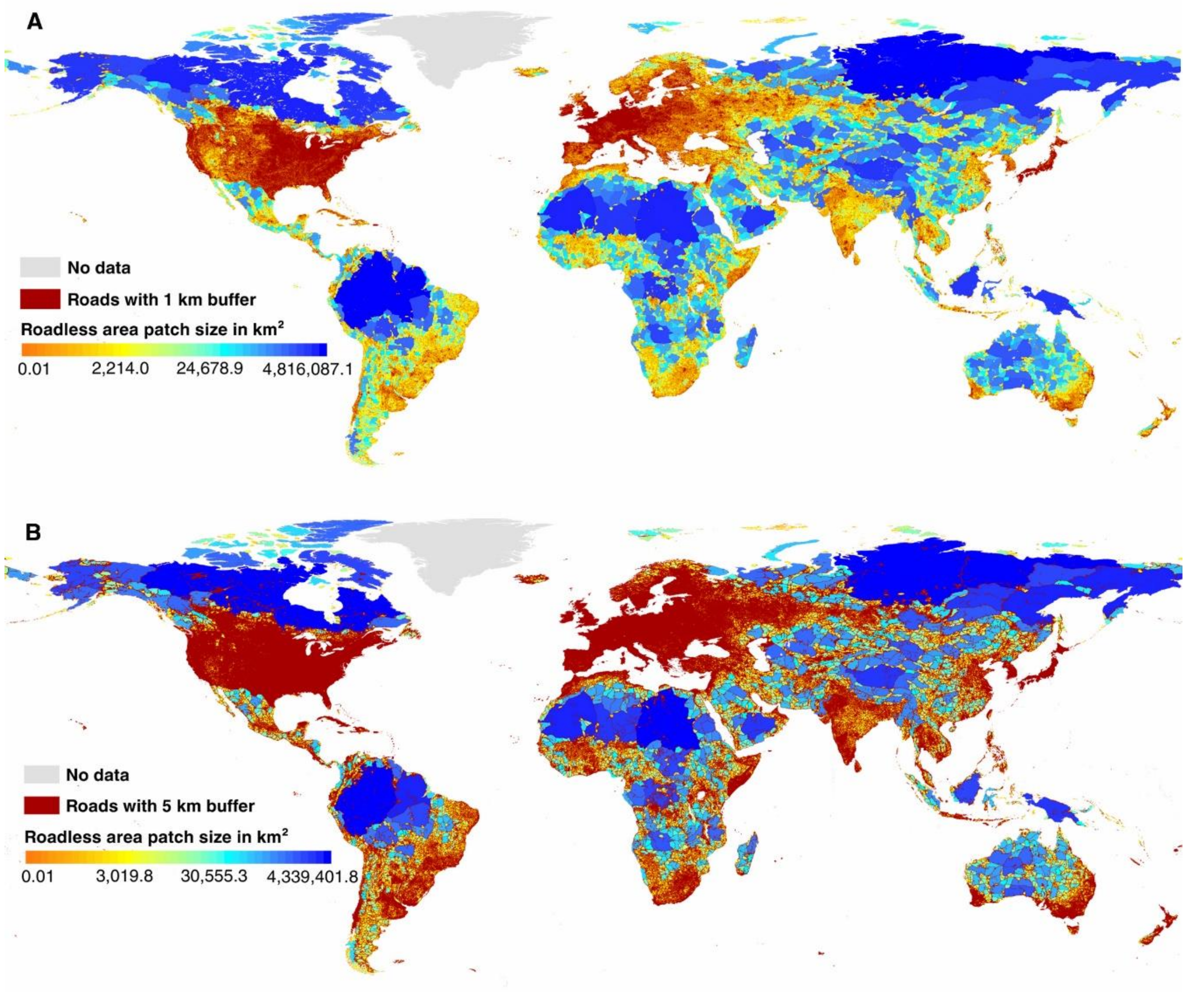

Fig. S2. The global distribution of roadless areas based on a (A) 1-km and a (B) 5-km buffer to all roads included in the OpenStreetMap data set (11/2013).

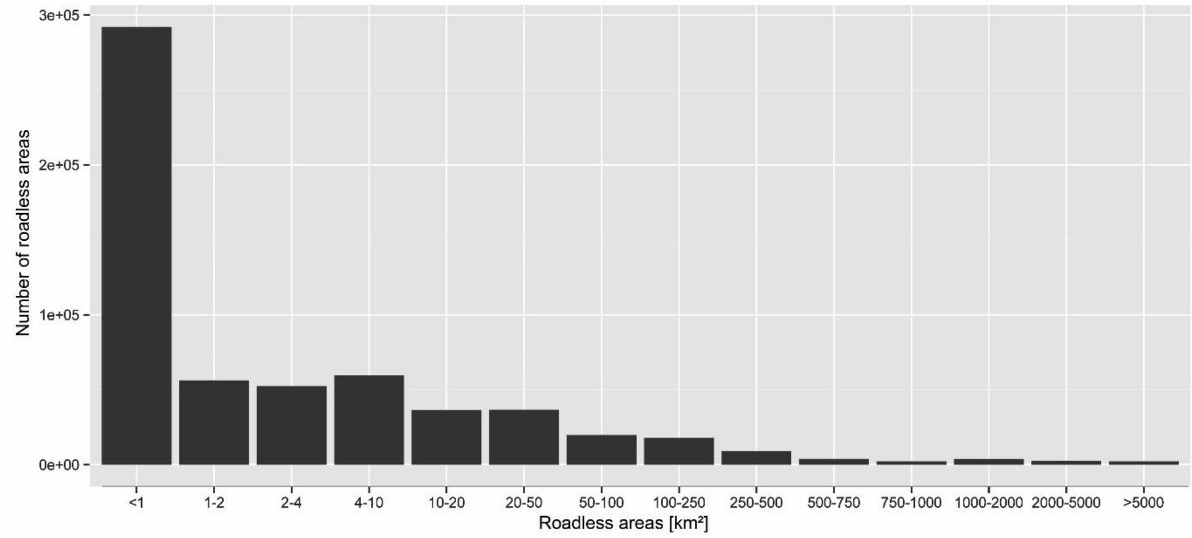

Fig. S3. Frequency of global roadless areas size classes based on 1-km buffer to all roads included in the OpenStreetMap data set (11/2013).

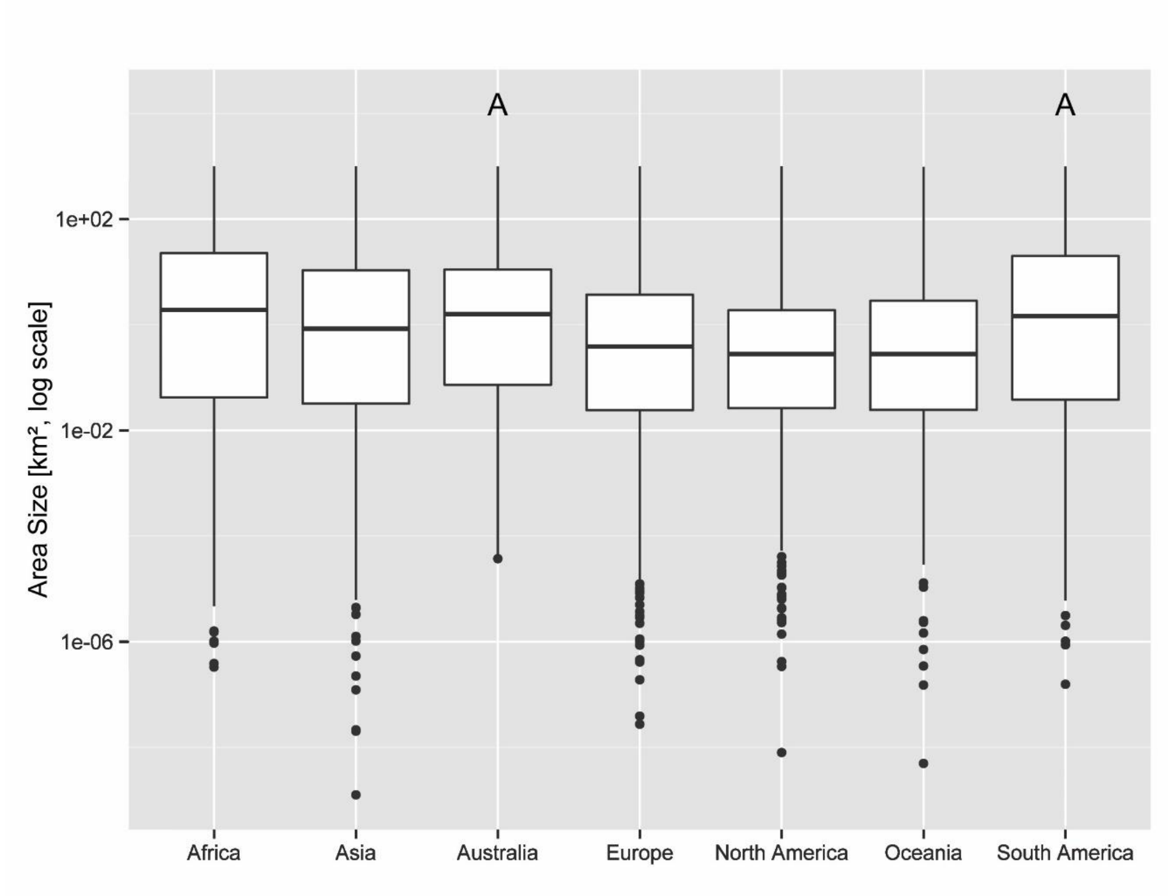

Fig. S4. Sizes of roadless areas across continents based on 1-km road buffer using the OpenStreetMap data set (11/2003) (Pairwise Wilcox test; “A” indicates that the corresponding distributions are not significantly different; p<0.001).

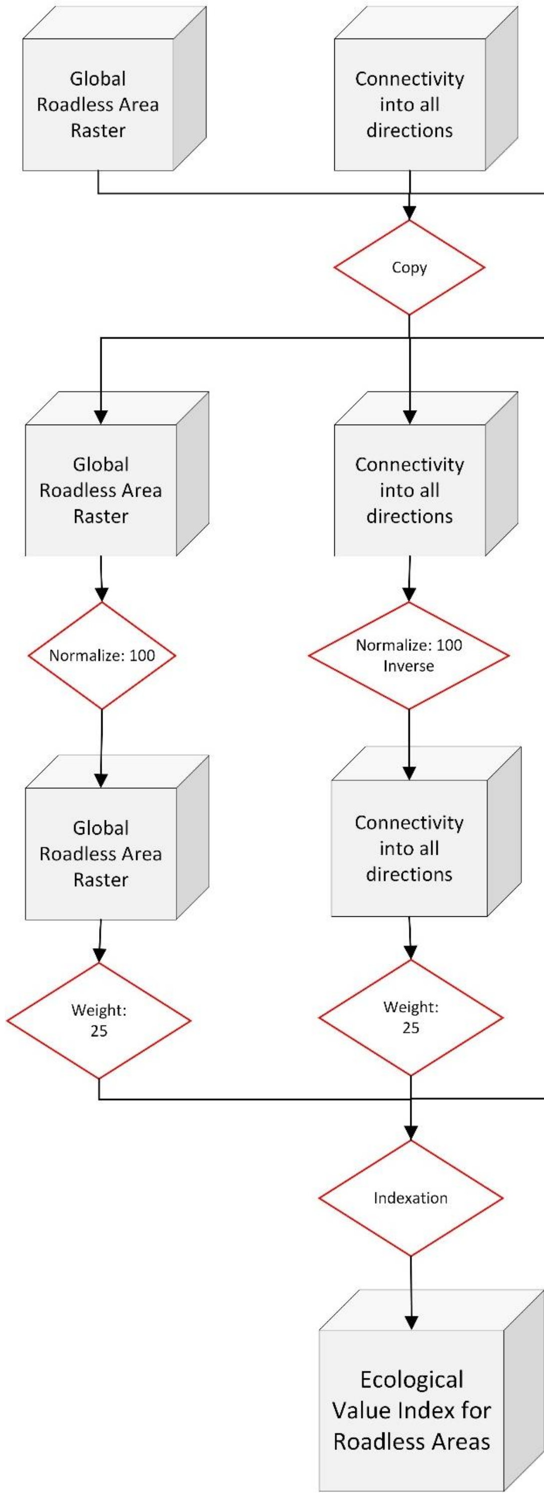

Fig. S5. Workflow of the indexation process for creating the *Ecological Value Index of Roadless Areas* (EVIRA).

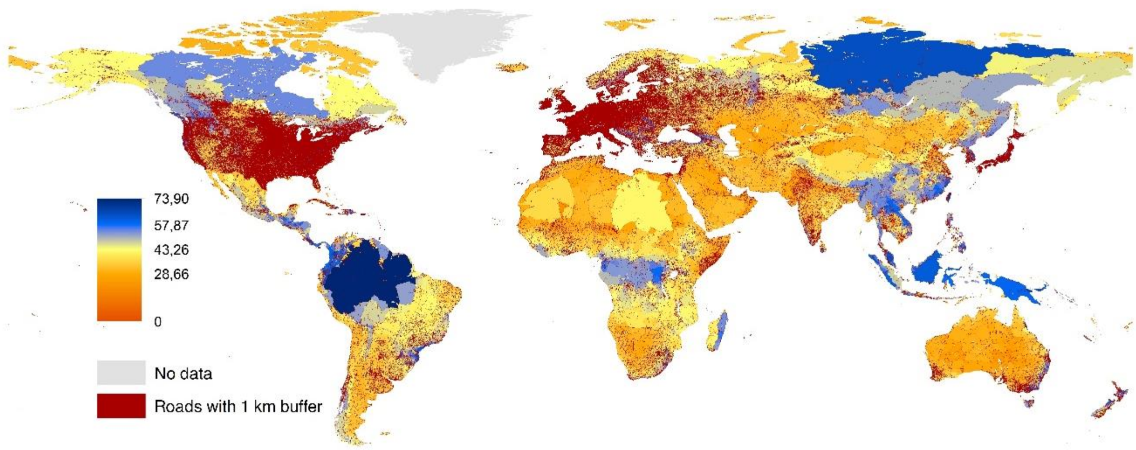

Fig. S6. Global map of mean values over 14 different index variations for the Ecological Value Index of Roadless Areas (EVIRA). Class breaks were calculated using the Jenks breaks algorithm.

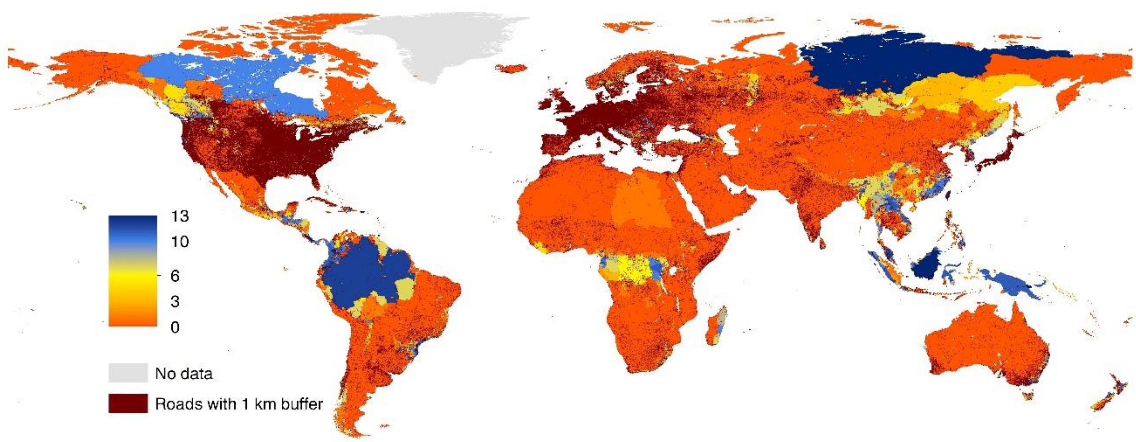

Fig. S7. Global map of volatility (frequency of that the value achieved at least 70% of the maximum index value) of the ecological value index of roadless areas (EVIRA) over all 14 index variations.

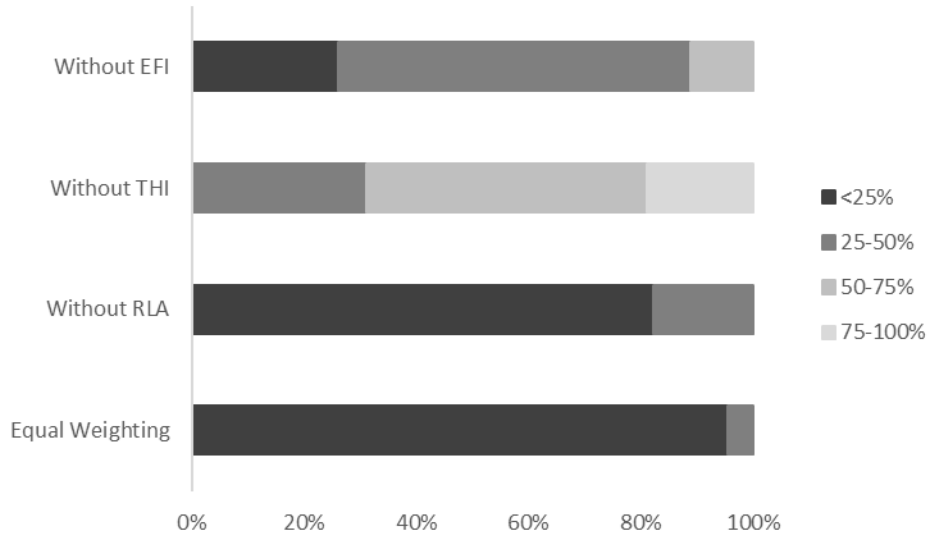

Fig. S8. Proportion of global area whose EVIRA value is changing < 25%, 25-50%, 50-75% and >75%, as shown by the sensitivity analysis. The three indicators making up the EVIRA index are the Ecosystem Functionality Index (EFI), the Thiessen connectivity into all directions (THI) and the Roadless area patch size (RLA).

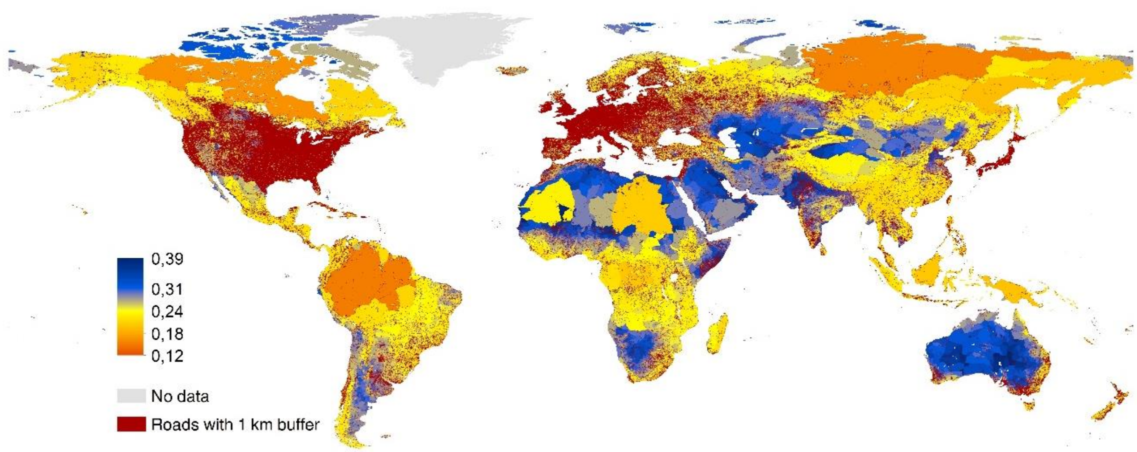

Fig. S9. Mean statistical sensitivity of the Ecological Value Index of Roadless Areas (EVIRA) as overall coefficient of variation of 14 index variations.

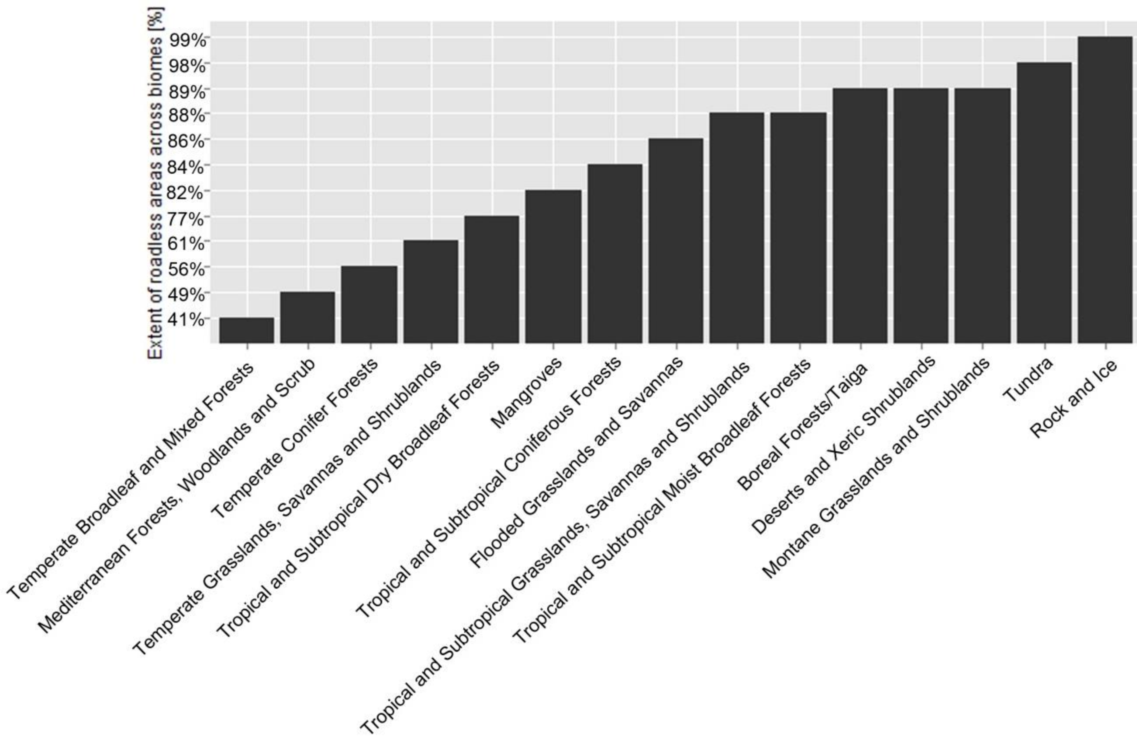

Fig. S10. Extent of roadless areas across biomes (without freshwater bodies, Antarctica and Greenland) according to classification by Olson et al. (2001) *(51)* and based on 1-km buffer to all roads included in the OpenStreetMap data set (11/2013).

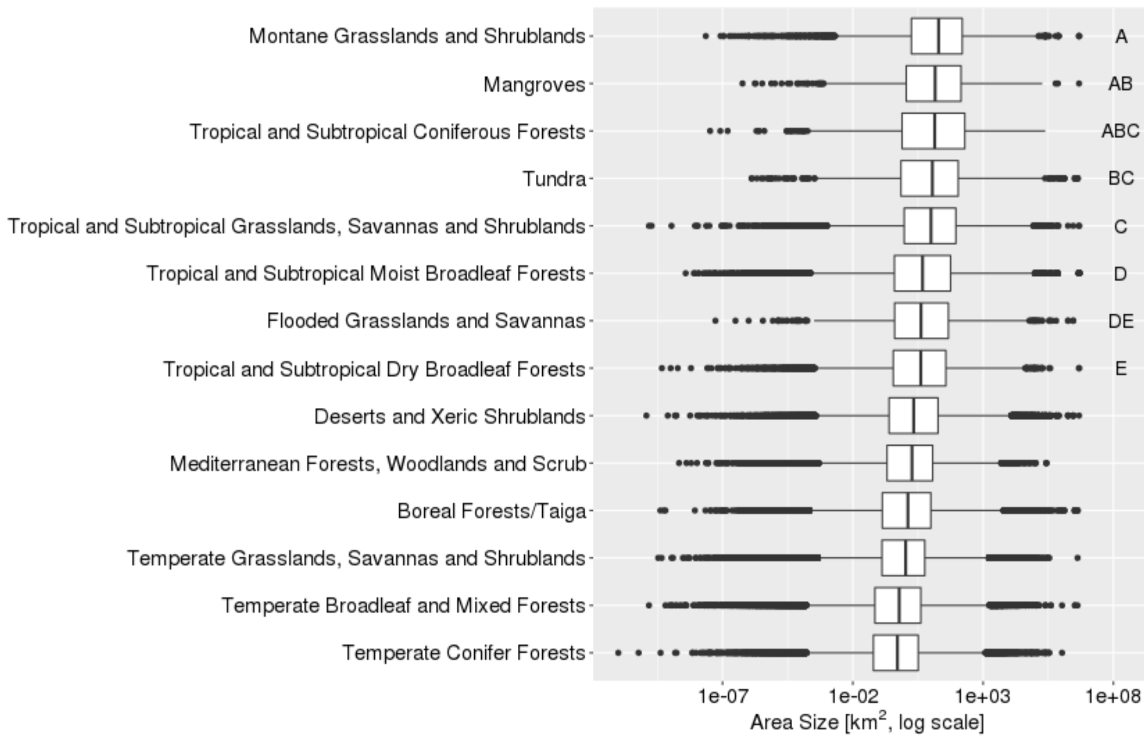

Fig. S11. Size distribution of roadless areas across different biome types assessed with a 1-km road buffer using the OpenStreetMap data set (11/2003) (Pairwise Wilcox test; if biomes share the same capital letters, then corresponding distributions are not significantly different; p<0.001).

SUPPLEMENTARY TABLES (Table S1-S11)

Table S1. Extent of 1-km-buffer roadless areas for Sabah, Malaysia, comparing three different road data sets (OpenStreetMap 11/2013, CIESIN 2013, CIFOR 2014).

	Roadless areas (km²)	**Roadless areas coverage (% of the territory of Sabah)**
Sabah total area	73,841.91	
Roadless areas using OSM data	66,944.69	91
Roadless areas using CIESIN data	68,271.54	92
Roadless areas using CIFOR data	29,700.56	40

Table S2. List of studies documenting or assuming road-effect zones or investigating the spatial influence of road effects. Studies are ordered according to the most important effect described (some studies dealt with more than one effect).

Road type or data	**Study system and location**	**Road effect tested**	**Effect description**	**Spatial range of influence of the road effect**	**Reference**
CHANGES IN ANIMAL ABUNDANCE, DENSITY AND POPULATION SIZE					
Highway, secondary, rural and cyclist road	Polders, farming areas, reclaimed marshland (Netherlands)	Changes in population density of four bird species	Population density increases with distance from the road for black-tailed godwit (*Limosa limosa*) and the lapwing (*Vanellus vanellus*), but not the other species	Up to 1,800 m	*(52)*
Highway	Willow coppices and shrubs (central Netherlands)	Density of territorial males of willow warblers (*Phylloscopus trochilus*)	Lower density of territorial males, lower presence of older males, 50% higher proportion of yearling males and 50% lower success of yearling males in the road zone Total annual output of males/ha 40% lower in the road zone	Road zone assumed as 200 m from the road; intermediate between 200-400 m, and control 400 m	*(53)*
Paved major roads with different traffic volume	Deciduous and coniferous woodland crossed by main roads (Netherlands)	Breeding density of woodland birds	Reduced density in 60% of the species adjacent to roads, due to noise	The maximum reduction of car noise at 200 m from the road The majority of the species (75%) showed maximum effect distances	*(54)*

				between 100 and 1,500 m For all species combined, the effect distances varied between: - 40-1,500 m and 70-2,800 m for roads with 10,000 and 60,000 cars/day, respectively, in deciduous woodland - 50-79 m and 100- 1,750 m for roads with 10,000 and 60,000 cars/day, respectively, in coniferous woodland	
Paved major roads with different traffic volume	Open moist grassland (N and W Netherlands)	Breeding densities of bird species, including waders	Most species had reduced density close to the road; this effect was very strong for the summed density of all species	For the density of all species combined, the disturbance distance was 120 m and 560 m for 5,000 and 50,000 cars/day, respectively. Among species, disturbance distance varied between 20-1,700 m at 5,000 cars/day, and 75- 3,530 m at 50,000 cars/day At 5,000 cars/day, 7 out of 12 species had an estimated population loss of 12-56% within 100 m of roads. At further distances, such reduction occurred in the black-tailed godwit (*Limosa limosa*, 22% in the 0-500 m zone), and the oystercatcher (*Haematopus ostralegus* 44% up to 500 m and 36% for 0-1,500 m zone). At 50,000 cars/day all species showed an estimated population loss of 40-74% within 100 m of the road and >10% at 0-500 m. Five species showed reductions of 14-44% up to 1,500 m	*(55)*
All roads	Rural area (Ontario, Canada)	Effect of traffic on population abundance of green frogs (*Rana clamitans*) and leopard frogs (*Rana pipiens*)	Negative effect of traffic density on leopard frog abundance (more vagile species), but not on green frog abundance	Leopard frog population density negatively affected by traffic density within a radius of 1.5 km	*(56)*
Highway	Desert (California, USA)	Tortoise activity and presence	Tortoise signs increasing with distance from the highway edge	Tortoise populations depressed in a zone extending at least 400 m from the road	*(57)*
Unpaved roads, mostly	Lowland tropical	Abundance of	Most species responded	Effects measures up to 1.2	*(58)*

from oil and logging companies	rainforest (SW Gabon)	mammal species	negatively to roads	km from the road	
Low-traffic road within forest	Deciduous forest (USA)	Change in abundance of salamander species	Reduction in salamander abundance	>35 m	*(59)*
Highway	Protected forest and commercial timberland (Adirondack Mountain, New York, USA)	Impact of road de-icing salts on the reproduction of adults and growth and survival of embryonic and larval of spotted salamander (*Ambystoma maculatum*) and wood frog (*Rana sylvatica*)	High concentration of salt reduced amphibian species survival close to the road (decline of embryo and larvae survival rate) A demographic model predicting population size decrease due to exposure to road salt (embryo and larva mortality effect); stronger effect closer to the road	Salt traveled up to 172 m from the highway into wetlands The negative effect of road salt on population sizes up to 200 m	*(60)*
Highway	Desert (Utah, USA)	Abundance and density of small mammals	No clear abundance, density, or diversity effects relative to distance from the road Species-specific response	No road-effect zone measured up to 400 and 600 m from the road in each of the two study years	*(61)*
All road types and also other infrastructure	Various; meta-analysis of 49 studies on 234 mammal and bird species	Road avoidance and reduced population density of birds and mammals	Mammal and bird population densities declined with their proximity to infrastructure Stronger avoidance in open areas compared to forested areas Habitat- and species-specific response	Up to about 1 km for birds, and up to about 5 km for mammal populations	*(62)*
Paved highway	Boreal forest (Canada)	Population density of brook charr (*Salvelinus fontinalis*) in streams	Population density differed markedly between upstream and downstream sites near highway crossings (of intermediate and low passability)	Up to 800 m from highway	*(63)*
Phantom road	Fir forest and cherry bushes (Idaho, USA)	Simulated traffic noise effect on bird abundance	Serious (25%) decline in bird abundance and almost complete avoidance by some species between noise-on and noise-off periods along the phantom road; such effect was not detected at control sites	Control sites at ca 800 m	*(64)*
Highway	Mountainous area with shrub-steppe vegetation (Ghamishloo Wildlife Refuge, Iran)	Loss of suitable habitat and disruption of the distribution pattern of two ungulate species, the goitered gazelle (*Gazella subgutturosa subgutturosa*) and the wild sheep	51% and 10% of high quality habitat unavailable for gazelle and sheep, respectively, due to road construction Presence points increased with road distance	Large increase in presence at > 3km from the road	*(65)*

		(*Ovis orientalis isphahanica*)			
Highways and national roads	Mediterranean agricultural landscape and cork oak woodland (Alentejo, Portugal)	Likelihood of owl species (barn owls *Tyto alba*, tawny owls *Strix aluco* and little owls *Athene noctua*) occurrence	Higher probability of owl occurrence at longer distance from major roads, particularly for barn owl	Owl presence occurred at further distances (1,591 ± SD 960 m) than absences (1,097 ± SD 826 m)	*(66)*
Paved interstate and county roads	Desert (Mojave, California, USA)	Signs of Mojave Desert tortoise presence (*Gopherus agassizii*)	Tortoise signs increased significantly with distance from roads	Reductions in signs extended farther from the high-traffic interstate than from the smaller, lower-traffic county roads (306 m versus 230 m)	*(67)*
Wide paved and minor unpaved roads	Mediterranean scrubland, dunes and wetlands (Doñana Biosphere Reserve, S Spain)	Presence probability of two ungulates, red deer (*Cervus elaphus*) and wild boar (*Sus scrofa*)	Presence probabilities for both species increased with the distance to the nearest road, in most cases were unpaved roads with negligible traffic volume	At 180 m from the nearest road, wild boar presence probability was lower than 0.2, and for red deer was lower than 0.7	*(68)*
MODIFICATION OF ANIMAL BEHAVIOR					
Highway	Willow coppices and shrubs (central Netherlands)	Breeding dispersal of male willow warblers (*Phylloscopus trochilus*)	Higher proportion of yearlings dispersing and longer dispersal distance in the road-zone	Road zone assumed as 200 m from the road; intermediate between 200-400 m, and control 400 m	*(69)*
Highway and major railroad line	Mountain areas covered mostly with mixed coniferous forest, valleys and prairies (Montana, USA)	Movements of grizzly bears (*Ursus arctos*)	Highway crossing frequency declined exponentially with increasing traffic volume Avoidance of areas close to the highway	Bears strongly avoided areas within 500 m of the highway (asymptote within the 500-600 m category)	*(70)*
Roads in rural areas	Steppe (Patagonia, Argentina)	Flying and feeding behavior of scavenger species	Flying activity and carcass detection was greater near roads (500 m buffer) Andean condors (*Vultur gryphus*) and black-chested buzzard-eagles (*Geranoaetus melanoleucus*) fed far from roads, while other species fed close to roads	Optimal distance for feeding activities for condors and eagles was 3,110 and 10,460 m from the road, respectively, and for the other species, from 218 to 365 m	*(71)*
Paved and unpaved roads	Steppe (Patagonia, Argentina)	Andean condor (*Vultur gryphus*) behavior at carcasses	In the patches far from roads many more condors came to feed, the average time spent per individual was longer, the proportion of time spent vigilant was lower, and the amount of food left uneaten on the carcasses was lower	Up to 350 m	*(72)*

Two-lane roads	Arid shrublands and grasslands (California, USA)	Changes in survival, reproduction, space use, den-site selection, prey availability, and diet of San Joaquin kit foxes (*Vulpes macrotis mutica*)	No effects of the distance to the road on survival, reproduction, litter size, space-use patterns and diet	No effects from 0 m to > 1,760 m from the road	*(73)*
Several types, from highways to unpaved roads	Lentic water bodies including ponds, lakes, dams, and quiet pools within streams (S Victoria, Australia)	Traffic noise effect on the pitch of advertisement calls in two species of frogs, the southern brown tree frog (*Litoria ewingii*) and the common eastern froglet (*Crinia signifera*)	Tree frogs call at a higher pitch in traffic noise and shift the call frequency	Maximum noise at 40 m from highway	*(74)*
Paved roads	Various, review of 25 studies on 13 raptor species	Raptor nest location	Meta-analysis showed an overall positive impact on the displacement of nests from roads Big raptors nesting in trees exhibited greater displacement distances from nests to roads than big raptors nesting in cliffs Distance from nests to roads increase 20–30% compared to control random points	The absolute magnitude of the displacement distance of raptor nests ranged between 200 and 800 m from the road, and 1,400 m for tree nesting raptors of big size, such as large eagles and vultures	*(75)*
Highway and railway line	Mixed woodland (Buunderkamp, Netherlands)	Traffic noise and effects on vocal activity and reproductive success of great tits (*Parus major*)	Traffic noise strongly decreased with distance from the motorway and varied with the time of day, season and weather conditions Noise levels affected negatively the reproductive success of great tits (smaller clutches and fewer fledged chicks in noisier areas)	Average drop of 20 dB SPL in sound levels over less than 500 m from the road Over 400 m from the motorway, mainly bird vocal activity influenced variation in sound levels in the 4 kHz band	*(76)*
Highway	Road verges, bushes, open fields, intermittent trees, woodland (UK)	Bat activity and diversity	Total bat activity, the number of species and the activity of *Pipistrellus pipistrellus* (the most abundant species) were all positively correlated with distance from the road	Activity and diversity increased up to 1.6 km either side of the road	*(77)*
Several road types (paved roads, gravel roads, unimproved roads, truck trails and ATV trails)	Montane ecosystem (Rocky Mountains, Canada)	Alteration of red deer (*Cervus elaphus*) behavior	Deer close to roads decreased their feeding time and increased vigilance and time spent travelling More evident when traffic surpasses 12 vehicles per day	Switch into a more-alert behavior closer than 500 m to roads with more than 12 vehicles/day Twice longer foraging bouts, 20% increase in feeding time, 23% vigilance decrease and 10% decrease in travelling	*(78)*

				time in deer >1 km from roads	
Forest and main roads	Fir–beech forests (Dinaric Mountains, Slovenia)	Home-range size of red deer (*Cervus elaphus*)	Home-range size increased as the distance of main roads from the edge of the home range increased	Home range stabilizes at ca 1,800 m from the road	*(79)*
Highway and dirt roads	Tropical forest in metropolitan area (SE Brazil)	Scavenger removal of experimentally-placed carcasses	High carcass removal for both road categories, with a peak during the day on the highway and at night on dirt roads	Road-effect zone as assumption: >1 km from the highway there is no effect of highway on the carcass removal rate in dirt roads	*(80)*
Forest roads	Scrublands and oak and mixed forests, and portions of natural grasslands, and agricultural areas (central and northern Greece)	Rendezvous site selection by wolves (*Canis lupus*)	Rendezvous sites were located away from forest roads (most important factor at home-range scale)	Wolves selected rendezvous sites farther from forest roads (mean= 435 m, range=73–1,614 m)	*(81)*
Paved and unpaved roads for visitors use	Open grasslands, bush, savanna and woodlands (Kruger National Park, South Africa)	Behavioral response and local spatial distribution of impala (*Aepyceros melampus*)	Impalas change their local spatial distribution near paved and well-traveled roads; unpaved roads largely unaffected their local distribution Greater tolerance distances on paved roads compared to unpaved roads. More flight response in unpaved roads Few flight response (19.5%); habituation may exist	Mean flight distance from the road 30.5 m (range 0–154) vs 35.0 m (range 0–215) for those animals that did not respond. Animals avoid close proximity (first 10 m) to paved roads	*(82)*
REDUCTION OF SPECIES RICHNESS AND DIVERSITY					
Two-lane roads	Mosaic of forest, shrubland and pastures, among 12 cities and close to cities (NW Madrid, Spain)	Abundance and species richness patterns of the native avifauna in fragmented landscape	Total number of bird species, total bird abundance and number of threatened species was negatively influenced by the distance to the nearby roads The abundance of urban-exploiter bird species increased closer to roads	In general, significant threshold distances averaged 300 m for roads, but varied among parameters Mean species richness was lowest <110 m from the road and highest >1,030 m Number of threatened species decreased <400 m from road Highest bird abundance at 290-540 m from the road in deciduous forest areas Abundance of urban exploiters increased if roads <510 m	*(83)*
Paved roads	Wetlands (Southern	Richness of four different wetland	Plant, bird, and herptile species richness diminishes	Strongest relationships at distances up to 1,000 to	*(84)*

	Ontario, Canada)	taxa (birds, mammals, herptiles, and plants)	with increasing density of paved roads on adjacent lands	2,000 m from the wetland edge Critical distance for plants is between 1 and 2 km from the wetland edge; for birds, between 0.5 and 1 km, and for herptiles and mammals at least 2 km	
Unpaved forest roads	Forest (S Appalachian Mountains, Tennessee, USA)	Abundance and richness of the macroinvertebrate fauna of the soil and leaf-litter depth	Reduced both the abundance and the richness of the macroinvertebrate soil fauna and the depth of the leaf-litter	Effects on faunal abundance and leaf-litter depth up to 100 m into the forest (max distance tested), whereas persists to 15 m	*(85)*
Unpaved forest roads	Temperate deciduous forest (USA)	Change in the distributions of understory plants, and site variables (species cover, canopy cover, litter depth and cover, and bare ground)	Richness and diversity of native species were lower on roadsides Exotic species were most prevalent near roads Roads created a disturbance corridor that affected site variables	Native species richness back to normal levels after 5 m distance Prevalence of exotic species and effects on site variables up to 15 m	*(86)*
Highways (plus other anthropogenic barriers)	Desert regions (California, USA)	Genetic diversity in metapopulation of desert bighorn sheep (*Ovis canadensis nelson*)	Reduction in the relative gene flow among study populations Decline in genetic diversity at a rate of 0.4% per year	Barrier effect distance (at which relative gene flow decrease equivalently) estimated at c. 40 km	*(87)*
Several road types (highway, paved rural road, unpaved dirt road)	Second-growth forest (Orange County, New York, USA)	Diversity, abundance and species density of carrion beetles	No consistent effects of distance from road on the diversity, abundance or species density of beetles across road types Forests near highways and paved rural roads were less diverse than near dirt roads	No effect up to 120 m from the roads (suggestion that road effect can permeate further)	*(88)*
Highway	Rural area (Ontario, Canada)	Anuran species richness and relative abundance for seven species	Species richness and abundance declined closer to the road Suggestion that new roads should be at least 500 m from wetlands (conservative estimate of the road-effect zone for species richness), but greater buffer distances recommended (at least 3,000 m for leopard frogs *Rana pipiens*)	Road-effect zones of 250–1,000 m for four of seven species and species richness, and well beyond 1,000 m for two species. Breakpoint at approximately 450-800 m from the highway for species richness; 200-300 m for the spring peeper (*Pseudacris crucifer*), American toad (*Bufo americanus*), and gray treefrog (*Hyla versicolor*); 600–1,000 m for the wood frog (*Rana sylvatica*); and 1,100 to 2,400 m for the chorus frog (*Pseudacris triseriata*)	*(89)*

High-traffic paved roads	Boreal forest (Canada)	Change in breeding bird occurrence	Bird species richness increased with increasing distance from roads Traffic noise declined with distance from the roads	Bird species richness reached a maximum at about 350 m from the road Traffic noise reached a minimum at about 450 m from the roads	*(90)*
Low-traffic unpaved roads	Tropical rainforest (Amazon, Ecuador)	Change in species richness and diversity of amphibians, butterflies and birds	Amphibian richness and understory bird richness and diversity decreased near roads Butterfly and overall diurnal bird richness increased near roads Taxon-specific response to roads	Up to 200 m from the road for butterflies, up to 250 m for amphibians and up to 350 m for birds	*(91)*
PROMOTION OF INVASIVE SPECIES					
Paved roads	Grasslands (California, USA)	Native and exotic plant diversity	In non-serpentine grasslands the percentage cover by native species, the percentage of species that were native, and the number of native grass species increased with distance from roads, while the cover by exotic species and number of exotic forb species decreased No effect of road proximity in serpentine grasslands	Native cover was greatest in sites >1,000 m from roads (23%) and least in sites 10 m from roads (9%) Percentage of species that were native was significantly greatest in sites >1,000 m from roads (44%) and least in those 10 m from roads (32%)	*(92)*
Paved roads	Grasslands (California, USA)	Survival and biomass of the invasive plant yellow starthistle (*Centaurea solstitialis*)	In non-serpentine grasslands, *Centaurea* survival and biomass was greater in sites closer to roads No effect of road proximity on the performance of planted *Centaurea* on serpentine soil	Survival and biomass greater in near (10 m) than in distant (>1,000 m) plots	*(93)*
All types, from highways to dirt roads, typically two-lane dirt and paved roads	Mature sugar maple-dominated forests (W Great Lakes, Minnesota and Wisconsin, USA)	Extent and patterns of earthworm invasion	Distance to the nearest road was the best predictor of earthworm invasion in Wisconsin Negative relationship between the distance to the nearest road and the presence of four taxonomic groups, except *Dendrobaena* which had positive	The invasion of the *Lumbricus–Aporrectodea* assemblage generally extends nearly 1,200 m from roads. The probability of occurrence does not decline below 50% until 470-930 m, and to 5% until the nearest road is > 1,300 m away Probability of finding *Dendrobaena* alone increases with road distance crossing 50% at >1,540 m.	*(94)*
Paved and forest roads	Deciduous forest (Maryland, USA)	Presence and percent cover of invasive plant species	More invasive species close to roads; sites containing three or more invasive species observed along paved roads Spread rates are higher in roadsides; roadside populations occupied a larger patches and expand more	Effects measured up to 150 m from the road; the range of influence is greater following the spread of the species	*(95)*

			rapidly		
High, medium and low traffic roads	Dry deciduous forest (India)	Presence of invasive plants	Increase in the presence of invasive plant species near roads, especially in medium and high traffic roads	Up to 100 m (not measured further)	*(96)*
Primary roads	Terrestrial, freshwater and marine ecosystems (NW Europe, encompassing Great Britain, France, Netherlands and Belgium)	Distribution of invasive species (72, including 17 terrestrial plants, 19 terrestrial animals, 17 freshwater and 19 marine organisms)	Roads promote the dispersal of non-native species Proximity to roads was a particularly important driver for plant species distribution	Maximum probability of invasion of two plants, the Kudzu (*Pueraria lobata montana*) and Kahili ginger (*Hedychium gardnerianum*) within 2 km from roads	*(97)*
INDUCING DEFORESTATION					
Highways	Tropical rainforest (Amazon, Brazil)	Deforestation through forest conversion to crops, pastures and secondary forest	Deforestation has claimed 29-58% of the forests within 50 km of paved roads	More than two-thirds of Amazon deforestation within 50 km of major paved highways	*(98)*
Highways and unpaved roads	Tropical rainforest and adjoining woodlands and savannas (Amazon, Brazil)	Deforestation	Proximity to roads, particularly to highways, increased deforestation	Deforestation rose mostly sharply within 50-100 km of highways and within 25-50 km of unpaved roads	*(99)*
Paved and unpaved roads	Tropical rainforest (Amazon, Brazil)	Deforestation spillover	Deforestation rises in sites that lack roads but are in the same county as site with a new paved or unpaved road	100 km	*(100)*
State and federal roads, some private roads	Tropical rainforest (Amazon, Brazil)	Deforestation fires (measured by hot pixels)	Exponential declines in hot pixel frequency with increasing distance from roads Fewer deforestation fires within protected areas than outside	Almost 90% fires were ≤10 km from roads	*(101)*
Paved and unpaved roads	Tropical rainforest (Southern Amazon, Peru, Brazil, Bolivia)	Deforestation	Deforestation rates drop with distance from major roads, although the distance before this drop off appears to relate to degree of road paving at regional level	45 km for roads where paving is complete; 18 km where paving is underway	*(102)*
Highway	Cerrado Savannas (Brazil)	Deforestation and habitat degradation	Deforestation increases closer to the roads, with pasture growing near the road, and forest cover growing further away	32.6% loss of Cerrado up to 9 km from the highway	*(103)*
Official and unofficial roads	Tropical rainforest (Amazon,	Deforestation	Deforestation was much higher near roads Protected areas near roads had	Nearly 95% of all deforestation occurred within 5.5 km of roads	*(104)*

	Brazil)		lower deforestation than did unprotected areas near roads	Highways begin to have a rapidly diminishing influence only at 32 km	
CHANGE OF LANDSCAPE PATTERNS AND FRAGMENTATION					
All road network, mainly composed of minor roads	17 townships across three ecoregions of forested landscapes (n. Wisconsin, USA)	Changes in landscape patterns and road density in a six-decade study period	Substantial changes in landscape patterns Road density doubled and the immediate area affected by roads increase twofold (5% to 10%). Reduction of median, mean and largest roadless patch size by a factor of four. Increases in housing density and fragmentation	Road-effect zone as assumption: 15 m	*(105)*
FACILITATION OF RESOURCE EXTRACTION AND HUNTING					
Road for oil extraction and access from rivers	Amazon Basin (Yasuní Biosphere Reserve, Ecuador)	Probability of hunting by the Waorani indigenous group	Spatial extent of hunting doubled in the presence of road, and include remote areas	Mean distance walked from a point of access (road, river) to a kill site was 1.36 km (SD=1.18), and the maximum distance was 7 km (99% records <5 km)	*(106)*
NOISE INCREASE					
Busy roads (and other sources of noise)	Various (review paper)	Effect of noise (sound pressure level) on response curve of species occupancy (general model)	Spatial propagation of elevated noise levels from a point source (such as a single car, which decays at a spreading loss of 6 dB or more per doubling of distance, line sources (such as a busy highway) lose only 3 dB per doubling of distance	The sound pressure level of noise decreases with increasing distance but may not reach "baseline" ambient levels until ~1 km away (this distance will vary depending on noise source and the environment)	*(107)*
VARIOUS					
Highway	Suburban landscape, including swamps, streams, wetlands, deciduous forest, open-fields, residential areas (Massachusetts, USA)	Alteration of streams, wetland drainage, road salt reaching water bodies, invasion by exotic species, changes in habitat and movement patterns of large mammals such as moose *Alces alces* and deer *Odocoileus virginianus*, forest and grassland birds, and amphibians	The effects of all factors extended >100 m from road. Moose corridors, road, avoidance by grassland birds and road salt extended >1 km	The road-effect zone averages approximately 600 m wide and is asymmetric	*(108)*
Highways, secondary and	Various, all	Estimation of the percentage of	One-fifth of the U.S. land area is ecologically affected by	Road-effect zone as	*(109)*

primary roads	USA	land ecologically affected by the public road system	public roads system	assumption: primary roads (10,000 vehicles/day): 305 m in woodland and 365 m in grassland primary roads (50,000 vehicles/day): 810 m in natural ecosystems in urban areas secondary roads: 200 m	

Table S3. Extent and amount of roadless areas (5-km-buffer) per continent using the OpenStreetMap data set (11/2003) (without Antarctica, Greenland, and freshwater bodies).

	Asia	**Africa**	**North America**	**South America**	**Europe**	**Australia**	**Oceania**	**Global land**

Table S5. Rationale of indicators used for *Ecological Value Index of Roadless Areas* (EVIRA).

Indicators	Rationale	Description
Roadless area patch size	Large roadless areas provide a much wider range of ecological benefits than smaller ones where road edge effects impact a larger share of the roadless patch (see Table S2).	Habitat fragmentation and corresponding negative environmental changes have been extensively treated in many studies (a comprehensive overview is given by Bennett et al. (2010) *(110)*. The impacts do not just relate to gene flow, population viability and loss of (less dispersive) species in habitat fragments, but also to ecosystem functioning. For example, there is certain evidence related to nutrient cycling, dung removal, pollination, and seed dispersal *(111)*. "The impacts of fragmentation on ecosystem functioning are often exacerbated by synergistic effects such as interactions with the matrix and increased hunting pressure in fragmented forests" *(111)*. There is growing evidence that certain species avoid areas with even minimal anthropogenic disturbance *(112, 113)*, which is another argument for conservation of large roadless areas. Especially in tropical regions, many species exist at rather low population densities, are seasonal migrants (often across different altitudinal belts) following scarce resources, or otherwise require large habitats for maintaining viable populations *(114-116)*.
Thiessen connectivity into all directions for roadless area patches	The larger the Thiessen connectivity value, the closer neighboring roadless patches can be found. This is important for the integrity of ecological landscape-scale processes (e.g., genetic exchange of populations confined to roadless areas).	Roaded forest ecosystems, for instance, are far more vulnerable than intact ones to predatory logging, wildfires, illegal mining, exotic species invasions, and other anthropogenic threats *(7, 114)*.
Ecosystem Functionality Index comprising the following sub-indicators:	Ecosystem Functionality is defined as the state of ecosystems, characterized by inherent structures, ecological functions and dynamics, that provide ecosystems with both, the necessary efficiency and resilience to develop without abrupt change of system properties and geographical distribution, and allows for flexible response to external changes.	This Ecosystem Functionality Index has been published by Freudenberger et al. (2012a) *(38)*.
- Vegetation density	Vegetation density is an indicator for biomass and the ecosystems' ability to dissipate incoming solar energy. Furthermore, a higher number of primary producers increase the capture of solar energy thereby improving ecosystem functionality.	Rationale from Freudenberger et al. (2012a, b) *(9, 38)*. Further references and sources provided in the corresponding methods sections.
- Tree height	Tree height is used as an indicator for biomass as well as structural complexity of an ecosystem. Old-growth forest conditions and complex vegetation stratification including foliage layering is dependent on tree height, thereby enhancing biodiversity and ecosystem functioning. Furthermore, it plays an important part in the absorption of solar radiation and in moderating microclimatic conditions.	Rationale from Freudenberger et al. (2012a, b) *(9, 38)*. Further references and sources provided in the corresponding methods sections.
- Carbon storage	Carbon storage is considered as an indicator for biomass and the ability of ecosystems to dissipate incoming solar energy. Areas with	Rationale from Freudenberger et al. (2012a, b) *(9, 38)*. Further references provided in the corresponding methods sections.

	higher carbon storage are also characterized by more intensive interactions with the atmosphere and higher regulating capacity.	
- Species richness of vascular plants	Species richness is considered to represent functional and structural redundancy, which is relevant for the resistance and resilience of ecosystems to e.g. climate change. Additionally, species richness is also associated with complex trophic structure and higher cycling rates of biomass, energy and information.	Rationale from Freudenberger et al. (2012a, b) *(9, 38)*. Further references and sources provided in the corresponding methods sections.
- Plant functional richness	Plant functional richness is an indicator derived from modelling survival probabilities of different plant functional types under climate change. Ecosystems with higher functional species richness are more likely to adapt to environmental change and therefore increase the adaptive capacity of an ecosystem.	Rationale from Freudenberger et al. (2012a, b) *(9, 38)*. Further references and sources provided in the corresponding methods sections.
- Slope	Topographical heterogeneity is connected to habitat diversity and species richness. At macro-scale habitat diversity increases along altitudinal gradients. Geographical barriers increase opportunities for allopatric speciation, and contribute to the genetic information that is stored within an ecosystem.	Rationale from Freudenberger et al. (2012a, b) *(9, 38)*. Further references and sources provided in the corresponding methods sections.

Table S6. Pearson (dark grey) and Spearman rank (light grey) correlation coefficient matrix for the three indicators of the ecological value index for roadless areas (EVIRA). All correlation coefficients are highly significant with $p<0.0001$. Correlation coefficients with values higher than 0.7 are displayed in bold.

	Ecological value index of roadless areas (EVIRA)	Roadless area patch size	Thiessen connectivity into all directions	Ecosystem functionality index (EFI)
Ecological value index of roadless areas (EVIRA)	1.000	**0.768**	-0.005	**0.818**
Roadless area patch size	0.488	1.000	-0.006	0.260
Thiessen connectivity into all directions	-0.272	-0.875	1.000	-0.002
Ecosystem functionality index (EFI)	**0.881**	0.155	0.048	1.000

Table S7. Distribution of roadless areas (1-km buffer) across anthromes (km^2) (according to Ellis et al. 2010 (*10*); analysis based on OpenStreetMap data set 11/2013).

Anthrome classes	South America	Central and North America	Europe	Asia	Africa	Australia	Oceania	Global	Share of global roadless areas (%)

Table S10. Synergies and conflicts between conservation of roadless areas and the United Nations' Sustainable Development Goals (SDGs) and their corresponding targets. Left column: Assessment of goals (large boxes): grey: at most weak synergies and conflicts with goal, blue: conflicts with goal prevail, yellow: mixture of synergies and conflicts with goal, green: synergies with goal prevail. Assessment of targets (insert boxes): grey: not applicable, blue: conflict, yellow: ambivalent relationship, green: synergy. Numbers in italics: target numbers. Bold number at bottom: conflict-synergy score of goals. →: reference to target(s).

Sustainable Development Goals and targets	**Brief analysis of synergies and conflicts between conservation of roadless areas and Sustainable Development Goal targets**
Goal 1. End poverty in all its forms everywhere *1* *2* *3* *4* *5* **-0,5** Compare AICHI BIODIVERSITY TARGETS 2, 14.	**Synergies:** The SDGs explicitly acknowledge the importance of integrating ecosystem and biodiversity values into poverty reduction strategies and accounts (compare to 15.9). In remote areas inhabited by indigenous or traditional people in the developing world, where governance is weak, road development may trigger uncontrolled frontier expansion and associated poverty. In the Amazon, frontier expansion through road construction has fostered large-scale economic activities (e.g. oil extraction, livestock and soy production), but often at the expense of the local communities. Road development in the region is associated to dire conflicts over land and natural resources *(117, 118)*. A better planning of the road development process and a prioritization of roadless areas for conservation purposes can help to reduce risks related to poverty (→ targets 1.1, 1.2, 1.4). In the Amazon, for instance, a more sensitive proposed development strategy should focus on strengthening governance in areas where roads have been established for a long time (and human population is relatively large and human development indices are low), while leaving more remote areas roadless or with roads unpaved *(119)*. Functional ecosystems, as they exist in roadless areas, effectively reduce human exposure to environmental shocks and disasters, including climate-related extreme events (such as floods: e.g., *(120)*, water scarcity: e.g., *(121)*, compare goal 6, fires: e.g., *(122);* → target 1.5). It is of great importance to maintain ecosystem functionality on the landscape scale, e.g. by prioritizing conservation of roadless areas around the headwaters of rivers against extreme fluctuations in run-off along the densely populated and intensively managed tailwater.
	Conflicts: Poverty often is related to the lack of access to markets and employment options (compare goal 8), health (compare goal 3) and education infrastructure (compare goal 4; *(123-126)*). Case studies have shown how roads significantly reduce poverty and increase consumption growth (→ targets 1.1, 1.2, 1.4; *(127-129)*). Reduced mobility also hampers organizational capacities, especially in remote rural areas, where it is difficult for poor people to meet and coordinate activities. In general, poor people will ask for better roads and mobility. Goal 9 explicitly addresses the relevance of infrastructure (see below). The conservation of roadless areas seems to represent a serious conflict and obstacle to development – if this development is thought along conventional lines and without exploring more sustainable alternatives for providing mobility.

Goal 2. End hunger, achieve food security and improved nutrition and promote sustainable agriculture *1* *2* *3* *4* *5* **-0,6** Compare AICHI BIODIVERSITY TARGETS 7, 8, 14.	**Synergies:** In remote regions, as they are found in parts of the western Amazon forests, the subsistence of many indigenous communities depends on forest products. However, new roads built into previously remote areas of low human population density have often triggered conversion of forest to croplands and pastures *(130)* and unsustainable exploitation of wildlife that can then be marketed easily as bushmeat in cities. Bushmeat can thus become scarce for residents who rely on this protein source *(131, 132)*. Functional ecosystems, as they exist in roadless areas, effectively reduce human exposure to environmental shocks and disasters, including climate-related extreme events (→ target 2.4; compare goal 1).
	Conflicts: At many places of the world, undernourishment increases with distance from roads and with it from markets and health services, among others *(133)*. Hunger can also be promoted by limited options for reaching poor rural people with food aid and development assistance (*(134)*; → targets 2.1-2.3, 2.5; compare goals 1, 3, 4, 6, 9).
Goal 3. Ensure healthy lives and promote well-being for all at all ages *1* *2* *3* *4* *5* *6* *7* *8* *9* **-0,1** Compare AICHI BIODIVERSITY TARGETS 6, 14.	**Synergies:** In general, roadless areas guarantee high ecosystem functionality (compare goal 1) and with it a variety of ecosystem services that are fundamental to people's health. Among others, tropical forest-dwelling indigenous communities use a variety of medicinal forest plants that can become scarce in the course of road construction and subsequent deforestation *(135)*. Roadless areas exclude deaths and injuries from road traffic accidents (→ target 3.6) as well road and traffic-related hazardous chemicals and air, water and soil pollution and contamination (*(136, 137)*; → target 3.9; compare goal 6). Road development in the Amazon and Indonesia has been shown to be associated with the spread of diseases (*(117);* → target 3.3). Abrupt contact with modern life-styles via new roads increases the vulnerability of formerly remote human populations to drug abuse and alcohol consumption (*(138);* → target 3.5).
	Conflicts: Remote rural populations mostly have reduced access to health care and medical assistance (*(133);* → targets 3.1, 3.2, 3.4, 3.7, 3.8).
Goal 4. Ensure inclusive and equitable quality education and promote lifelong learning opportunities for all *1* *2* *3* *4* *5* *6* *7* **-0,9** Compare AICHI BIODIVERSITY TARGETS 1.	**Synergies:** Experiencing wilderness has become an important element of education. While roadless areas are less accessible by motorized ways, they provide opportunities for this kind of education (*(139)* compare goal 8: nature tourism).
	Conflicts: With increasing distance from roads, access to "quality" education becomes more difficult. Among others, remote rural populations often lack literacy in the use of emerging technological devices (computers, internet etc., *(140);* → targets 4.1-4.7).
Goal 5. Achieve gender equality and empower all women and girls	**Synergies and conflicts: -**
Goal 6. Ensure availability and sustainable management of water and sanitation for all *1* *2* *3*	**Synergies:** Roads significantly harm the integrity and functionality of ecosystems and several services they provide to people (compare goal 1). Roads (including their construction) and traffic have been known for a long time as a source for water pollution (*(141);* → targets 6.1, 6.3, 6.5, 6.6).

4 5 6 **0,4** Compare AICHI BIODIVERSITY TARGETS 6, 8, 14.	**Conflicts:** In general, remote rural populations often have reduced access to technology, infrastructural development and assistance. It is cost-efficient, and practical for maintenance, to install water and sewer systems in the course of road construction (→ targets 6.1, 6.2).
Goal 7. Ensure access to affordable, reliable, sustainable and modern energy for all 1 2 3 **-0,5** Compare AICHI BIODIVERSITY TARGETS 7, 8, 14.	**Synergies:** none. **Conflicts:** In general, remote rural populations often have reduced access to technology and infrastructural development (compare goal 6). Electric wires can relatively easily be installed and maintained along roads (→ targets 7.1, 7.2). However, small-scale renewable (solar, wind) energy plants can be an alternative with additional advantages (low cost, energy autonomy; → target 7.2).
Goal 8. Promote sustained, inclusive and sustainable economic growth, full and productive employment and decent work for all 1 2 3 4 5 6 7 8 9 10 **-0,3** Compare AICHI BIODIVERSITY TARGETS 2.	**Synergies:** Roadless areas can contribute substantially to slowing down environmental degradation (→ target 8.4; compare goal 15, 13). In addition, certain micro- and small enterprises can arise in spite of relatively great distances from roads (→ target 8.3) – or even depend on remoteness (nature tourism, e.g., *(142);* → target 8.9). It has been shown for the Amazon region that road development is associated with slave labor (*(118);* → target 8.7). Facilitated access to markets by roads may not always improve the income levels of poor people, as they will not be able to afford goods such as cars and petrol. **Conflicts:** Ease of mobility of people and goods promotes economic productivity and growth (*(143)*; → targets 8.1, 8.2; compare goals 9, 1). Young people of remote rural areas mostly have reduced access to good education and training opportunities (compare goal 4) and subsequently lower chances on the labor market (*(144);* → target 8.6).
Goal 9. Build resilient infrastructure, promote inclusive and sustainable industrialization and foster innovation 1 2 3 4 5 **-0,3** Compare AICHI BIODIVERSITY TARGET 2.	**Synergies:** Upgrades of roads in the existing network can be a cost-efficient and environmentally less problematic alternative to building new roads (*(4);* → target 9.4). **Conflicts:** Economic development, especially in developing economies or those in transition, depends on an effective road network (*(143)*; → targets 9.1, 9.2; compare goals 8, 1).
Goal 10. Reduce inequality within and among countries 1 2 3 4 5 6 7 **-0,7**	**Synergies:** none. **Conflicts:** Modern road traffic has increased the mobility of people and goods, but comes with an increased risk of accidents (*(145);* → target 10.7). Roads have a variety of homogenizing effects - in terms of biological diversity (e.g., aided dispersal of invasive species: *(146)*, culturally (*(147);* → target 10.2) etc. Economically, road building provides poor rural societies a better access to economic dynamics and is thus a standard element of economic development strategies (*(143)*; → target 10.1; compare goals 9, 8, 1).

Goal 11. Make cities and human settlements inclusive, safe, resilient and sustainable *1* *2* *3* *4* *5* *6* *7* **0,5** Compare AICHI BIODIVERSITY TARGET 14.	**Synergies:** "Indigenous peoples in voluntary isolation" request participation in road and human settlement planning and want to be exempted from any such development *(117)*. Targeting roadless areas will help concentrate development in urban areas and their immediate surroundings (*(105);* → target 11.3). Failing to do so regularly results in "contagious development", i.e., unleashing a positive feedback of road construction and intensive land-use in a formerly road-free landscape *(4, 7)*. Remote areas, which provide vital ecosystem services to cities, can thus be kept functioning (→ target 11.5; compare goal 13, 1, 2). The status of natural heritage sites ("Criteria for the assessment of Outstanding Universal Value": vii, ix and x; *(148)*) is vitally coupled with remoteness (→ target 11.4). **Conflicts:** Further road construction may be deemed necessary to provide convenient access to public transport for a larger part of the population. However, people in remote rural regions may not be able to pay for public transport (*(149);* → target 11.2).
Goal 12. Ensure sustainable consumption and production patterns *1* *2* *3* *4* *5* *6* *7* *8* **1,0** Compare AICHI BIODIVERSITY TARGET 4.	**Synergies:** Road construction and maintenance consume significant amounts of material (and energy) and thus enlarge the national and per capita material footprint (*(150);* → target 12.2). Including roadless and other important areas for biodiversity and ecosystem services for people would make sustainability reports of companies *(151)* more diagnostic and could thus provide guidance for the adoption of sustainable practices (→ target 12.6). **Conflicts:** none.
Goal 13. Take urgent action to combat climate change and its impacts *1* *2* *3* **1,0** Compare AICHI BIODIVERSITY TARGETS 15, 10, 14.	**Synergies:** Functional ecosystems, as they exist in roadless areas, strengthen the resilience and adaptive capacity of human societies to climate-related hazards and natural disasters (→ target 13.1; compare goals 1-3). Roadless areas conservation would thus form a meaningful element of policies, strategies and planning for climate change adaptation (*(2);* → target 13.2). Road construction and maintenance (with cement production being a relevant source of greenhouse gas emissions *(152)*) as well as traffic *(153)* also contribute large shares to overall greenhouse gas emissions. Policies, strategies and planning for climate change mitigation should therefore strive to reduce these activities to the lowest level possible (→ target 13.2). **Conflicts:** none.
Goal 14. Conserve and sustainably use the oceans, seas and marine resources for sustainable development *1* *2* *3* *4* *5* *6* *7* **1,0** Compare AICHI BIODIVERSITY TARGET 6.	**Synergies:** Considerable river sediment loads can result from road construction and erosion along roads *(121)*. Runoff from subsequent development, such as logging in mountain areas *(154)*, or agriculture, can also impact rivers and, finally, estuaries and near-coast marine waters (→ target 14.1). **Conflicts:** none.

Goal 15. Protect, restore and promote sustainable use of terrestrial ecosystems, sustainably manage forests, combat desertification, and halt and reverse land degradation and halt biodiversity loss *1* *2* *3* *4* *5* *6* *7* *8* *9* **1,0** Compare AICHI BIODIVERSITY TARGETS 5, 11, 15, 12, 10.	**Synergies:** The conservation of roadless areas represents an effective and inexpensive means to conserving terrestrial and inland freshwater biodiversity and ecosystem services (*(2, 4);* → targets 15.1, 15.4, 15.5, 15.7, 15.8). This includes halting deforestation (*(98);* → targets 15.2) and combating desertification (*(155);* → targets 15.3). The inclusion of roadless areas would be a meaningful contribution to integrating ecosystem and biodiversity values into national and local planning as well as development processes, as is already the case in the United States of America and Germany (*(2, 4);* → targets 15.9). The present study demonstrates roadless areas are a tangible and transparent indicator for environmental accounting (→ target 15.9). **Conflicts:** none.
Goal 16. Promote peaceful and inclusive societies for sustainable development, provide access to justice for all and build effective, accountable and inclusive institutions at all levels *1* *2* *3* *4* *5* *6* *7* *8* *9* **1,0**	**Synergies:** Road development in the Brazilian Amazon is associated with an increase in homicide rate (*(118)*; → target 16.1). **Conflicts:** none.
Goal 17. Strengthen the means of implementation and revitalize the global partnership for sustainable development *1* *2* *3* *4* *5* *6* *7* *8* *9* *10* *11* *12* *13* *14* *15* *16* *17* *18* *19* **-1,0**	**Synergies:** none. **Conflicts:** Roads connect national economies (compare goal 8) and thus facilitate import-export traffic across borders (→ target 17.11), especially for landlocked regions or countries *(156)*.

Table S11. Synergies and conflicts between conservation of roadless areas and the United Nations' Aichi Strategic Goals and Biodiversity Targets. The color scheme indicates the level of synergy or conflict of goals and targets with roadless areas conservation (green: synergies prevail; grey: not applicable; yellow: ambivalent relationship). The numbers in insert boxes represent the conflict-synergy score of goals.

Aichi Strategic Goals and Biodiversity Targets	Brief analysis of synergies and conflicts between conservation of roadless areas and Aichi Biodiversity Targets
Strategic Goal A: Address the underlying causes of biodiversity loss by mainstreaming biodiversity across government and society $\boxed{0{,}5}$	
Target 1. By 2020, at the latest, people are aware of the values of biodiversity and the steps they can take to conserve and use it sustainably. Compare Sustainable Development Goal 4.	On the one hand, pristine ecosystems, such as they occur in roadless areas, are key for effective biodiversity conservation *(2)*. In agreement with modern concepts of sustainable land use, such as in biosphere reserves, these ecosystems are an essential element of sustainable use of the overall landscape *(157)*. Remote roadless areas provide opportunities for learning about natural ecosystems, i.e., wilderness (see goals B and C). On the other hand, roadless areas reduce accessibility of nature in general, thus making it more difficult to value biodiversity emotionally.
Target 2. By 2020, at the latest, biodiversity values have been integrated into national and local development and poverty reduction strategies and planning processes and are being incorporated into national accounting, as appropriate, and reporting systems. Compare Sustainable Development Goals 9, 8, 1.	While road infrastructure is related to economic growth and poverty alleviation *(158, 159)*, it has a crucial impact on biodiversity loss (see goal C), which in turn is directly linked with poverty aggravation *(160, 161)*. In remote areas inhabited mostly by indigenous or traditional people, road development may increase the spread of diseases, trigger conflicts over land and natural resources, and disrupt the traditional modes of production (which then have to compete with the global market), ultimately pushing these people towards poverty *(117, 162)*. The role of road development on poverty alleviation is hence conflicting, which calls for a better planning integrating roadless areas prioritization for biodiversity maintenance towards poverty alleviation.
Target 3. By 2020, at the latest, incentives, including subsidies, harmful to biodiversity are eliminated, phased out or reformed in order to minimize or avoid negative impacts, and positive incentives for the conservation and sustainable use of biodiversity are developed and applied, consistent and in harmony with the Convention and other relevant international obligations, taking into account national socio economic conditions.	Road transport receives between one- and two-thirds of worldwide conventional subsidies that are harmful in the long run to both the economy and the environment *(163)*. Road transport sector figures among the five most prominent sectors receiving such perverse subsidies *(164)*. An outstanding example refers to road infrastructure subsidies in the Amazon that have led to cattle ranching, extensive deforestation and biodiversity loss *(165)*. Alternatively, the integration of roadless areas into governmental policies could help in reducing and eliminating a substantial part of the harmful subsidies for the road transport sector.
Target 4. By 2020, at the latest, Governments, business and stakeholders at all levels have taken steps to achieve or have implemented plans for sustainable production and consumption and have kept the impacts of use of natural resources well within safe ecological limits. Compare Sustainable Development Goal 12.	Roadless areas, and relatively undisturbed areas in general, are of high resilience and ecosystem functionality *(2)*. Conserving these areas therefore contributes to maximizing ecosystem functionality of the wider landscape - they are an essential element of its sustainable use (compare targets 1, 7).
Strategic Goal B: Reduce the direct pressures on biodiversity and promote sustainable use $\boxed{0{,}8}$	
Target 5. By 2020, the rate of loss of all natural habitats, including forests, is at least halved and where feasible brought close to zero, and degradation and fragmentation is significantly reduced. Compare Sustainable Development Goal 15.	Road development is a major driver of habitat loss and fragmentation *(166)*. Roads act as barriers for species *(167)* and deforestation has been shown to increase along roads [*(98)*, Table S2]. Conserving roadless areas therefore directly helps to achieve this target.
Target 6. By 2020 all fish and invertebrate stocks and aquatic plants are managed and harvested sustainably, legally and applying ecosystem based approaches, so that overfishing is avoided, recovery plans and measures are in place for all depleted species, fisheries have no significant adverse impacts on threatened species and vulnerable ecosystems and the impacts of fisheries on stocks, species and ecosystems are within safe	Roads facilitate the accessibility to remote terrestrial or freshwater ecosystems and increase the efficiency of natural resources exploitation and exportation, which are often depleted above their safe ecological limits *(1)*. For instance, a single road construction has been reported to have severe effect to a lake trout population, due to improved access for fishermen *(168)*. In addition, roads, their construction and traffic emit water pollutants *(137, 141)*. Similarly, road construction and roads can produce large sediment loads in rivers, particularly detrimental in wetlands and mountain areas.

ecological limits. Compare Sustainable Development Goals 14, 6, 3.	Roads also open up a landscape for logging and agriculture, and resulting runoff equally enters rivers *(154)*. Large part of this sediment ends up in estuaries and coastal waters.
Target 7. By 2020 areas under agriculture, aquaculture and forestry are managed sustainably, ensuring conservation of biodiversity. Compare Sustainable Development Goal 2.	On one side, roadless areas exclude certain types of local development and even sustainable land use. And to keep up with demand for natural resources, any additional roadless area may require the intensification of land use in developed areas. On the other side, conservation of functional ecosystems, as they are still found in roadless areas, is essential for the larger landscape to stay functional. From this perspective, the remaining roadless areas can be seen as key elements of sustainably managed landscapes (compare targets 1, 4, 8).
Target 8. By 2020, pollution, including from excess nutrients, has been brought to levels that are not detrimental to ecosystem function and biodiversity. Compare Sustainable Development Goals 6, 2.	Agricultural intensification might be necessary to make up for setting aside roadless areas (compare target 7). This might lead to increased use of fertilizers and pollution. It should be noted, however, that in many developing countries in particular there is a large amount of degraded land that can be restored and replace set-asides. However, conservation of roadless areas as relatively pristine ecosystems are a cost-efficient way of maximizing the provisioning of regulating ecosystem services such as nutrient uptake and water purification *(121)*.
Target 9. By 2020, invasive alien species and pathways are identified and prioritized, priority species are controlled or eradicated, and measures are in place to manage pathways to prevent their introduction and establishment.	Road density is a strong correlate of spatial patterns in biological invasions *(146)*. Limiting road development in roadless areas can, therefore, help to directly reduce the spread of invasive species (Table S2).
Target 10. By 2015, the multiple anthropogenic pressures on coral reefs, and other vulnerable ecosystems impacted by climate change or ocean acidification are minimized, so as to maintain their integrity and functioning. Compare Sustainable Development Goals 13, 15.	Roadless areas often represent areas with large carbon pools and sequestration potential. Furthermore, they represent areas of high ecosystem functionality important for climate regulation and long-term climate change adaptation. The conservation of roadless areas, thus, helps to mitigate and adapt to the impacts of climate change *(2, 4)*. Regarding marine ecosystems in particular, roadless areas prevent road-related sediment and agricultural runoff from impacting near-shore waters (compare target 6).
Strategic Goal C: To improve the status of biodiversity by safeguarding ecosystems, species and genetic diversity **0,3**	
Target 11. By 2020, at least 17 per cent of terrestrial and inland water, and 10 per cent of coastal and marine areas, especially areas of particular importance for biodiversity and ecosystem services, are conserved through effectively and equitably managed, ecologically representative and well connected systems of protected areas and other effective area-based conservation measures, and integrated into the wider landscapes and seascapes. Compare Sustainable Development Goal 15.	The conservation of roadless areas directly contributes to the conservation of valuable terrestrial ecosystems for biodiversity conservation. These areas also typically provide a wide array of ecosystem services, especially regulating services, and do this in large quantities. Furthermore, the conservation of these unfragmented and pristine areas directly contributes to the target of increasing connectivity. Conservation of the functionality of the watershed is highly dependent on the preservation of vegetation cover *(169)*, which benefits from conservation of roadless areas.
Target 12. By 2020 the extinction of known threatened species has been prevented and their conservation status, particularly of those most in decline, has been improved and sustained. Compare Sustainable Development Goal 15.	Threatened species typical of anthropogenically disturbed ecosystems, such as old cultural landscapes in Europe and elsewhere, depend on certain semi-intensive, often historical, land use regimes (*170*). Therefore, in human-modified landscapes, the conservation of roadless areas in cases may be found little useful, or even counterproductive, to the target of improving the conservation status of some species. At the same time, other species (e.g., some amphibians) may experience reduced mortality in the absence of roads. After all, most threatened species are endangered by man-made loss of pristine ecosystems *(171)*. Roadless areas can retain populations of threatened species, supporting the native flora and fauna and buffering changes in the environmental conditions. Roadless areas which are large enough to host source populations can then serve as the origin for recolonization of areas where threatened species had disappeared *(172)*.
Target 13. By 2020, the genetic diversity of cultivated plants and farmed and domesticated animals and of wild relatives, including other socio-economically as well as culturally valuable species, is maintained, and strategies have been developed and implemented for minimizing genetic erosion and safeguarding their genetic diversity.	For one thing, on-farm conservation and use of cultivated species often requires the application of relatively extensive agricultural practices *(173)*. This could lead to competition for area between the conservation of roadless areas and more extensive agricultural practices for the preservation of the diversity of cultivated plants and animals. Then again, wild relatives of domesticated plant and animal species can often only be found in pristine natural areas *(174)*.
Strategic Goal D: Enhance the benefits to all from biodiversity and ecosystem services **1,0**	
Target 14. By 2020, ecosystems that provide essential services, including services related to water, and	Functional ecosystems, as they exist in roadless areas, provide large quantities of many ecosystem services, especially of regulating services.

contribute to health, livelihoods and well-being, are restored and safeguarded, taking into account the needs of women, indigenous and local communities, and the poor and vulnerable. Compare Sustainable Development Goals 6, 11, 1, 2, 3, 13.	They effectively reduce human exposure to extreme environmental events [e.g., fires, *(122)*]. Remote areas are often also of high value especially to indigenous and traditional people *(117)*. Remote areas also provide vital ecosystem services to poor city dwellers, such as purification and stable provisioning of water *(121)*.
Target 15. By 2020, ecosystem resilience and the contribution of biodiversity to carbon stocks has been enhanced, through conservation and restoration, including restoration of at least 15 per cent of degraded ecosystems, thereby contributing to climate change mitigation and adaptation and to combating desertification. Compare Sustainable Development Goals 15, 13.	Roadless areas comprise relatively little disturbed areas. Many of these harbor large carbon pools and sinks, e.g., peatlands and intact forests in tropical and boreal regions *(175)*. Furthermore, they provide many regulating ecosystem services and high ecosystem functionality and are, therefore, crucial for ecosystem-based adaptation to climate change (see above targets 1, 4, 7). They also provide a natural buffer against increasing desertification through maintenance of vegetation cover *(155)*.
Target 16. By 2015, the Nagoya Protocol on Access to Genetic Resources and the Fair and Equitable Sharing of Benefits Arising from their Utilization is in force and operational, consistent with national legislation.	
Strategic Goal E: Enhance implementation through participatory planning, knowledge management and capacity building **1,0**	
Target 17. By 2015 each Party has developed, adopted as a policy instrument, and has commenced implementing an effective, participatory and updated national biodiversity strategy and action plan.	
Target 18. By 2020, the traditional knowledge, innovations and practices of indigenous and local communities relevant for the conservation and sustainable use of biodiversity, and their customary use of biological resources, are respected, subject to national legislation and relevant international obligations, and fully integrated and reflected in the implementation of the Convention with the full and effective participation of indigenous and local communities, at all relevant levels.	Indigenous communities are most vulnerable to the impacts of road development. Road construction in former roadless areas can cause traditional environmental knowledge loss and even a depopulation of indigenous communities *(176)*. Indigenous people may lose their land *(177)*, or use it less after road construction *(178)*, benefit less from biological resources and face an alteration of traditional roles and practices *(179)*.
Target 19. By 2020, knowledge, the science base and technologies relating to biodiversity, its values, functioning, status and trends, and the consequences of its loss, are improved, widely shared and transferred, and applied.	Natural ecosystems, as they still exist in remote roadless areas, are unique learning sites not only for education (see above target 1). They also provide important insights into ecosystem properties and processes such as biomass stocks, ecological dynamics, or resistance and resilience to natural disturbances *(180)*.
Target 20. By 2020, at the latest, the mobilization of financial resources for effectively implementing the Strategic Plan for Biodiversity 2011-2020 from all sources, and in accordance with the consolidated and agreed process in the Strategy for Resource Mobilization, should increase substantially from the current levels. This target will be subject to changes contingent to resource needs assessments to be developed and reported by Parties.

Spotted Owls and forest fire: a systematic review and meta-analysis of the evidence

Derek E. Lee[1,2,]†

[1]Wild Nature Institute, 15 North Main Street #208, Concord, New Hampshire 03302 USA

Citation: Lee, D. E. 2018. Spotted Owls and forest fire: a systematic review and meta-analysis of the evidence. Ecosphere 9(7):e02354. 10.1002/ecs2.2354

Abstract. Forest and Spotted Owl management documents often state that severe wildfire is a cause of recent declines in populations of Spotted Owls and that mixed-severity fires (5–70% of burned area in high-severity patches with >75% mortality of dominant vegetation) pose a primary threat to Spotted Owl population viability. This systematic review and meta-analysis summarize all available scientific literature on the effects of wildfire on Spotted Owl demography and ecology from studies using empirical data to answer the question: How does fire, especially recent mixed-severity fires with representative patches of high-severity burn within their home ranges, affect Spotted Owl foraging habitat selection, demography, and site occupancy parameters? Fifteen papers reported 50 effects from fire that could be differentiated from post-fire logging. Meta-analysis of mean standardized effects (Hedge's *d*) found only one parameter was significantly different from zero, a significant positive foraging habitat selection for low-severity burned forest. Multi-level mixed-effects meta-regressions (hierarchical models) of Hedge's *d* against percent of study area burned at high severity and time since fire found the following: a negative correlation of occupancy with time since fire; a positive effect on recruitment immediately after the fire, with the effect diminishing with time since fire; reproduction was positively correlated with the percent of high-severity fire in owl territories; and positive selection for foraging in low- and moderate-severity burned forest, with high-severity burned forest used in proportion to its availability, but not avoided. Meta-analysis of variation found significantly greater variation in parameters from burned sites relative to unburned, with specifically higher variation in estimates of occupancy, demography, and survival, and lower variation in estimates of selection probability for foraging habitat in low-severity burned forest. Spotted Owls were usually not significantly affected by mixed-severity fire, as 83% of all studies and 60% of all effects found no significant impact of fire on mean owl parameters. Contrary to current perceptions and recovery efforts for the Spotted Owl, mixed-severity fire does not appear to be a serious threat to owl populations; rather, wildfire has arguably more benefits than costs for Spotted Owls.

Key words: adaptive management; evidence-based decision making; meta-analysis; mixed-severity fire; Spotted Owls; *Strix occidentalis;* systematic review; wildfire.

Introduction

Wildfires are major natural disturbances in forests of the western United States, and native plants and animals in this region have been coexisting with fire for thousands of years of their evolutionary history (Pierce et al. 2004, Power et al. 2008, Marlon et al. 2012). Western forest fires typically burn as mixed-severity fires with each fire resulting in a mosaic of different vegetation burn severities, including substantial patches (range, 5–70% of burned area; mean, 22%) of high-severity fire (Beaty and Taylor 2001, Hessburg et al. 2007, Whitlock et al. 2008, Williams and Baker 2012, Odion et al. 2014*a*, Baker 2015*a*). High-severity fire (high vegetation burn severity) kills most or all of the dominant vegetation in a stand (>75% mortality; Hanson et al. 2009, Baker 2015*a*, *b*) and creates complex early seral forests, where standing dead trees, fallen logs, shrubs, tree seedlings, and herbaceous plants comprise the structure (Swanson et al. 2011, DellaSala et al. 2014). Post-fire vegetation processes (i.e., succession) then commence according to the pre-fire vegetation, local wildfire processes, propagules from outside the disturbance, and the dynamic biotic and abiotic conditions at the site (Gutsell and Johnson 2006, Johnson and Miyanishi 2006, Mori 2011).

Spotted Owls (*Strix occidentalis*) occur in western U.S. forests and have been intensively studied since the 1970s (Fig. 1). The species is strongly associated with mature and old-growth (i.e., late-successional) conifer and mixed conifer–hardwood forests with thick overhead canopy and many large live and dead trees and fallen logs (Gutiérrez et al. 1995). Its association with older forests has made the Spotted Owl an important umbrella indicator species for public lands management (Noon and Franklin 2002). The scientific literature has established that the optimal habitat for Spotted Owl nesting, roosting, and foraging is provided by conifer and mixed conifer–hardwood forests dominated by medium (30–60 cm) and large (>61 cm) trees with medium (50–70%) to high (>70%) canopy cover (Gutiérrez et al. 1995). The populations of all three subspecies have declined due to widespread historical and ongoing habitat loss, primarily from logging mature and old-growth forests favored by the owls for nesting and roosting (Seamans et al. 2002, Forsman et al. 2011, USFWS 2011, 2012, Conner et al. 2013, Tempel and Gutiérrez 2013, Dugger et al. 2016).

Research on Spotted Owl in fire-affected landscapes did not begin until the early 2000s, and much of what scientists previously understood about habitat associations of Spotted Owl was derived from studies in forests that had generally not experienced recent fire, and where the non-suitable owl habitat was a result of logging (Gutiérrez et al. 1992, Franklin et al. 2000, Seamans et al. 2002, Blakesley et al. 2005, Seamans and Gutiérrez 2007, Forsman et al. 2011, Tempel et al. 2014). Because Spotted Owls are associated with dense, late-successional forests, it has often been assumed that fires that burn at high severity are analogous to clear-cut logging and have a negative effect on population viability. It has become widely believed among wildlife management professionals that severe wildfire is a contributing cause of recent Spotted Owl population declines (USFWS 2011, 2012, 2017), and many land managers believe that forest fires currently pose the greatest risk to owl habitat and are a primary threat to population viability (Davis et al. 2016, Gutiérrez et al. 2017). These beliefs result in fuel-reduction logging projects in Spotted Owl habitat (USDA 2012, 2018) which the USDA Forest Service and US Fish and Wildlife Service state are actions consistent with Spotted Owl recovery (USDA 2012, 2018, Gutiérrez et al. 2017, USFWS 2017). Narrative literature reviews have attempted to summarize the effects of fire on Spotted Owl (Bond 2016, Gutiérrez et al. 2017), but evidence-based conservation decisions should be based upon systematic, transparent reviews of primary literature with quantitative meta-analysis of effects (Sutherland et al. 2004, Pullin and Stewart 2006, Pullin and Knight 2009, Koricheva et al. 2013).

The following systematic review and meta-analysis summarize all available published scientific literature on the effects of wildfire on aspects of Spotted Owl demography (survival, recruitment, and reproduction), site occupancy, and habitat selection, from studies using empirical data to answer the question: How does fire, especially mixed-severity fire with substantial patches of high-severity fire within their home ranges, affect Spotted Owl demography, site occupancy, and habitat selection in the first few post-fire years?

Methods

Literature search

I conducted a systematic review of the primary scientific literature and used meta-analyses and meta-regression to examine the evidence for the direct effects of wildfire on Spotted Owl demography, site occupancy, and habitat selection. My subject was Spotted Owls; the intervention was

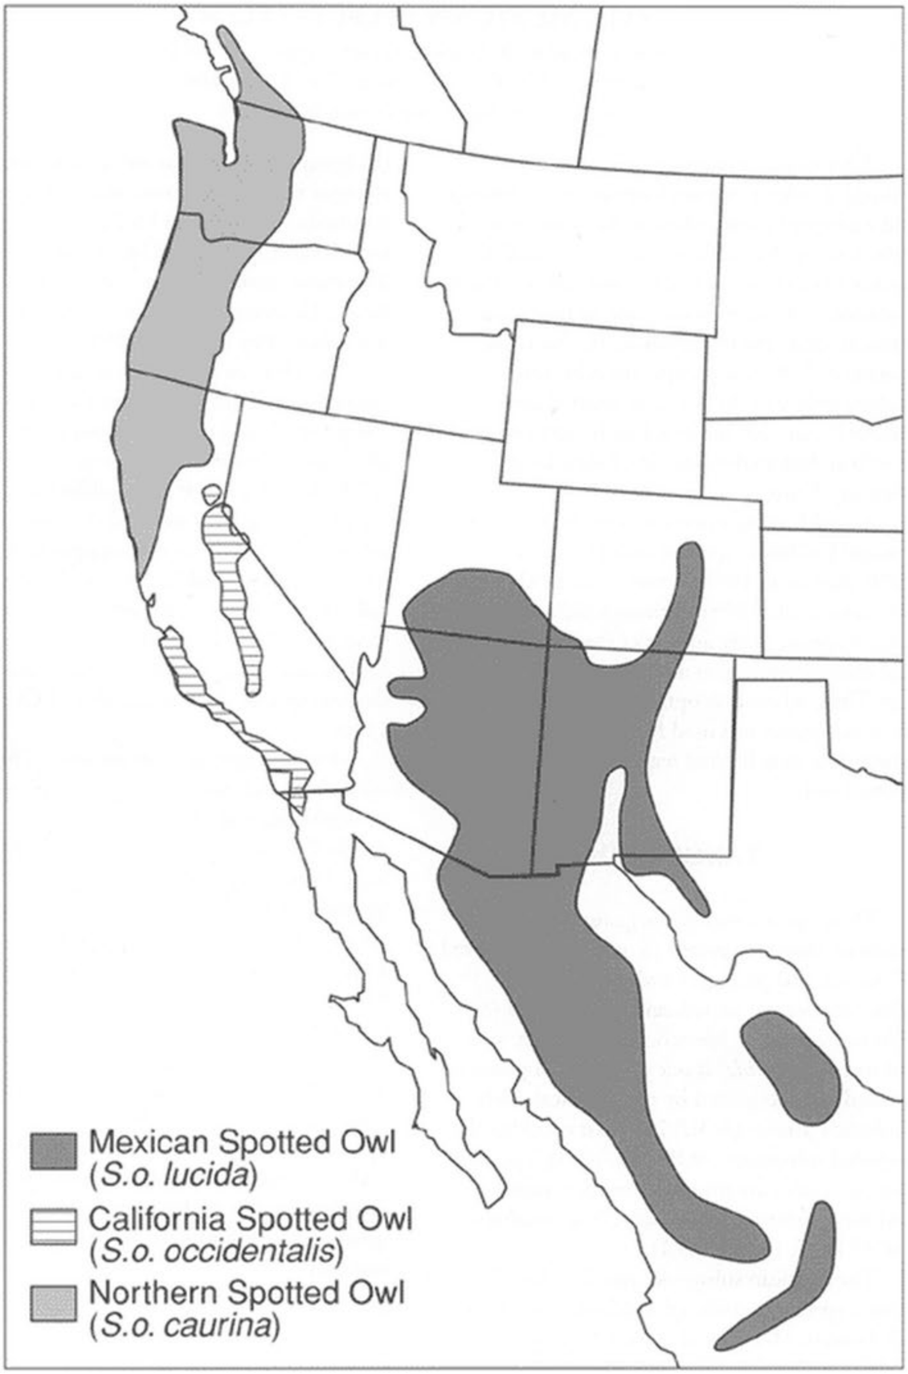

Fig. 1. Range map for the three subspecies of the Spotted Owl (*Strix occidentalis*).

wildfire; the outcomes were change or difference in estimates of demography, site occupancy, and habitat selection probabilities; and the comparator was pre-fire estimates or control estimates from unburned areas (Pullin and Stewart 2006). I searched the following electronic databases on 1 April 2018: Agricola, BIOSIS Previews, ISI Web of Science, and Google Scholar. Search terms were as follows: spotted AND owl AND *fire, Strix AND occidentalis AND *fire. My search included papers published in any year.

I used a threefold filtering process for accepting studies into the final systematic review. Initially, I filtered all articles by title and removed any obviously irrelevant material from the list of articles found in the search. Subsequently, I examined the abstracts of the remaining studies with regard to possible relevance to the systematic review question, using inclusion criteria based on the subject matter and the presentation of empirical data. I accepted articles for viewing at full text if I determined that they may contain information pertinent to the review question or if the abstract was ambiguous and did not allow inferences to be drawn about the content of the article. Finally, I read all remaining studies at full text and either rejected or accepted into the final review based upon subject matter (Pullin and Stewart 2006, Koricheva et al. 2013). Studies that only modeled effects of simulated fires on Spotted Owl habitat and demography were not considered here.

Because post-fire logging often occurred, I also recorded effects of this disturbance where they were reported. I believe all studies in the final review were generally comparable because time since fire and percent of high-severity burn were similar among studies (Tables 1, 2), and the high number of non-significant results reported indicates little to no publication bias exists in this topic (Tables 1, 2; Appendix S1: Fig. S1). I considered the basic sampling unit of all studies to be the central core of the owl breeding-season territory (~400 ha, or a circle with radius 1.1 km centered on the nest or roost stand) because this is the spatial and temporal scale for sampling used in almost all Spotted Owl studies. In contrast, Spotted Owl year-round home ranges vary according to latitude and dominant vegetation, but range from 300 to 11,000 ha, or circles with radius 1.0–5.9 km (Zabel et al. 1992). I considered forest fires to affect the landscape scale (~10,000 ha/decade), but that fires would affect numerous individual owl breeding-season territories (1200 ha) and year-round home ranges (300–19,000 ha) in various ways.

Meta-analyses and meta-regression

I evaluated all final review papers and included all papers where effects of fire were reported and could be differentiated from other disturbances such as post-fire logging. I extracted evidence by reading every paper and tabulating all quantified results from text, tables, and figures (Table 1). I noted the mean ($\bar{x}$) and variation (SD) of burned and unburned groups for all significant and non-significant parameters, the parameters being estimated, sample sizes (n = number of owl breeding sites in burned and unburned groups), amount of high-severity fire in the total fire perimeter and/or within the owl territory core areas examined, time since fire (years), amount of post-fire logging that occurred, subspecies (California = *Strix occidentalis occidentalis*, Mexican = *Strix occidentalis lucida*, or northern = *Strix occidentalis caurina*), and whether the result was statistically significant (as defined in each paper).

I conducted all analyses in R 3.3.1 (www.r-project.org). For meta-analysis, I noted or calculated the mean, variance (SD), and sample size for burned (treatment) and unburned (control) groups. I calculated raw effect sizes as mean differences ($\bar{x}_{\text{burned}} - \bar{x}_{\text{control}}$) and signs (positive or negative) for all reported effects, regardless of their statistical significance. Most papers reported effect sizes as probabilities (occupancy, survival, and foraging habitat selection) so raw effect sizes were scaled between negative and positive one with a mean of zero, making comparison among studies easy. When papers reported multiple effects (e.g., occupancy and reproduction, or survival and recruitment), I recorded each effect individually. Where papers did not report any effect size for a parameter determined to have no significant effects from fire, I included a zero to represent the presence of no significant effect and to avoid a significance bias in the meta-analysis. I stratified data by subspecies (California, Mexican, or northern) and parameter type according to whether the study estimated site occupancy, foraging habitat selection (substratified into selection for low-, moderate-, and high-severity burned forest), and demographic rates (substratified into survival, reproduction, and recruitment). I performed meta-analyses on parameters for which ≥4 estimates existed from ≥4 different fires.

I used three quantitative methods for evaluating the evidence (Koricheva et al. 2013): a random-effects meta-analysis of mean effect sizes as

Table 1. Summary of systematic review of studies examining effects of fire on Spotted Owls.

No.	Ref.	Sample size	HOD	Time since fire	Context	Fire effects (* = statistically significant, NS = non-significant)	Fire	Any effect	Signif. effect	Post-fire logging
1	Bond et al. (2002)	21 owls in 11 burned sites	OD	1 yr post-fire	No effect on survival, site fidelity, mate fidelity, or reproduction. 50% of territories burned 36–88% high severity, 50% burned mostly low –moderate severity, unknown amount of post-fire logging	No significant effects. (3% higher survival NS, 1% lower site fidelity [occupancy] NS, 26% higher repro NS)	0/+/−	+0.032 −0.013 +0.259	na	na

21	Hanson et al. (2018)	54 burned sites in eight fires that were occupied immediately before fire, before–after comparison	O	14-yr study, 1 yr post-fire	Eight large fires (4 included in Tempel et al. 2016). Four groups: 20–49% and 50–80% high-severity fire; and <5% and ≥5% post-fire logging within 1500 m of site center. Mean 63% high severity in core areas, mean 17% logged if ≥5% of core was post-fire logged Compared burned site occupancy with unburned occupancy from Tempel et al. (2016)	No significant effect from fire, significant negative effect of post-fire logging (3% reduction in occupancy if 50–80% of core burned high-severity fire NS, 52% reduction in occupancy from ≥5% post-fire logging*)	0/-	−0.017 −0.013	na	−0.52

Notes: HOD indicates habitat selection (H), occupancy (O), or demographic (D) parameters were estimated. A question mark (?) indicates confounded fire and post-fire logging effects, so fire effects could not be estimated.

the standardized difference in means (Hedge's *d*; Hedges and Olkin 1985); multi-level linear mixed-effects models (hierarchical models) meta-regression of time since fire and percent of high-severity fire in the study area as covariates to explain heterogeneity in mean effect sizes (Hedges and Vevea 1998, Nakagawa and Santos 2012); and a random-effects meta-analysis of variation to examine differences in parameter variances due to fire with effect sizes as the natural logarithm of the ratio between the coefficients of variation (lnCVR; Nakagawa et al. 2015). For analyses, I used the metafor package of R (Viechtbauer 2010) and used function metacont for random-effects meta-analyses, function rma.mv for multi-level linear mixed-effects model meta-regression, and function rma for random-effects meta-analysis of variation (Viechtbauer 2010). Study within geographic area was included as multi-level random effects to properly estimate study site- and region-specific variation and to account for repeated measurements (pseudo-replication) within a study or region. Regions were defined as Sierra Nevada, southern California, national parks, not California, and the Eldorado density study area (because several studies used data from there).

I used all three methods at three levels: on all parameters, on three main groups of parameters (occupancy, foraging habitat selection, and demography), and on subgroups of habitat selection (for low-, moderate-, and high-severity burned forest) and demography (survival, reproduction, and recruitment). In meta-analyses, I used z tests to determine if effects were significantly different from zero (95% confidence interval excluded zero). In meta-regression, z tests determined whether intercepts or slope coefficients were significantly different from zero. I quantified heterogeneity among effects as Cochran's Q (Hedges and Olkin 1985) and I^2 (Higgins and Thompson 2002). I used a funnel plot and the rank correlation test (Kendall's τ) to assess publication bias (Begg and Mazumdar 1994).

Results

Literature search

I found 21 papers reporting empirical evidence relevant to direct fire effects on owls (Table 1). Three papers presented data from a study area which was extensively logged post-fire and results did not discriminate between effects of fire and post-fire logging (Clark et al. 2011, 2013, Comfort et al. 2016), so these three papers were not included in meta-analyses with the meta-analysis set of papers that were not confounded

Notes: Study indicates first author and year. Subspecies are C, California (*Strix occidentalis occidentalis*); N, northern (*Strix occidentalis caurina*); M, Mexican (*Strix occidentalis lucida*); CNM, study included all subspecies. Regions are SN, Sierra Nevada, California (except El Dorado study area and national parks); SoCal, southern California; Eldorado, El Dorado study area in Sierra Nevada, California; NotCal, not California Spotted Owl subspecies; NP, national parks. Parameters: habitat selection (foraging or roosting) in low-, moderate-, (mod) or high-severity burned forest; occupancy, recruitment, reproduction, and survival. Sample sizes (n) are number of breeding site territories burned and unburned. Raw mean effect size is $\bar{x}_{\text{burned}} - \bar{x}_{\text{control}}$, significant repeats effects that the individual study determined was statistically significant. Time since fire is the median number of years between the fire and the parameter estimate(s). Percent high-severity fire in burned study territories is the mean relevant to the estimate, or the grand mean if percentage of high severity was not reported (see ‡).

† Habitat selection occurred within territories that contained a mosaic of burn severities and unburned forest.

‡ Percent high-severity fire was not reported for burned territories only for all territories burned and unburned, so the grand mean of reported percentages was used.

by extensive post-fire logging (Table 2). All 21 papers are summarized in Appendix S1.

Fifteen of the 18 papers in the meta-analysis set reported evidence explicitly pertaining to mixed-severity wildfires that burned during the past few decades and which included proportions of high-severity burn characteristic of this fire regime, while three reported evidence from an undifferentiated mix of wildfire and prescribed fires. The studies reported varying amounts of high-severity fire, a defining feature of mixed-severity fires, and the burn severity type that is most responsible for vegetation changes in wildfires, with an overall mean percent of high-severity fire of 26% (standard error [SE] = 3.6, range 6–64) within the study area. Because almost all the studies in this review reported on effects from recent wildfires (all fires burned in the past 30 yr, mean time since fire = 4 yr, SE = 1.1, range 1–26), the reported effects are representative of natural mixed-severity fires as they burned through currently existing forest structure, fire regime, and climate conditions. Papers reported effects of fire on site occupancy (11), foraging habitat selection (4), reproduction (4), apparent survival (3), overwinter roosting habitat selection (2), site fidelity (1), mate fidelity (1), breeding-season nesting and roosting habitat selection (1), home-range size (1), and recruitment (1). Sample sizes measured as number of burned sites were variable among studies (demography CV = 122%, site occupancy CV = 56%, and habitat selection CV = 24%).

Meta-analyses

Meta-analysis of 50 reported effects on occupancy, foraging habitat selection, and demographic rates found effect sizes and signs were variable (Table 2 and Fig. 2), with high heterogeneity among effects ($Q = 1091$, df = 51, $P < 0.0001$; $I^2 = 95.3\%$). Funnel plot (Appendix S1: Fig. S1) and rank correlation test (Kendall's $\tau = 0.108$, $P = 0.27$) showed no publication bias or unusual heterogeneity. Sample sizes (n = number of reported effects) were variable among parameter types (Fig. 3). The number of reported effects were occupancy = 20; demography = 14; and foraging habitat selection = 16. The number of reported effects by demography subtype were survival = 6; reproduction = 4; and recruitment = 4. The number of reported effects by habitat selection subtype were low-severity burned forest = 4; moderate-severity burned forest = 6; and high-severity burned forest = 6.

The mixed-effects model meta-analysis of fire effects on Spotted Owl parameters grouped by type (occupancy, demography, and foraging habitat selection), and subtypes of demography (survival, reproduction, and recruitment) or foraging habitat selection (selection for low-, moderate-, and high-severity burned forest), found mixed-severity fire has generally no significant effect on Spotted Owls (Fig. 3a). Mean overall raw effect size was positive (+0.001), but weighted mean Hedge's d from the random-effects model was not significantly different from zero (Fig. 3a, 95% confidence interval included zero). Mean raw effect sizes were negative for occupancy (−0.060), demography (−0.006), and survival (−0.095), but no Hedge's d value for these three negative effects was significantly different from zero (Fig. 3a). Mean raw effect sizes were positive for reproduction (+0.047), recruitment (+0.073), foraging habitat selection (+0.083), selection of high-severity (+0.004), moderate-severity (+0.087), and low-severity burned forest (+0.195), but Hedge's d values were not significantly different from zero for any of these positive effects, except for significant selection of low-severity burned forest (Fig. 3a).

Variation was generally higher among parameter estimates from burned areas compared to estimates from unburned areas (mean $CV_{burned} - CV_{unburned} = 23\%$; range 4–57%). The mixed-effects meta-analysis of variation in fire effects on Spotted Owl parameters (lnCVR) found mixed-severity fire resulted in significantly higher variation in parameter estimates in all parameters and in occupancy, demography, and survival (Fig. 3b). There was significantly lower variation in estimates of foraging habitat selection probability for low-severity burned forest (Fig. 3b).

Meta-regression

Meta-regression of all standardized mean effects found significant effect of time since fire (Table 3), and a nearly significant effect of percent high-severity burn in territory cores (Table 3), so those effects were included in parameter-specific meta-regressions. Subspecies was not a significant factor (Table 3), so effects from different subspecies were pooled in subsequent parameter-specific analyses.

Meta-regression of occupancy probability found no significant immediate effect of fire on occupancy (intercept not significantly different from zero; Table 4). There was a significant negative effect of time since fire (Fig. 4, Table 4), but no effect of percent high-severity fire in study territories (Table 4). The negative effect of time since fire was sensitive to one study (Roberts et al. 2011), and when that study was omitted, the effect disappeared.

Meta-regression of demographic parameters found a significant positive effect on recruitment immediately after the fire (intercept significantly different from zero), but the effect diminished

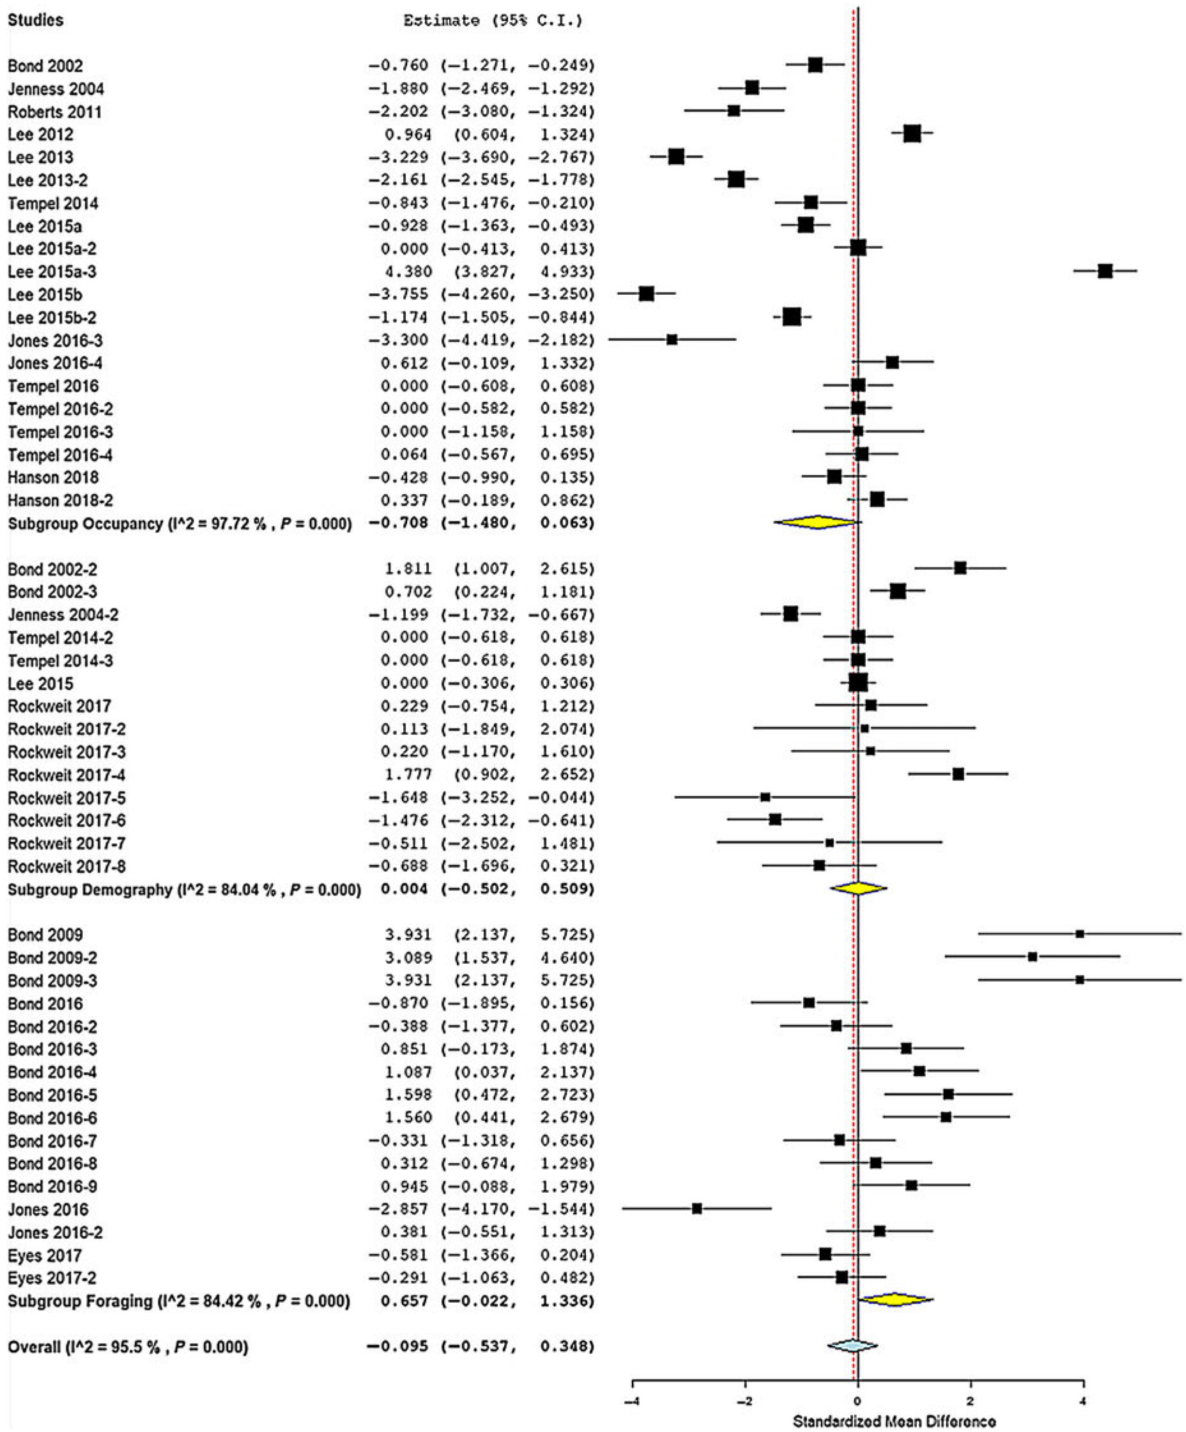

Fig. 2. Forest plot of effect sizes for 50 Spotted Owl (*Strix occidentalis*) parameters (grouped into occupancy, demography, and foraging habitat selection) affected by mixed-severity wildfire as standardized mean difference (Hedge's *d*) between burned and unburned samples. Studies and parameters are listed in Table 2.

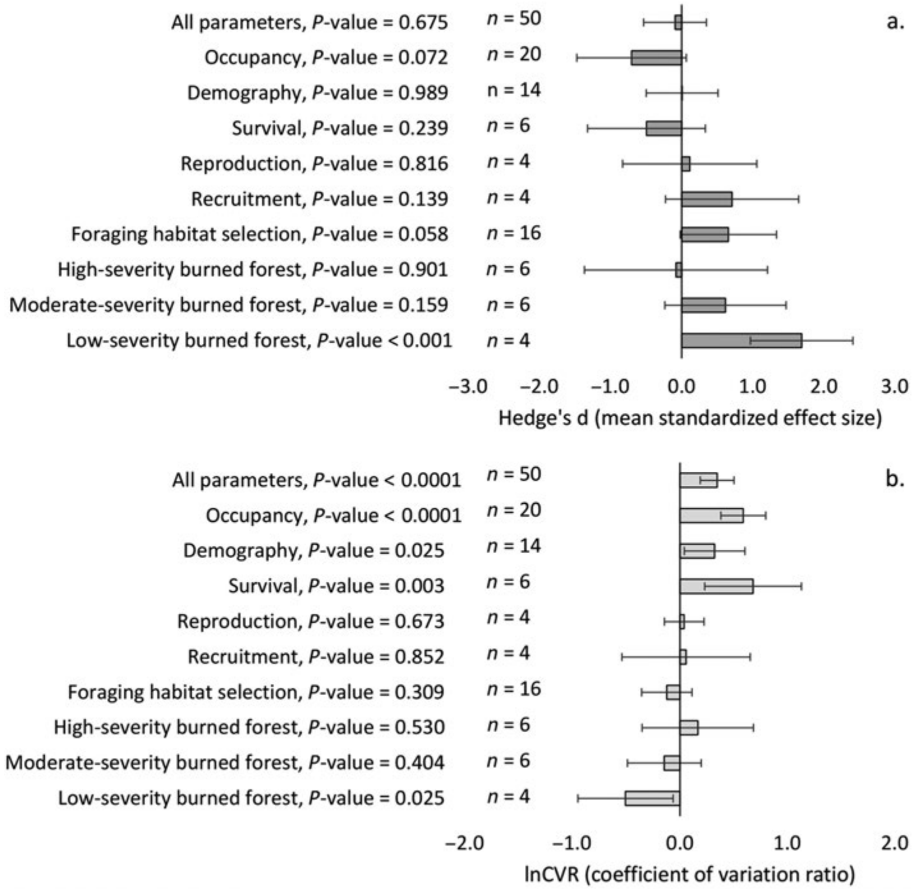

Fig. 3. Results of mixed-effects meta-analyses of mixed-severity fire effects (n = 50 effects from 21 studies) on Spotted Owl (*Strix occidentalis*) parameters grouped by type (occupancy, demography, and foraging habitat selection) and subtype of demography (survival, reproduction, and recruitment), or habitat selection (selection for low-, moderate-, and high-severity burned forest). (a) Hedge's d is standardized mean effect size, and error bars are 95% confidence intervals. The only significant effect (95% confidence intervals excluded zero) was a positive effect of habitat selection for low-severity burned forest. (b) lnCVR is the natural logarithm of the ratio between the coefficients of variation, a measure of differences in variation of parameter estimates between burned and unburned areas. Mixed-severity fire resulted in significantly higher variation in parameter estimates in all parameters, occupancy, demography, and survival, and significantly lower variation in habitat selection for low-severity burned forest.

with time since fire (Fig. 5, Table 4). Reproduction intercept was not significantly different from recruitment (Table 4), and not significantly different from zero ($z = -0.218$, $P = 0.86$), but reproduction was significantly positively correlated with the percent of high-severity fire in owl territories (Fig. 5, Table 4). Survival was significantly lower than recruitment (Table 4), but survival intercept was not significantly different from zero ($z = -0.052$, $P = 0.97$). There were no significant survival effects of time since fire or percent of high-severity fire (Table 4).

Meta-regression of foraging habitat selection parameters found a significant positive selection for low- and moderate-severity burned forest, with high-severity burned forest used in proportion to its availability, but not avoided (Fig. 5, Table 4). Time since fire did not affect foraging habitat selection during the period covered by the studies I examined (up to 7 yr), and the

Table 3. Results from multivariate mixed-effects meta-regression model of mixed-severity fire effects (n = 50 effects from 21 studies) on Spotted Owl (*Strix occidentalis*) parameters related to occupancy, demography, and foraging habitat selection.

Covariates	β	SE	z	P
Intercept (California subspecies)	1.601	1.070	1.497	0.134
Time since fire	−0.199	0.099	−2.017	**0.044**
Percentage of area high-severity fire in study territories	−0.044	0.023	−1.866	0.062
Mix of California, northern, Mexican subspecies	0.467	1.592	0.294	0.769
Mexican subspecies	−1.947	1.608	−1.211	0.226
Northern subspecies	0.360	1.571	0.229	0.819

Notes: SE, standard error. Time since fire was significant, and percent high-severity burn in territory cores was nearly significant, so those effects were included in parameter-specific meta-regressions. Subspecies was not a significant factor, so effects from different subspecies were pooled in subsequent parameter-specific analyses. Bold values are significant at alpha = 0.05.

amount of high-severity fire did not affect habitat selection overall (Table 4).

Post-fire logging had negative effects on Spotted Owls in 100% of the papers that examined this disturbance and where effects from fire and post-fire logging could be differentiated, with large effect sizes (−0.18 occupancy, −0.07 survival).

Discussion

This systematic review and summary of effects from the primary literature indicated Spotted Owls are usually not significantly affected by mixed-severity fire as 83% of all studies and 60% of all effects found no significant impact of fire on owl parameters. Meta-analysis of mean effects found no significant effects of fire on owls, except a positive effect on foraging habitat selection for low-severity burned forest. Meta-regression indicated significant positive effects in recruitment, reproduction, and foraging habitat selection for low- and moderate-severity burned forest. Meta-regression found a significant negative effect of time since fire on occupancy probability. Meta-analysis of variation found mixed-severity fire resulted in greater parameter variation overall, and specifically in occupancy, demography, and survival, and significantly less variation in foraging habitat selection for low-severity burned forest.

These results represent Spotted Owl responses to mixed-severity wildfires that burned within the past 30 yr with representative proportions of high-severity fire in a landscape mosaic. Additionally, because most of the studies in this review reported on effects from wildfire, rather than prescribed fire, the fires and their effects are representative of wildfires as they burned through currently existing forest structure, fire regime, and climate conditions. Several studies have reported that fires during the past few decades have been larger and more severe than the historical mean (Miller and Safford 2012, 2017, Mallek et al. 2013, Steel et al. 2015), but others have disputed this

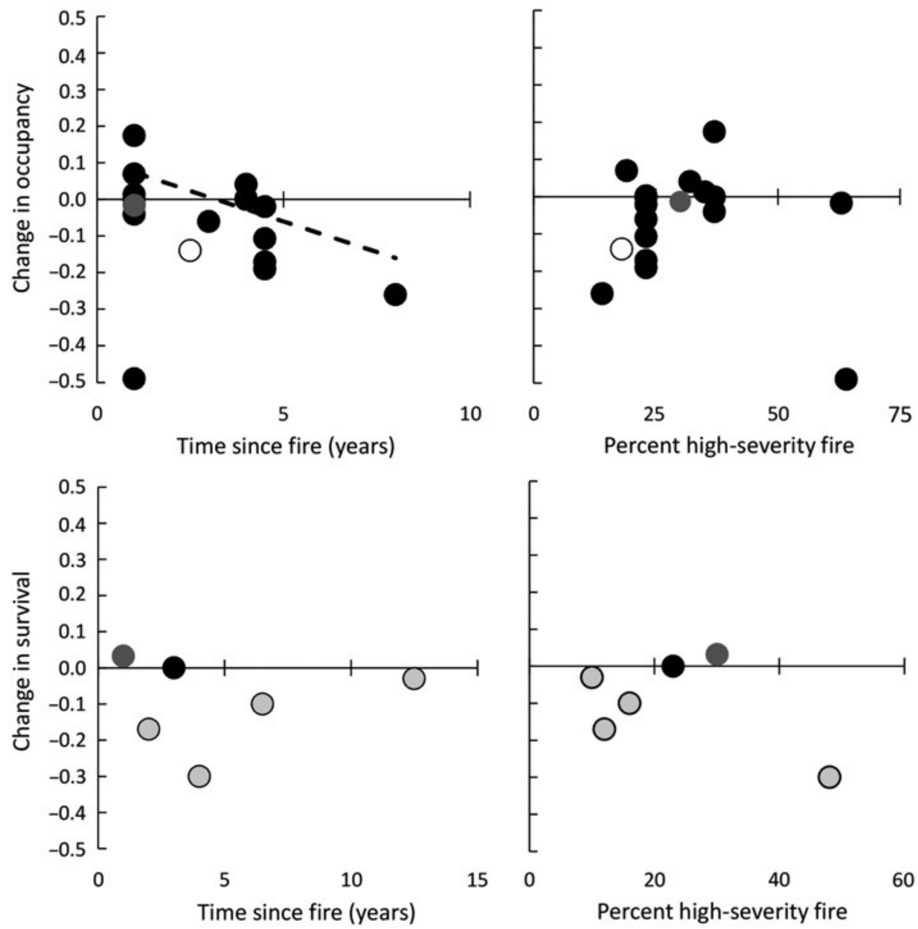

Fig. 4. Results of multi-level linear mixed-effects models (hierarchical models) meta-regression of time since fire and percent of high-severity fire in the study area as covariates to explain heterogeneity in effect sizes from mixed-severity fire on Spotted Owl (*Strix occidentalis*) parameters of breeding site occupancy and survival. The only significant effect was a reduction in occupancy with increasing time since fire, but the effect was sensitive to one study. Symbols indicate subspecies: filled black circles, California; white circles with black outline, Mexican; light gray circles with black outline, northern; and dark gray circles, all three subspecies.

point (Odion and Hanson 2006, Hanson et al. 2009, Odion et al. 2014*a*, Baker 2015*a*). Regardless of what is correct about trends in fire severity, Spotted Owls appear fairly resistant and/or resilient to effects from recent hot, large fires, wherever these fires fall in the long-term range of variability for size and amount of high-severity burn. This is corroborated by the meta-regressions that explicitly quantified the relationship between amount of high-severity fire and Spotted Owl parameters and found only a positive significant correlation (reproduction). My finding of no significant negative relationships between amount of high-severity fire and Spotted Owl parameters demonstrates that large high-severity fire patches, including territories that burn 100% at high severity as was seen in sites within several of the studies in this review, do not have unequivocally negative outcomes for Spotted Owls.

Contrary to current perceptions, recovery efforts, and forest management projects for the Spotted Owl (USFWS 2011, 2012, 2017, USDA 2012, 2018, Gutiérrez et al. 2017) mixed-severity fire as it has been burning in recent decades does not appear to be an immediate, dire threat to owl populations that require landscape-level fuel-reduction

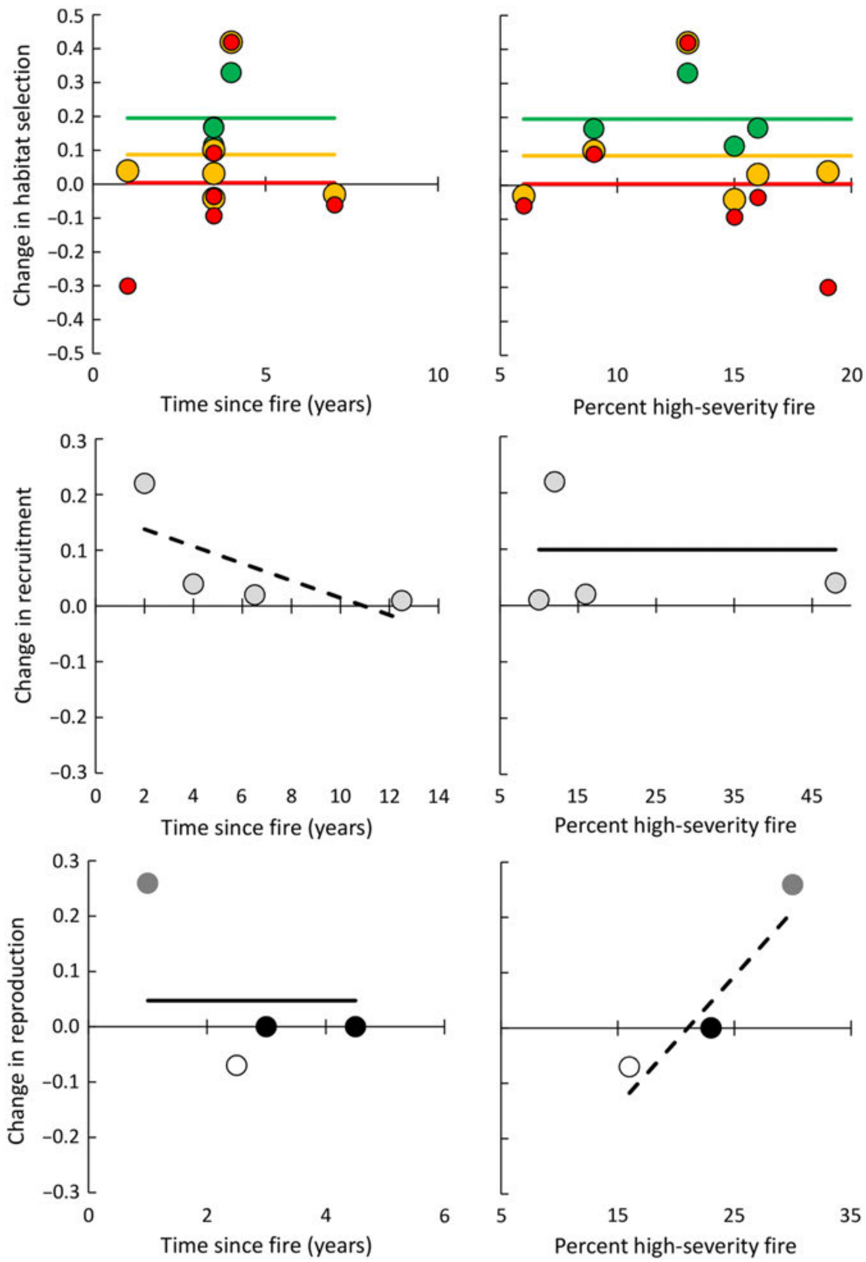

Fig. 5. Results of multi-level linear mixed-effects models (hierarchical models) meta-regression of time since fire and percent of high-severity fire in the study area as covariates to explain heterogeneity in effect sizes from mixed-severity fire on Spotted Owl (*Strix occidentalis*) parameters of foraging habitat selection, recruitment, and reproduction. Significant effects included positive selection for low- and moderate-severity burned forest for foraging, increased recruitment immediately post-fire that diminished with increasing time since fire, and increased reproduction with a positive correlation with amount of high-severity fire. In top two panels, all studies were California subspecies, and colors indicate forest in different burn severity categories: green, low severity; orange, moderate severity; red, high severity. In bottom four panels, symbols indicate subspecies: filled black circles, California; white circles with black outline, Mexican; light gray circles with black outline, northern; and dark gray circles, all three subspecies.

treatments to mitigate fire severity. Empirical studies reviewed here demonstrated that wildfires can generally have no significant effect, but effects can include improved foraging habitat, reduced site occupancy, and improved demographic rates. Most territories occupied by reproductive Spotted Owl pairs that burn remain occupied and reproductive at the same rates as sites that did not experience recent fire, regardless of the amount of high-severity fire in core nesting and roosting areas.

To place my results into perspective, mixed-severity fire typically affects (≥50% vegetation basal area mortality) a very small portion (0.02–0.50%) of Spotted Owl nesting and roosting habitat per year (Odion et al. 2014*b*, Baker 2015*b*, Stephens et al. 2016). Breeding sites that experienced a typical mixed-severity burn mosaic can be expected to have occupancy probability reduced by −0.06 on average. A 0.06 decline in occupancy is less than typical annual declines in occupancy rates observed in the Sierra Nevada in the absence of large fires (Jones et al. 2016: Fig. 3f). In comparison, post-fire logging caused a mean occupancy probability reduction of −0.18.

Post-fire logging is likely to be partially responsible for some of the negative effects attributed to high-severity fire in the studies reviewed here (Tempel et al. 2014, Jones et al. 2016, Rockweit et al. 2017, Hanson et al. 2018). Because Spotted Owl studies typically characterize territory vegetation only in the breeding core area within 1.1 km of the nest, these studies ignore habitat changes and alterations in the year-round home-range area that can extend up to 5.9 km from the nest (Zabel et al. 1992). Spotted Owl habitat protections have generally not included areas beyond 1 km from the nest, a management policy that has not contributed to population recovery.

Complex early seral forests created by fire differ from post-fire salvage-logged forests in that dead trees remain on-site, providing perching sites for hunting owls as well as food sources and shelter for numerous wildlife species (Hutto 2006, Swanson et al. 2011, DellaSala et al. 2014). Longitudinal studies also indicated that burned breeding sites where owls were not detected immediately after fire were often recolonized later (Lee et al. 2012, 2013, Tempel et al. 2016), and this review shows burned forest habitat is used for foraging, demonstrating the mistake of concluding severely burned sites or habitats are lost to Spotted Owls or require restoration (Davis et al. 2016). A recent global meta-analysis found post-fire logging is generally not consistent with ecological management objectives (Thorn et al. 2018).

This review on fire and Spotted Owls forms one portion of the evidence base for data-driven forest management. A recent systematic review of thinning and fire found 56 studies addressing fuel treatment effectiveness in real (not simulated) wildfires from eight states in the western United States (Kalies and Kent 2016). There was general agreement that thin + burn treatments (thinning immediately followed by burning) had some positive effects in terms of reducing fire severity, while treatments by burning or thinning alone were less effective or ineffective (Kalies and Kent 2016). There is also evidence that doing nothing can achieve many forest restoration goals related to age structure and fuels' density (Zachmann et al. 2018). Additional systematic reviews are needed to examine (1) the quantifiable risk of fire to Spotted Owl habitat, as there are disparate lines of evidence regarding whether fire is impeding the recovery of late-seral-stage forests; and (2) the impacts of fuel treatments on Spotted Owl demography and site occupancy. Thinning immediately followed by burning to reduce wildfire risk may or may not have adverse effects on Spotted Owls (Franklin et al. 2000, Dugger et al. 2005, Tempel et al. 2014, 2016, Odion et al. 2014*b*), but the evidence presented here indicates fire itself has arguably more benefits than costs to the species and thus suggests thinning is not necessary.

The results presented here should serve to guide management decisions, but also should be understood as limited by the available data. The sample sizes of number of estimated effects from mixed-severity fire on survival and recruitment were small and limited mainly to the northern subspecies. There were also very few studies from the Mexican subspecies. A few studies presented effect sizes that were influential on results, especially meta-regression results (Roberts et al. 2011), so studies examining longer times since fire are needed. We encourage future studies to increase sample sizes of each parameter and to provide a more balanced sample of studies from all subspecies, and over longer time frames.

Management Implications

The preponderance of evidence presented here shows mixed-severity forest fires, as they have burned through Spotted Owl habitat in recent decades under current forest structural, fire regime, and climate conditions, have no significant negative effects on Spotted Owl foraging habitat selection, or demography, and have significant positive effects on foraging habitat selection, recruitment, and reproduction. Forest fire does not appear to be a serious threat to owl populations and likely imparts more benefits than costs for Spotted Owls; therefore, fuel-reduction treatments intended to mitigate fire severity in Spotted Owl habitat are unnecessary. These findings should inform revisions to planning documents to consider burned forest, including large patches of high-severity burned forest, as useful habitat that imparts significant benefits to Spotted Owls. Forest and wildlife planning documents promote a diverse mosaic of heterogeneous tree densities and ages (USFWS 2017, USDA 2018), the very conditions created by mixed-severity wildfire, and it follows that heterogeneous post-fire structure would lead to greater variation in some Spotted Owl parameters, as was observed in the meta-analysis of variation. Planning documents (USFWS 2011, 2012, 2017, Gutiérrez et al. 2017, USDA 2018) claiming that forest fires currently pose the greatest risk to owl habitat and are a primary threat to population viability appear outdated in light of this review.

Acknowledgments

I thank the many Spotted Owl researchers and field technicians who are responsible for the collection and analyses of the data reviewed here. I also thank Monica Bond and Justin Augustine for thoughtful comments on the manuscript. I have no conflict of interest.

Contributed by Gene E. Likens, August 4, 2011 (sent for review May 28, 2011)

We describe the "landscape trap" concept, whereby entire landscapes are shifted into, and then maintained (trapped) in, a highly compromised structural and functional state as the result of multiple temporal and spatial feedbacks between human and natural disturbance regimes. The landscape trap concept builds on ideas like stable alternative states and other relevant concepts, but it substantively expands the conceptual thinking in a number of unique ways. In this paper, we (*i*) review the literature to develop the concept of landscape traps, including their general features; (*ii*) provide a case study as an example of a landscape trap from the mountain ash (*Eucalyptus regnans*) forests of southeastern Australia; (*iii*) suggest how landscape traps can be detected before they are irrevocably established; and (*iv*) present evidence of the generality of landscape traps in different ecosystems worldwide.

altered ecosystem processes | old growth

In many environments worldwide, key drivers of ecosystem change interact and reinforce one another to trigger cascades of ecosystem modification that are difficult or impossible to reverse (1–3). These cascades are often referred to as regime shifts (4–6). Examples of significant regime shifts include overfishing and trophic cascades in marine predator–prey systems (7) and human disturbance-driven losses of detritivore populations and subsequent changes in the decomposition of organic matter (8). Regime shifts are almost always identified in retrospect, making it difficult to know how to avoid them in advance and problematic to reverse their effects. Therefore, understanding of the mechanistic processes by which regime shifts occur may provide opportunities to change resource management and avoid irreversible and undesirable ecological changes.

In this paper, we describe the "landscape trap" concept, of which the outcome is a regime shift triggered by a series of feedback processes resulting from interacting natural and anthropogenic disturbances. We define a landscape trap as that wherein entire landscapes are shifted into a state in which major functional and ecological attributes are compromised. These shifts in a landscape lead to feedback processes that either maintain an ecosystem in a compromised state or push it into a further regime shift in which an entirely new type of vegetation cover develops. Landscape traps are large-scale ecological phenomena that arise through a combination of altered spatial characteristics of a landscape coupled with synergistic interactions among multiple human and natural disturbances. Thus, changes in the frequency and spatial contagion of large-scale disturbances are the key interacting factors driving entire landscapes into an undesirable and potentially irreversible state (i.e., landscape trap). We demonstrate the concept with examples involving spatial and temporal feedback between logging and fire in forest ecosystems and also provide examples of landscape traps in other environments.

Like other kinds of ecological traps, the landscape trap concept shares characteristics like shifts between alternative stable states and multiple feedback processes (9). However, a focus at a landscape scale and on temporal and spatial changes in disturbances sets the landscape trap concept apart from other kinds of ecological traps and regime shifts, such as population traps and extinction vortices in small populations of animals (10) and elevated rates of animal species loss below threshold levels of native vegetation cover (11).

To the best of our collective knowledge, the landscape trap concept has not been previously reported, yet we argue that landscape traps may be more prevalent in ecosystems around the world than currently recognized. Common ingredients contributing to landscape traps are (*i*) overharvesting of natural resources in a landscape; (*ii*) climate change effects on species' life histories and/or the frequency and severity of ecological disturbances; (*iii*) major changes in the spatial characteristics of landscapes; (*iv*) feedback loops between the changed environmental conditions and other major stressors; and (*v*) severely impaired ecological functions of a landscape in an altered state, such as, for example, reduced populations of species and habitat suitability, reduced carbon storage, and reduced water and timber production. The interaction of these factors is shown in a conceptual model in Fig. 1.

We suggest that landscape traps exist in many ecosystems. For example, logged tropical rainforests in parts of Asia have become more fire-prone (12). Postfire salvage logging in some of these rainforests, in turn, changes the vegetation composition toward more fire-prone grassland taxa. Additional fire further degrades fire-sensitive remnant rainforest, eventually leading to a regime shift to exotic fire-promoting grasslands, limiting opportunities for the vegetation to revert to tropical rainforest (13). Such kinds of interrelationships between logging and altered fire regimes are widespread in tropical rainforests in many other parts of the world, including South America and Africa (14), as are relationships between logging and exotic fire-prone grasses (15).

Temperate forests are not immune to such traps. In moist temperate forests of western North America, logging-related alterations in stand structure increase the risk for both occurrence and severity of subsequent wildfires through changes in fuel types and conditions (16, 17). High-severity wildfires kill young trees planted following previous logging operations. This necessitates reforestation efforts, but these young stands are susceptible to being killed in subsequent recurring high-severity fires (16). Similar kinds of relationships between logging regimes and altered fire regimes have been reported in a range of forest types elsewhere around the world (reviewed in 18).

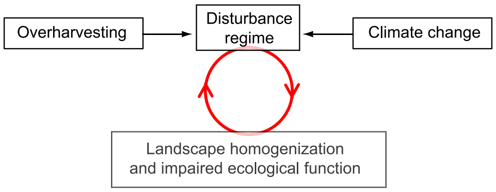

Fig. 1. Conceptual model of a landscape trap. The trap results from the reinforcing feedback loop shown in red.

Results and Discussion

Specific Example of a Landscape Trap: Mountain Ash Forests of Victoria, Southeastern Australia. The specific example of a landscape trap that we present comes from the mountain ash (*Eucalyptus regnans*) forests of southeastern Australia in the central highlands of Victoria. The likely regime shift is from landscapes dominated by old-growth forests that are 200–450 y of age to those dominated by young fire-prone forests that do not survive to become old growth. Evidence comes from new spatial information following massive wildfires in 2009, perhaps the most economically destructive in Australian history (19), coupled with understanding that has emerged from 28 y of extensive field information and associated data analyses in mountain ash forests (20).

The central highlands of Victoria support ∼121,000 ha of mountain ash forest. These are spectacular forests with old-growth trees reaching 90 m or more in height (14). Mountain ash forests persist only within a particular fire regime (*sensu* 21). Before European settlement over 150 y ago, the fire regime was infrequent severe wildfire that occurred in late summer (22). Young seedlings germinate from seed released from the crowns of burned mature trees to produce a new even-aged stand (20). Wildfires may be stand-replacing, because the young trees regenerating after fire belong to a single age cohort (23). When the interval between stand-replacing disturbances is less than 20–30 y (which is the period required for trees to reach sexual maturity and begin producing seed) (24), stands of mountain ash forest will be replaced by other species, particularly wattle (*Acacia* spp.) (20).

In the past century, a new disturbance regime (logging) has been added to the previous natural fire regime. Large areas of mountain ash have been subject to timber and pulpwood harvesting (Fig. 2). In the past 40 y, the traditional method of logging has been clear-cutting, in which all merchantable trees within a 15- to 40-ha area are cut in a single operation (25). Following clear-cutting, logging debris is burned to create a bed of ashes in which the regeneration of a new eucalypt stand takes place, often by artificial reseeding. The vast majority of mountain ash landscapes have become dominated by large areas of regrowth forest with small areas of old forest embedded within them. Old-growth mountain ash forest (*sensu* 20) typically covers less than 3% of the majority of the 3,000- to 6,000-ha wood production forest blocks in the central highlands; however, in some cases, it is less than 1% (20). Indeed, following more than a century of logging and wildfires in 1926, 1932, 1939, 1983, and, most recently, 2009, ∼1.1% of the entire mountain ash forest estate is now in an old-growth stage. This landscape is in stark contrast to mountain ash landscapes 100–150 y ago, which historical accounts (e.g., 26), coupled with stand reconstruction work relating to tree age and stem diameters of large dead (snag) trees remaining within young stands (27), suggest were dominated by large areas of old growth, possibly as high as 60–80% total cover in the central highlands of Victoria (20) (Fig. 2).

Development of a Landscape Fire-Trap in Mountain Ash Forests. The interacting effects of wildfire, logging, and the combination of wildfire and logging (i.e., salvage logging) (*sensu* 28) are creating a previously unrecognized landscape trap in which the disturbance dynamics of "trapped" mountain ash forest landscapes are markedly different from those before European settlement (Figs. S1 and S2). The core process underlying this landscape trap is a positive feedback loop between fire frequency/severity and a reduction in forest age at the stand and landscape levels, leading to an increased risk for dense young regenerating stands repeatedly reburning before they reach a more mature state (Fig. 3). The landscape trap will potentially create irreversible changes in disturbance dynamics, forest cover, landscape pattern, and vegetation structure, and thereby lead to a major regime shift or alternative state. We explain below the evidence for the positive feedback process that underpins this landscape trap (Fig. S2) and discuss why it is historically unprecedented and why it is beginning to dominate the contemporary landscape.

Positive feedback loop between reduced forest stand age and fire. Young stands of mountain ash forest are created by natural regeneration following wildfire. Detailed on-site measurements following the 2009 wildfires have revealed that young forest burns at higher severity than mature forest. We suggest this is for four key reasons:

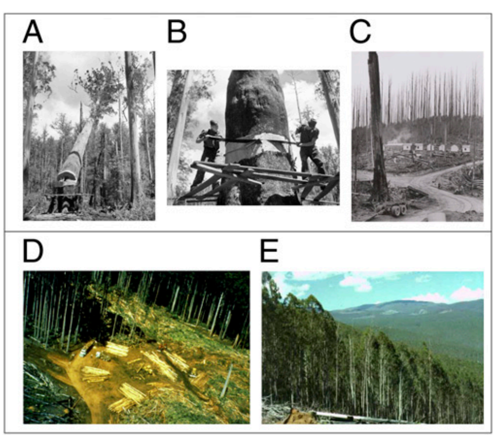

Fig. 2. Photo montage showing historical logging in extensive stands of old-growth forest (*A*–*C*) and extensive clear-cut areas of forest cut in the past 10 y (*D* and *E*) in the mountain ash forest in the central highlands of Victoria. (Photos courtesy of National Archives of Australia, State Library of Victoria and D.B.L.)

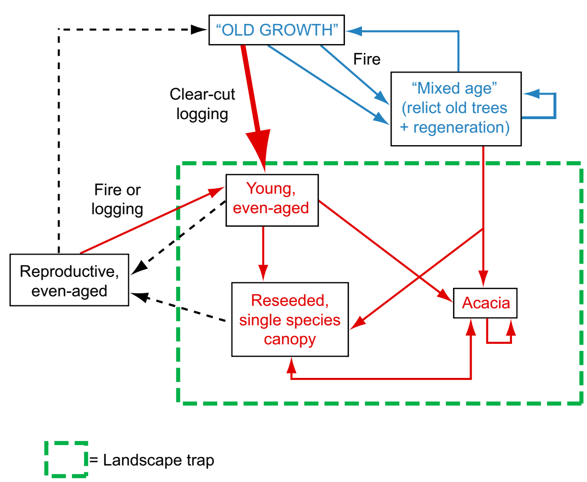

Fig. 3. Development of a landscape trap in the mountain ash forests of the central highlands of Victoria.

i) Young regenerating stands of mountain ash trees are characterized by densely spaced regrowth saplings. There can be several million eucalypt seedlings per hectare soon after a fire or logging. Through processes of rapid natural self-thinning, this declines to ∼400 stems per hectare at 40 y and 40–80 stems per hectare in mature forest after 150–200 y (29). The marked reduction in the number of stems per unit area over time is primarily attributable to competition-derived death and collapse of small suppressed pole and sapling trees, which add greatly to the density of the vegetation in young regrowing forests but do not generally occur in mature and old-growth mountain ash forests (30). Densely spaced stands of regrowth saplings, coupled with the subsequent natural processes of rapid self-thinning that characterize the early stages of stand regeneration in mountain ash forests, create significantly more fine and medium fuels than in old forests (31).

ii) The closely spaced crowns in densely stocked young stands are readily susceptible to carrying a crown fire. This is in contrast to old-growth stands, which are characterized by large relatively well-spaced trees with open crowns and small lateral subcrowns (24).

iii) Trees in young stands are shorter than those in old-growth stands. The flame height needed to scorch or consume the canopy in young stands is therefore significantly lower than in old-growth stands (22).

iv) Young forests support significantly smaller diameter logs on the ground than old-growth stands (32). Such smaller diameter logs support significantly less dense and luxuriant moss mats than larger diameter fallen trees. Moss mats hold large amounts of water (1,100% of dry weight) (33); they play a significant role in moisture retention within logs, and thereby may reduce the risk for burning.

Why has this positive feedback loop not occurred historically? Before European settlement, frequent, widespread, high-severity wildfires in mountain ash forests would have been suppressed by a combination of extended periods of wet climatic conditions and the absence of the intensive human disturbances resulting from clear-cut logging. This favored a negative feedback loop between forest age and fire, enabling young forest to mature into a less fire-prone state that was not conducive to widespread high-severity wildfire (Fig. S1).

Why is this positive feedback loop now beginning to develop? Two major changes have occurred relatively recently to favor the positive feedback loop: reduced forest age in mountain ash forests and increased fire frequency (Fig. 3 and Figs. S1 and S2). First, there has been a 25% reduction in rainfall in southeastern Australia over the past few decades (34). Second, logging has converted more than 90% of formerly old forest to young regenerating stands. Young forest resulting from clear-cut logging has two added elements of fire proneness: (*i*) fine fuels created by logging operations are added to those from the collapse of small-diameter stems and shedding of branches during natural self-thinning and self-pruning processes in densely stocked regenerating stands, and (*ii*) the spatial pattern of stand age classes in mountain ash landscapes has been altered, with an increased prevalence of young densely stocked forest and a significantly reduced area of (mesic) old-growth forest. This, in turn, has increased the fire contagion in the landscape.

Codes of logging practice and the practical logistics of harvesting operations mean that clear-cutting is applied to flatter and more accessible parts of mountain ash landscapes. However, these places are also where old-growth stands were formerly most likely to occur. Evidence for this comes from work in closed-water catchments of the central highlands of Victoria, where there were no confounding effects of past and present human disturbances that would have otherwise obscured key spatial patterns of forest age classes (22). Before the 2009 wildfires, old growth mountain ash occupied a subset of the overall environmental domain of mountain ash per se, typically within a narrow band of mesic sites rather than ridges or steep slopes. This environmental domain was not only favorable for tree growth but interacted with spatial differences in natural disturbance regimes (35). Mesic sites support taller trees. They are also places where both the fire frequency and the intensity of past wildfires were attenuated (22). Former areas of old-growth forest on flat terrain have now been converted to young regenerating stands and are spatially connected to young burned or logged forest on midslopes and ridges. Importantly, the more widespread that young logged and regenerated forest becomes, the greater is the risk for increasing spatial contagion in the spread of wildfire through landscapes (31), because moist remnant areas that would have slowed or halted the spread of fire (and formerly supported old forest) have been converted to young forest. Spatial contagion in recurrent high-severity fire may therefore reinforce a pattern of increasing homogeneity in the cover of young forest in a landscape (Fig. S2). This pattern occurs because some areas of fire refugia (e.g., flat plateau, deep south-facing valley floors) that were traditionally characterized by a long absence of fire (particularly high-severity fire) and supported stands of multiaged forest or old-growth forest (35) become more susceptible to being burned by high-severity conflagrations that spread from adjacent more flammable logged and young regenerating areas (Figs. S1 and S2). Notably, although natural disturbance regimes often increase heterogeneity in many landscapes (36), the opposite frequently occurs in areas subject to landscape trap phenomena, in which the combination of human and natural disturbance regimes can lead to increased landscape homogeneity.

Research in moist forests around the world suggests that other factors associated with logging may increase susceptibility of young regenerating forests to being burned or reburning at high severity. For example, the large quantities of logging slash created by harvesting operations can sustain fires for longer than fuels in unlogged forest (12). Similarly, lightning strike ignition is more likely to occur in harvested stands because of increased fine fuels resulting from logging slash, and this effect may remain for 10–30 y following logging (37). Finally, the removal of trees by logging creates microclimatic conditions that lead to increased drying of understory vegetation and the forest floor, and a correspondingly elevated fire risk (38).

Once a mountain ash forest landscape is dominated by widespread areas of young fire-prone forest, the elevated risk for high-severity spatially contagious fire decreases the probability that the landscape can return to its former mature state, particularly under the drier and warmer conditions associated with climate change. Hence, the dynamics of trapped mountain ash forest landscapes are different from those in the past (>100 y ago) (Fig. 3 and Figs. S1 and S2). The current set of interacting disturbance regimes of fire, logging, and postfire (salvage) logging did not exist before European settlement. Importantly, there is a major asymmetry in the period during which mountain ash forest ecosystems have coevolved with natural disturbances (>20 million y) compared with the 20–100 y during which the interacting human and natural disturbance regimes have produced a landscape trap.

End point: Regime shift? The positive feedback cycle of widespread young regenerating stands and frequent high-severity wildfire means that either extensive areas of trapped young mountain ash forest will be maintained or a further regime shift will occur in which a new type of vegetation cover develops, particularly wattle (*Acacia* spp.) (Fig. 3 and Figs. S1 and S2). Once mountain ash has been eliminated from an extensive area, it recolonizes slowly because the seed released from the crowns of burned mature trees disperses ∼1.5–2.0 crown heights from a source

ECOLOGY

tree and successful regeneration (fire) events may occur every 30–400 y. Therefore, the regeneration niche, which is a key part of the life cycle of mountain ash (39), is maladapted to the altered landscape conditions and altered fire regime created by recurrent logging and wildfire. Recurrent high-frequency wildfire may result in repeatedly burned areas that were formerly dominated by mountain ash being colonized by other eucalypt species that do not depend on seedling regeneration but, instead, recover after wildfire via strategies like epicormic resprouting [e.g., shining gum (*Eucalyptus nitens*), messmate (*E. obliqua*)].

Irrespective of whether mountain ash forest landscapes remain trapped as widespread, young, fire-prone stands or undergo a regime shift to extensive areas dominated by *Acacia* spp. and other species, such changes will result in significant impairment of ecological functions like carbon storage, water production (40, 41), and biodiversity conservation. For example, neither young small-diameter mountain ash trees nor *Acacia* spp. support the cavities that are crucial nesting and denning sites for many species of animals. They also lack critical structural features, such as extensive bark streamers, that are key foraging microhabitats for wildlife (42). These changes in vegetation structure are likely to lead to irreversible losses in habitat suitability for ∼40 species of vertebrates in mountain ash forests that are dependent on large 120- to 150+-y-old trees with hollows.

Avoiding a Landscape Trap in Mountain Ash Forests of Victoria. Three important strategies are needed to reduce the problems created by the landscape trap in the mountain ash forests of Victoria. First, large (>1,000 ha) areas of currently unburned forest need to be retained, wherein the number of anthropogenic stressors is reduced. The area of green forest was reduced dramatically by the 2009 wildfires; hence, relative biodiversity, carbon storage, and water production values of remaining unburned forest have increased. However, such uncommon areas of unlogged forest are increasingly sought after for timber and pulpwood harvesting because (*i*) they are among the declining number of places suitable for cutting as a consequence of past fires and past (prefire) logging operations, (*ii*) there are legislated guarantees to provide logging contractors with forest to cut for timber and pulpwood (43), and (*iii*) cutting burnt forest (i.e., salvage logging) has major negative environmental impacts and long-term effects on forest recovery and forest biodiversity (28). Targeting limited remaining areas of unburned forest for logging depletes the overall amount of these forests, with long-term economic implications for harvest contractors. Increased logging pressure on green areas has other ecological implications: Remaining areas of green forest are important refugia for biodiversity following wildfires and are critical for underpinning postfire ecological recovery (32). Legislative and other impediments to reducing harvest levels highlight the existence of management and socioeconomic traps within landscape traps, and these need serious and timely review.

A second strategy to avoid the development of a landscape trap in the now highly fire-prone mountain ash landscapes of Victoria is to recalculate the sustained yield to accommodate future losses of timber resulting from the inevitable burning of some parts of forest landscapes. This strategy has the advantage of not overcommitting remaining unlogged green forest in the event of wildfires, thereby resulting in more conservative management of natural resources and more explicit recognition of the uncertainty created by major natural disturbances.

Given the extent of recently burned forest in Victoria, a third important strategy to reduce the risks for development of a landscape trap is to try to limit the amount of future fire. Although mountain ash trees are dependent on fire to promote regeneration, fires have been extensive in the past 25–100 y; another fire in the coming 20 y within currently young regenerating stands is likely to lead to a major regime shift (Fig. 3). Reducing the amount of fire in mountain ash forests is a significant challenge. Broad-area prescribed burning is not a viable management option because high levels of moisture in the vegetation and large quantities of biomass make planned fires extremely difficult to control (20). However, prescribed burning as part of a regime of fire can be an appropriate management option in drier forest types that are adjacent to mountain ash forests. Carefully applied strategic burning in such drier environments may help to reduce the extent of spatial contagion in wildfire that occurs in these areas and, in turn, reduce the risk for adjacent stands of mountain ash forest being burned (44).

Examples of Landscape Traps in Ecosystems Other Than Forests. We contend that landscape traps may be prevalent in many ecosystems. For example, climate change and overfishing have facilitated the conversion of subtidal kelp (*Macrocystis pyrifera*) forests in Tasmanian coastal waters to "barrens" habitat resulting from overgrazing by the sea urchin *Centrostephanus rodgersii*. Ocean warming and altered circulation patterns have enabled the poleward spread of this sea urchin (45), and overfishing of predators, such as the southern rock lobster (*Jasus edwardsii*), has enabled *C. rodgersii* to establish high-population density barrens that result in the loss of biodiversity and a reduction in the productivity of fisheries and contribute to the decline of such predators as *J. edwardsii* (46). Aquatic environments where water quality can be radically altered by nutrient inputs from human activities (e.g., 47) also are susceptible to the development of landscape traps.

Grazing on public lands in the western United States has been blamed for reducing biodiversity and, together with exotic weeds, may have led these grassland ecosystems into a landscape trap that produces a plant community from which there is no going back (48). Livestock grazing in western United States may have reduced the abundance of preferred plant species while subjecting the soil to weed invasion, such that large areas are now degraded rangelands in the same manner illustrated in eastern Australia by the "woody weed" problem in semiarid woodlands (49). Introduced grasses, such as cheatgrass (*Bromus tectorum*), can similarly move grassland communities in the intermountain western United States into a regime change that is nearly impossible to reverse (50, 51). A lack of reversible change may be best illustrated by landscape traps in regions heavily impacted by disturbances like mountaintop mining (52).

Concluding Comments

We suggest that strategies and management interventions are needed to reduce the probability of landscape traps developing (Fig. 4). One approach is to recognize that landscape traps can exist and identify the suite of spatial and temporal characteristics that can combine to give rise to them, including (*i*) exploitation of the natural resources in a landscape through unsustainable levels of harvesting; (*ii*) alteration in the spatial characteristics of landscapes, including modifications to the frequency and severity of ecological disturbances; (*iii*) feedbacks between altered environmental conditions and other major anthropogenic stressors;

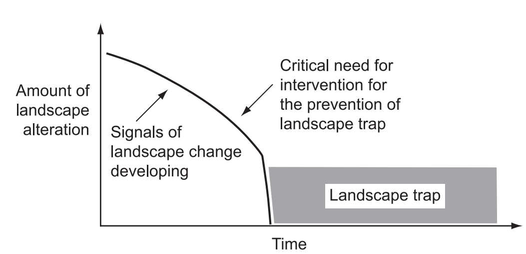

Fig. 4. Conceptual model highlighting signals and interventions required to reverse the development of a landscape trap.

and (*iv*) severely impaired landscape processes and functions. A second approach is to limit the number of anthropogenic stressors in landscapes and reduce the potential for negative interactions among multiple stressors. This may equate to a more conservative approach to the harvesting of natural resources or, in other cases, application of management strategies that reduce feedbacks (e.g., fuel reduction through prescribed burning). Sustained yields of natural resources also may need to be rapidly reassessed following catastrophic events to avoid overcommitting remaining intact areas and further increasing the risk for creating a landscape trap.

We suggest that the need for proactive management to prevent the development of landscape traps is critical, given that (*i*) landscape traps might be at increased risk for development in response to significant "events" like major natural disturbances, which are likely to become more frequent, more severe, or both under rapid climate change in many regions (e.g., 53, 54), and (*ii*) marked asymmetry exists between the rapidity with which landscape traps may develop and the prolonged time scales (hundreds to thousands of years) that characterize natural ecological processes and natural disturbance regimes.

Report

USDA Forest Service Roadless Areas: Potential Biodiversity Conservation Reserves

Colby Loucks[1], Nicholas Brown[2], Andrea Loucks[3], and Kerry Cesareo[1]

ABSTRACT. In January 2001, approximately 23 x 10^6 ha of land in the U.S. National Forest System were slated to remain roadless and protected from timber extraction under the *Final Roadless Conservation Rule*. We examined the potential contributions of these areas to the conservation of biodiversity. Using GIS, we analyzed the concordance of inventoried roadless areas (IRAs) with ecoregion-scale biological importance and endangered and imperiled species distributions on a scale of 1:24,000. We found that more than 25% of IRAs are located in globally or regionally outstanding ecoregions and that 77% of inventoried roadless areas have the potential to conserve threatened, endangered, or imperiled species. IRAs would increase the conservation reserve network containing these species by 156%. We further illustrate the conservation potential of IRAs by highlighting their contribution to the conservation of the grizzly bear (*Ursos arctos*), a wide-ranging carnivore. The area created by the addition of IRAs to the existing system of conservation reserves shows a strong concordance with grizzly bear recovery zones and habitat range. Based on these findings, we conclude that IRAs belonging to the U.S. Forest Service are one of the most important biotic areas in the nation, and that their status as roadless areas could have lasting and far-reaching effects for biodiversity conservation.

INTRODUCTION

In January 2001, the Clinton administration promulgated its *Roadless Area Conservation Rule,* which states that 237,000 km^2 of inventoried roadless areas (IRAs) within the U.S. National Forest System will remain roadless and protected from timber extraction (USDA Forest Service 2000). These lands represent 31% of the National Forest System or 2.5% of the total U.S. land base (DeVelice and Martin 2001). They would increase the amount of strictly protected land area in the United States in IUCN categories I–III from 4.8 to 8.5%. Beyond these most basic statistics, few studies have analyzed the potential contribution of IRAs to biodiversity conservation (Martin et al. 2000, DeVelice and Martin 2001).

DeVelice and Martin (2001) assessed the extent to which IRAs could contribute to building a representative network of conservation reserves in the United States. Using ecoregions as their unit of analysis (Ricketts et al. 1999), they found that IRAs could potentially expand ecoregional representation, increase the area of reserves at lower elevations, and increase the size of conservation areas to provide refuge for wide-ranging species. However, in their assessment they did not evaluate the contribution of IRAs toward the conservation of biodiversity and populations of specifically threatened, endangered, or imperiled species.

The lands belonging to the USDA Forest Service contain more than 80% of mammal and reptile species and more than 90% of the bird, amphibian, and fish species in the United States, including many that have been extirpated from large portions of their presettlement ranges (USDA Forest Service 1997). According to the NatureServe database, more than 1400 of these species have been designated as threatened and endangered (TE) species under the *Endangered Species Act* (ESA). The *Forest Service Roadless Area Final Environmental Impact Statement* identified approximately 400 TE or proposed species found on USDA Forest Service land and an estimated 220 (55%) that are directly or indirectly associated with IRAs (USDA Forest Service 2000). IRAs provide or influence designated critical habitat for at least 30 of these species (USDA Forest Service 2000).

However, the ESA list is not a complete listing of imperiled species. There are numerous species that are globally rare or threatened with extinction but for

[1]World Wildlife Fund; [2]NatureServe; [3]Pinchot Institute

various reasons do not appear on the ESA TE species list. Many of these species also occur on USDA Forest Service land. To fill this gap, we supplemented the TE species list with species categorized as critically imperiled or imperiled according to NatureServe's central database.

The objective of this paper is to assess three critical questions associated with IRAs:

> Is there a high concordance between IRAs and ecoregions of particular biodiversity values?
>
> Do IRAs overlap with threatened, endangered, or imperiled species?
>
> Is there potential for IRAs to assist in the conservation of wide-ranging species, such as the threatened grizzly bear (*Ursos arctos horribilis*), in the conterminous United States?

METHODS

We obtained the spatial coverages of the inventoried road areas (IRAs) in vector format from the roadless area conservation Web site (Table 1).

Fig. 1. Overlap of USDA Forest Service inventoried roadless areas (IRAs) with ecoregions that contain USDA Forest Service lands. The bold line indicates the separation of IRAs into three geographic regions: east, west, and Alaska.

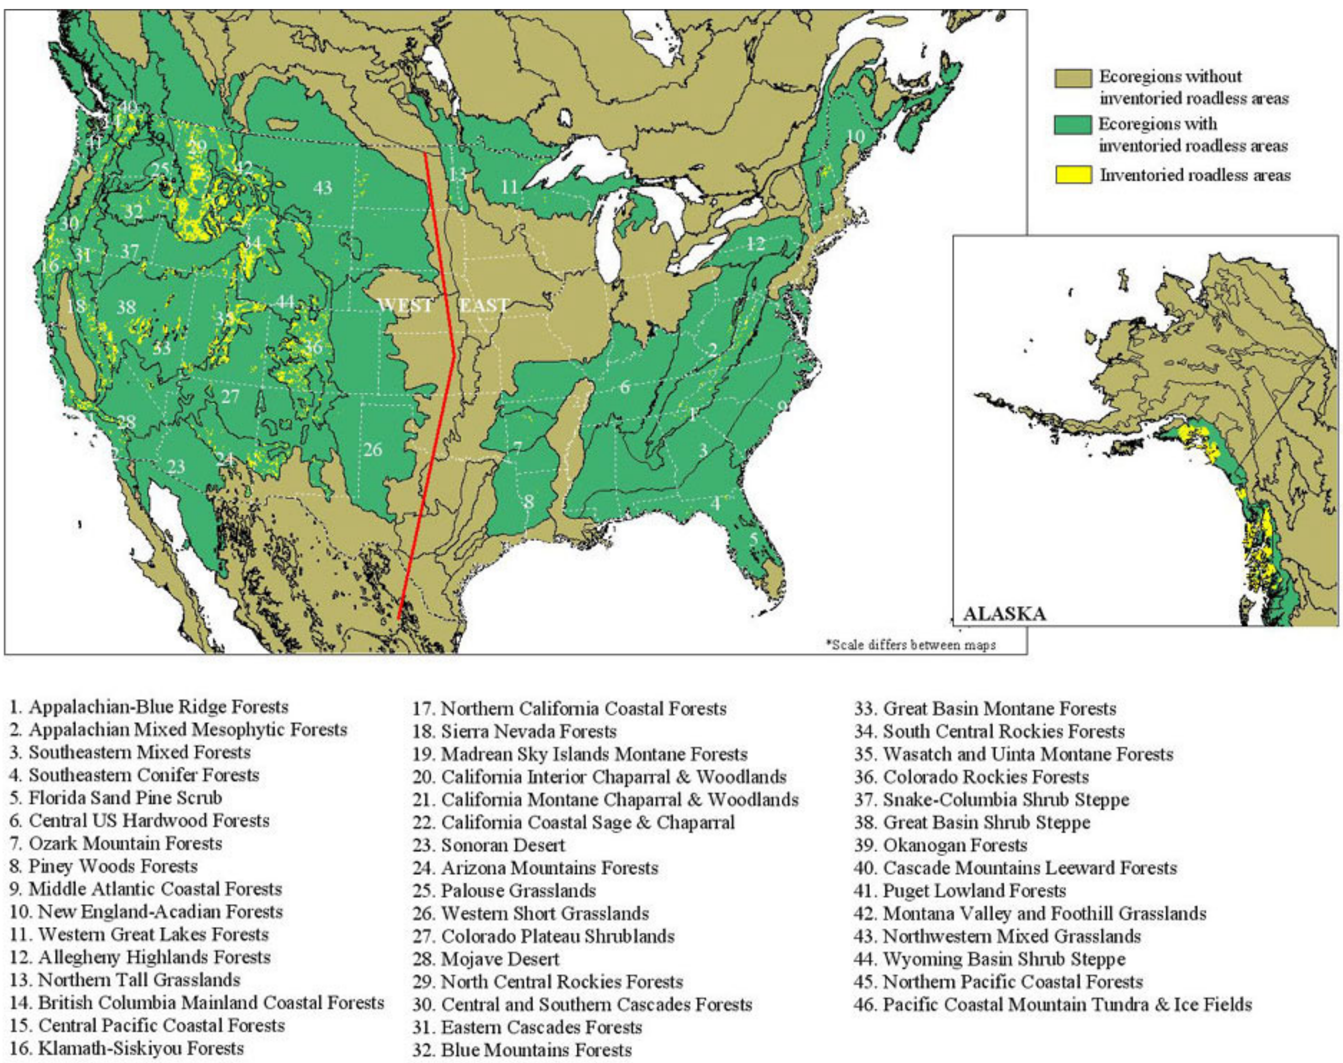

Table 1. Data sources. All data web data sources were accessed in February 2001.

Ecoregions

As seen in Fig. 1 and Table 1, we evaluated the potential benefit of IRAs for biodiversity conservation using the ecoregions and biological importance rankings provided in Ricketts et al. (1999). Using ArcView 3.2, we combined the IRAs and ecoregion coverages, both in vector format. To facilitate interpretation, we separated our analysis into three geographic regions, i.e., the eastern United States, the western United States, and Alaska, following the methodology used by DeVelice and Martin (2001).

Ricketts et al. (1999:7) defined an ecoregion as " ... a relatively large area of land or water that contains a geographically distinct assemblage of natural communities." Ecoregions were selected as the units of analysis because they integrate ecological, biological, and geographic considerations into land-use decision making and are being used to establish priorities for large-scale conservation efforts (Omernik 1995*a*,*b*, Ricketts et al. 1999, Groves et al. 2002). Where ecoregions extend into either Canada or Mexico, we included only those portions within U.S. boundaries for all analyses. Although we would have preferred to maintain ecoregional contiguity, the spatial nature of USDA Forest Service lands and the applicability of the *Endangered Species Act* required strict adherence to political boundaries.

Ricketts et al. (1999) classified the biological importance of each ecoregion based on species distribution, i.e., richness and endemism, rare ecological or evolutionary phenomena such as large-scale migrations or extraordinary adaptive radiations, and global rarity of habitat type, e.g., Mediterranean-climate scrub habitats. They used species distribution data for seven taxonomic groups: birds, mammals, butterflies, amphibians, reptiles, land snails, and vascular plants (Ricketts et al. 1999). Each category was divided into four rankings: globally outstanding, high, medium, and low. The rankings for each of the four categories were combined to assign an overall biological ranking to each ecoregion. Ecoregions whose biodiversity features were equaled or surpassed in only a few areas around the world were termed "globally outstanding." To earn this ranking, an ecoregion had to be designated "globally outstanding" for at least one category. The second-highest category, or continentally important ecoregions, were termed "regionally outstanding," followed by "bioregionally outstanding" and "nationally important" (Ricketts et al. 1999). Although our analyses focused on those ecoregions characterized as globally and regionally outstanding, even the lowest category, nationally important, contains important biodiversity in a local context.

Threatened, endangered, and imperiled species

Currently, public land managers are required to monitor populations of threatened and endangered (TE) species and, where appropriate, develop management plans to conserve these populations and their habitat requirements (U.S. Fish and Wildlife Service 1973). Previous studies have analyzed the distribution of TE species based on counties, or boroughs in Alaska, and identified high-concentration areas of TE species and associated habitats (Dobson et al. 1997, Flather et al. 1998, Stein et al. 2000). Despite their valuable findings, these previous studies were limited by the coarse level of spatial resolution and the use of political units of disparate sizes. To avoid similar limitations with our analysis, we use data of a finer resolution to identify levels of concordance between the locations of IRAs and TE species.

The NatureServe central database (Table 1) provided the finer-resolution data for the identification of the locations of TE species. Data for this database are developed by state natural heritage programs and managed by NatureServe. Natural heritage programs have documented and tracked the occurrence of threatened, endangered, and imperiled species for nearly 30 yr (Jenkins 1985, 1988, 1996). The system assigns global conservation status ranks known as "element global ranks" or "G-RANKS" to species and communities that are intended to estimate the extent of their imperilment or vulnerability. Conservation status ranks are assigned based on an assessment of rarity, the extent of recent decline of populations, threats, biological fragility, and other factors (Stein et al 2000). The most imperiled species and communities are ranked G1, and the most stable ones are ranked G5.

The NatureServe central database includes fields for federal ESA listing status and for global conservation status. We selected records of species that are federally listed as threatened or endangered (TE) according to the U.S. Fish and Wildlife Service or the National Marine and Fisheries Service and those that are ranked by NatureServe as critically imperiled (G1) or imperiled (G2). The output file was a vector file of 109,125 occurrences of species with G1 or G2 rankings or federal ESA listings. These occurrences were collated into 7.5-min quadrangles from the U.S. Geological Survey. The largest quadrangles, in the southern part of the United States, are 179 km^2. We used two data products for our analyses. The first contains only TE species (Fig. 2), and the second contains TE, G1, and G2 species (Fig. 3). The spatial resolution of the locational data varied according to the equipment and methodologies that natural heritage programs used in collecting the data. However, the maximum uncertainty for the data set was less than the area of a quadrangle grid cell.

Fig. 2. Threatened and endangered (TE) species distributions by the 7.5-min quadrangles of the U.S. Geological Survey.

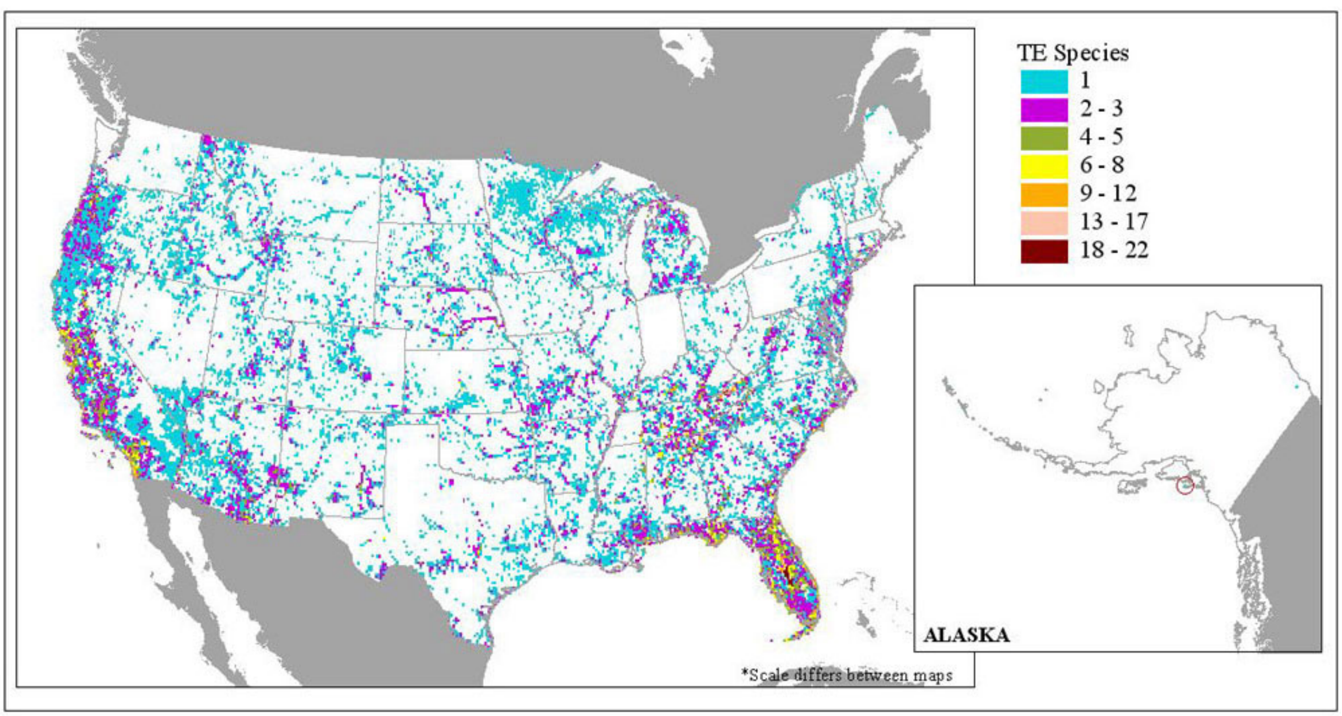

Fig. 3. Threatened and endangered (TE) species and critically imperiled (G1) and imperiled (G2) species distributions by the 7.5-min quadrangles of the U.S. Geological Survey.

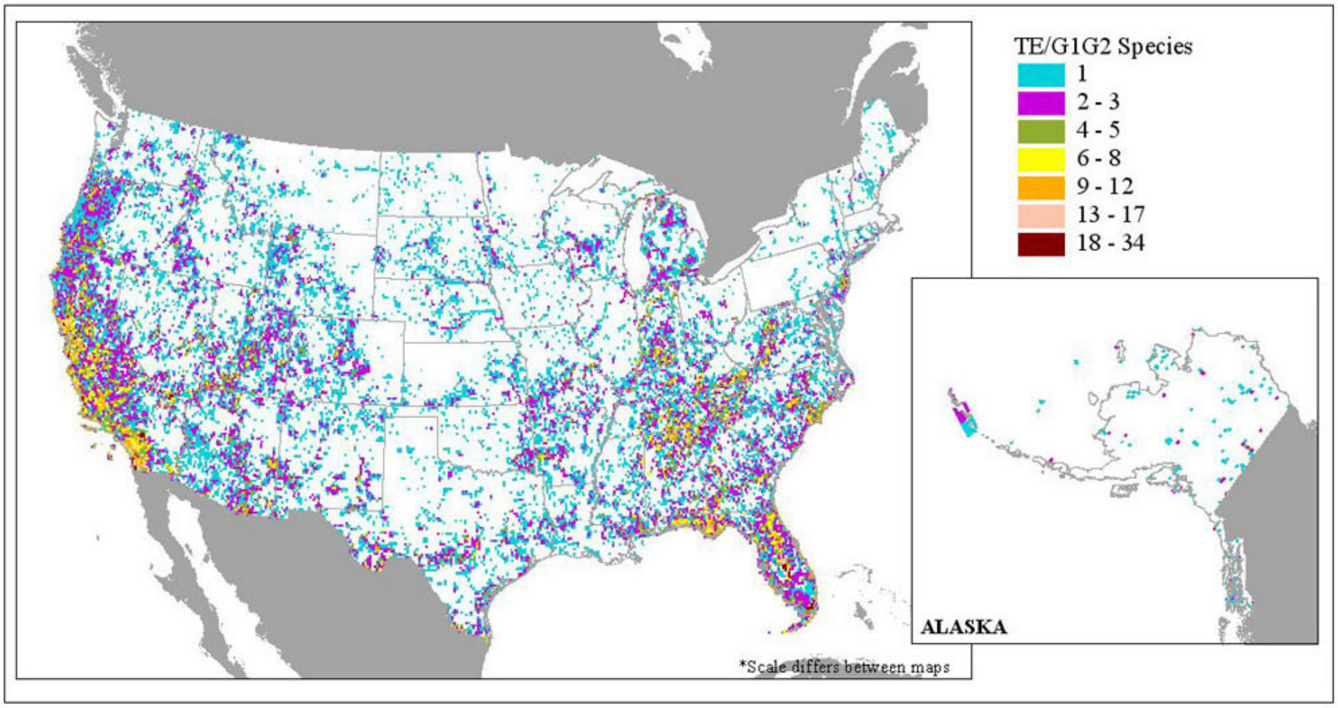

The TE, G1, and G2 data sets demonstrate only a moderate degree of overlap. These discrepancies occur partly because the NatureServe system evaluates only biological factors, whereas species are assigned to federal listings for both scientific and political reasons. There are 75,000 occurrences of TE species, but only 27,000 are ranked G1 or G2 by the NatureServe system. Of the 1409 ESA-listed TE species in the NatureServe database, 1109 are ranked G1 or G2. Conversely, there are 5997 species ranked G1 or G2 that are not classified as TE species. Of the 61,000 occurrences of G1 and G2 species recorded in the NatureServe database, more than 33,000 occurrences lack a TE species designation. One of the reasons for the disparity between the high concordance of species but the low concordance of occurrences is the fact that certain species are wide-ranging. For example, the grizzly bear, which is a threatened species but not a G1 or G2 species, is recorded often across its wide range, so that it accounts for far more records than a narrow endemic species that is both TE and listed as G1 or G2.

The NatureServe database contains information gaps (Table 2). However, although the missing data for Idaho, Montana, and Washington are critical for the conservation of individual species, the lack of them served only to make our analysis a more conservative estimate of the potential contributions of IRAs to species conservation. There are no IRAs in Massachusetts and only one in Maine, with a total area of 24 km^2.

We overlaid both the TE species and TE/G1–G2 species databases with the uniquely named IRAs to identify the percentage of IRAs that contain known occurrences of TE or G1–G2 populations. In instances where multiple quadrangles containing species occurred within a single IRA unit, we erred on the conservative side and used only the quadrangle that contained the most species, i.e., we assumed that multiple quadrangles would contain the same species.

We also analyzed the relative increase in conservation reserves that IRAs would confer to TE and TE/G1–G2 species. We overlaid the TE and TE/G1–G2 databases with a conservation area database compiled by the Conservation Biology Institute and World Wildlife Fund (Table 1). This database includes all federal, state, county, and municipal public lands and some private lands. The private lands have not been systematically surveyed and do not include conservation easements. We used only lands that are classified for strict biodiversity conservation, which we define as those designated as categories I–III by the IUCN. Category I is for Strict Nature Reserves/Wilderness Areas, category II covers National Parks, and category III includes National Monuments (The World Conservation Union 1978, The World Conservation Union 1994). Hereafter we refer to the areas that meet these criteria as "conservation reserves." We did not include protected-area categories IV–VI, which allow road building, timber harvesting, and other extractive activities in our analysis. Of 78 x 10^6 ha of National Forest land, 14 x 10^6 ha are designated as National Wilderness Areas, and an additional 2.5 x 10^6 ha are classified as Special Designated Areas that are IUCN category I reserves. The remaining 61.5 x 10^6 ha of National Forest land, which are not classified as conservation reserves, are governed by periodic management plans that may allow or restrict resource uses and extraction.

Table 2. Gaps in data available for this study.

State	Missing data
Idaho	Fish data
Maine	Animal data
Massachusetts	All data
Montana	Canada lynx, bull trout, gray wolf data
Washington	Most animal data

Grizzly bear case study

Finally, because national analyses can obscure important details of individual species, we also analyzed the potential contribution of IRAs to grizzly bears (*Ursos arctos horribilis*), specifically in relation to the regions designated as grizzly bear recovery areas by the U.S. Fish and Wildlife Service (Table 1). We overlaid these grizzly bear recovery zones with the IRAs to assess the concordance of these areas. We chose grizzly bears because they are a federally listed threatened species in the conterminous United States and require large and contiguous habitat areas to survive.

All spatial databases were in vector format and put into a common projection prior to the overlap analysis. All spatial estimates derived from our analyses were obtained by summarizing the area of overlap of the respective GIS databases. One caveat of our methodology is that the combination of multiple GIS layers may lead to the propagation of spatial errors and increased uncertainty (Flather et al. 1998, Heuvelink 1998). This concern is a generalized methodological one. Our errors are no greater or smaller than those of any similar analysis that uses multiple spatial data from multiple sources. The TE species databases, protected areas database, and IRA coverages represent a vast collection of data from many sources. It is likely that errors are associated with each of these layers. However, most of our analyses were conducted at a sufficiently broad scale that we believe the error rate is not large enough to affect our ultimate conclusions.

RESULTS

Ecoregions

Across the United States, we found that more than 20% of inventoried roadless areas (IRAs) were located within ecoregions that have been classified as globally outstanding (Table 3, Fig. 4). In the eastern region, approximately 70% of the IRAs are found in globally or regionally outstanding ecoregions (Table 3, Fig. 4). More than 50% of these forests occur in two Appalachian ecoregions, the Appalachian-Blue Ridge forests and the Appalachian mixed mesophytic forests. Both are considered globally outstanding for their diverse endemic species, which range across many taxa (Stephenson et al. 1993, Ricketts et al. 1999). The vast majority of the IRAs in eastern forests are less than 10.1 km^2 in size, and few are adjacent to existing wilderness areas (DeVelice and Martin 2001).

Table 3. Distribution of inventoried roadless areas (IRAs) by category of ecoregion biodiversity as per Ricketts et al. (1999). The percentage is the percentage of IRAs that fall into that particular category.

Biodiversity category	km^2	Percentage
Globally outstanding	50,221	21.2
Regionally outstanding	12,648	5.4
Bioregionally outstanding	164,600	69.5
Nationally important	9268	3.9

In the western region, IRAs are found predominantly in bioregionally outstanding ecoregions, with only 18% in globally or regionally outstanding ecoregions (Table 3, Fig. 4). Although globally and regionally outstanding IRAs are found mainly in the states of California, Oregon, Washington, and Arizona, the intermountain west contains most of the nation's bioregionally and nationally important IRAs. Western IRAs are on average larger than eastern IRAs, and the vast majority are adjacent to existing wilderness areas. If the IRAs were combined with the wilderness areas, the western forests would contain 34 of the 45 largest contiguous areas of strictly protected forests in the United States (DeVelice and Martin 2001).

Table 4. Comparison of the degree of overlap between inventoried roadless areas (IRAs) and quadranges containing threatened or endangered (TE) species or quadranges containing TE species that are also ranked as highly imperiled (G1–G2) by the IUCN. The mean number of TE or TE/G1–G2 species present in each IRA is given.

Region	Total no. of IRA units†	No. of IRA units with TE species quadrangles (% of total)	Mean no. of species‡	No. of IRA units with TE/G1–G2 species quadrangles (% of total)	Mean no. of species‡
Eastern United States	286	201 (70.3)	2.1	228 (79.7)	4
Western United States	2159	1317 (61.0)	1.6	1692 (78.3)	2.9
Alaska	150	2 (1.3)	1	88 (58.6)	1.3

†Units are defined by each named inventoried roadless area.
‡Where multiple quadrangles occurred in a single IRA unit, we used only the quadrangle with the greatest number of species.

Threatened, endangered, and imperiled species

Of the 2595 IRA units, approximately 58% of them overlap with TE species quadrangles (Table 4). When separated into geographic regions, the IRAs in the eastern and western United States demonstrate overlaps of 70.3 and 61.0%, respectively. Of the IRAs that contain TE species, the mean number of TE species found in IRAs is highest in the east (2.1 species) and lowest in Alaska (1.0 species).

When G1–G2 species are included in the analysis, both the number of IRAs that contain TE/G1–G2 species and the mean number of species of concern found in each IRA increase (Table 4). In sum, approximately 77% of the IRAs overlap with quadrangles that contain species at risk. The Alaska region contains the largest increase in IRAs when G1–G2 species are included, increasing to 58.6 from 1.3%. The west increases to 78.3%, and the east increases to 79.7%. However, the east shows the largest increase in mean number of TE/G1–G2 species found in IRAs, increasing from 2.1 to 4.0 species (Table 4).

The IRAs could also contribute a significant amount of land area to existing conservation reserves for both TE and TE/G1–G2 species in all geographic regions (Table 5). The largest increase in area and the greatest percent increase in conservation reserves are found in the western United States, with the exception of the 100% increase from the single quadrangle in Alaska. IRAs would contribute to a 96% increase in available habitat in conservation reserves for TE species, whereas the inclusion of G1–G2 species expands that increase to 210%. Although the eastern region would see similar but more modest gains, habitat in conservation reserves in the Alaska region would increase 113% for TE/G1–G2 species (Table 5). Overall, IRAs would increase the conservation reserve network containing TE, G1, or G2 species by 156%.

Table 5. The concordance of occurrences of threatened or endangered (TE) species or of TE species that are also classified as highly imperiled (G1–G2) by the IUCN with the existing conservation reserve network (IUCN I–III) and inventoried roadless areas (IRAs).

Region	No. of TE species quadrangles in IUCN I–III conservation reserves	No. of TE species quadrangles in IRAs	Percent increase	No. of TE/G1–G2 species quadrangles in IRAs	No. of TE/G1–G2 species quadrangles in IUCN I–III conservation reserves	Percent increase
Eastern United States	995	217	22	1027	431	42
Western United States	1752	1679	96	2200	4627	210
Alaska	0	1	100	38	43	113

Grizzly bear case study

As seen in Fig. 5, the inclusion of IRAs in the existing system of conservation reserves in Washington, Idaho, Montana, and Wyoming shows a strong concordance with the grizzly bear recovery zones of the U.S. Fish and Wildlife Service, as well as bear habitat range (Martin et al. 2000, USDA Forest Service 2000). In total, the six grizzly bear recovery zones include approximately 15,300 km^2 of IRAs. Approximately 24,750 km^2 of almost contiguous IRAs surround the Salmon-Selway (Bitterroot) Recovery Zone (SSRZ), which has already been designated a wilderness area and assigned to IUCN category I.

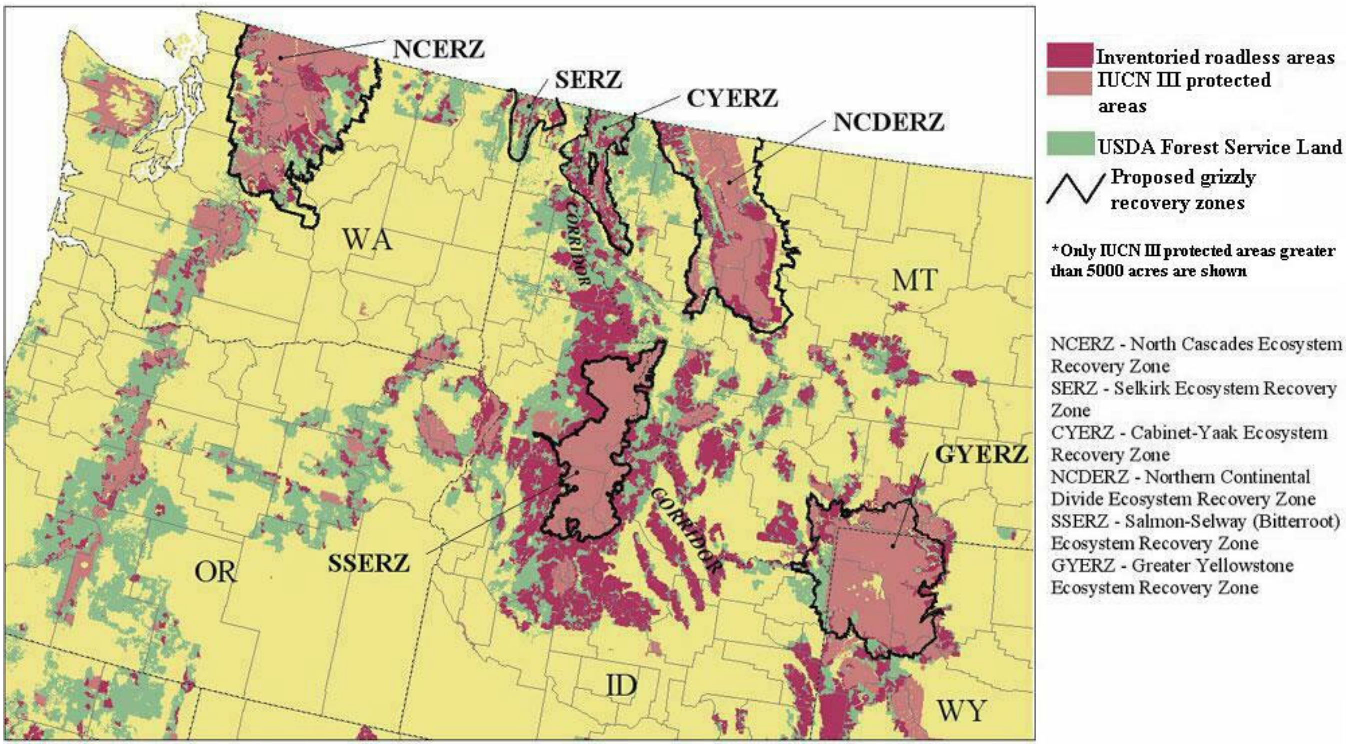
DISCUSSION

Our analyses found that one-quarter of the inventoried roadless ares (IRAs) are found in globally or regionally outstanding ecoregions, and that they have the potential to provide important habitat for numerous species, including threatened, endangered, and imperiled species. This conclusion is further illustrated by an investigation of the potential benefit of IRAs to grizzly bear conservation.

Based on these findings, the assignment of IRAs to IUCN category III or higher could increase the area of conservation reserves in the United States from 4.8 to 8.5%. This broad national conclusion has different implications depending on geographic region. For example, whereas fewer than 3% of the IRAs are found in the eastern United States, the vast majority of eastern IRAs are found in the ecoregions with the greatest amount of biodiversity and the least amount of existing protection. In addition, despite the fact that western forests currently have some of the highest existing protection levels in the United States, Scott et al. (2001) found that many existing reserves in the United States are concentrated in areas of high elevation and low soil productivity. Therefore, despite the current levels of perceived protection, the nation's biological diversity may be under-represented in the current system, particularly in the mountainous west (Scott et al. 2001). DeVelice and Martin (2001) have shown that approximately 40% (about 91,300 km^2) of the IRAs are at an elevation below 1500 m and that 35% of the total IRAs are adjacent to designated wilderness areas. The combination of increased protection of forest habitat and the potential increase in size of conservation reserves would have a positive effect on the conservation of large mammals in the western United States.

The purpose of the *Endangered Species Act* is to " ... provide a means whereby the ecosystems upon which endangered and threatened species depend may be conserved ... " (U.S. Fish and Wildlife Service 1973). The act further directs that " ... all Federal departments shall seek to conserve endangered species and threatened species." In this regard, many IRAs function as biological refugia for terrestrial and aquatic species, including numerous threatened, endangered, and imperiled species. The maintenance of natural values in IRAs could contribute to their long-term viability (Brown and Archuleta 2000). IRAs contain more than 220 TE species, i.e., approximately 25% of listed or proposed animal species and 13% of listed plant species (USDA Forest Service 2000).

Fig. 5. Overlap of USDA Forest Service inventoried roadless areas and grizzly bear recovery zones.



Among TE species, 88% are imperiled by habitat destruction and degradation (Wilcove et al. 1998). Dobson et al. (1997) found that, if the habitats of TE species were more extensively protected, a large number of them would be efficiently conserved. Our analysis showed that the vast majority of IRAs hosted TE or G1–G2 imperiled species and that, by adding the IRAs to the existing conservation reserve system, the conservation of species at risk and their habitat could be better realized. Although we recognize that not all threatened, endangered, or imperiled species require lands free of active land management to survive, limiting the human footprint by placing IRAs off limits to road construction and maintenance, resource extraction, and other development activities could provide a counterpoint to the multiple-use activities taking place elsewhere within the National Forest System.

Furthermore, although there may be duplicate species populations within IRAs or existing conservation reserves, the high level of endangerment of these species should predicate that we conserve as many populations as possible. Therefore, the potential issues of complementarity or duplication of species across IRAs should not diminish the contribution that IRAs could make to conserving species at risk. Our analyses have shown that, despite the small size and extent of IRAs in the eastern United States, they contain a greater number of endangered or imperiled species across more IRAs than do the west and Alaska. However, many of the western IRAs are missing data or have not been surveyed. This error of omission serves only to emphasize that our findings are a conservative estimate of potential species endangerment particularly in IRAs in Alaska and the western United States.

Top carnivore species, such as the grizzly bear, often have the largest species-level area requirements in an ecosystem and maintain ecological structures and resilience by top-down trophic interactions. They need large, contiguous habitat blocks to persist, and there must be landscape connectivity among core areas to ensure sufficient habitat for viable populations (Soulé and Noss 1998, Carroll et al. 2001). As a result of these requirements, large reserves are necessary to maintain populations of these wide-ranging species. Woodroffe and Ginsberg (1998) recently estimated that habitats of 20,000 km^2 are needed to provide a 90% chance for the long-term survival of the grizzly bear in the wild. Indeed, only those wilderness areas that were 20,000 km^2 or larger in 1920 still support grizzly bears today (Mattson and Merrill 2002). The 40,000 km^2 of IRAs in and near designated grizzly recovery zones in the northern Rockies will help improve the long-term habitat viability for grizzly bears in the region (Martin et al. 2000, USDA Forest Service 2000).

Carroll et al. (2001) proposed the need for a comprehensive conservation strategy for carnivores in the Rocky Mountains that considers the requirements of several species, including grizzly bear, wolverine, fisher, and lynx. The regions where these four species overlap show a strong concordance with grizzly bear recovery zones. IRAs may benefit all of these species by providing expanded and buffered habitat and, in turn, secure the ecological integrity of those ecosystems (Terborgh and Soulé 1999, Conner et al. 2000, Martin et al. 2000). If grizzly bear populations remain limited by the size and configuration of current conservation reserves, their long-term survival in the conterminous United States cannot be assured (Mattson and Merrill 2002).

Bruner et al. (2001) found a clear relationship between the existence of a viable and well-connected system of conservation reserves and biodiversity conservation. Because of the stable long-term ownership tenure associated with USDA Forest Service lands, as opposed to privately held forests, many of these forested areas contain a wealth of biological diversity. Historically, land within the Forest Service has been managed under a multiple-use strategy, with timber extraction being a main component of many of these plans. However, multiple-use management may not ensure the protection of the full range of biodiversity, because anthropogenic habitat degradation and destruction are the primary causes of biodiversity loss (Ehrlich 1988, Myers 1988, Wilcove et al. 1996, Haila 1999, Wood 2000).

Setting aside IRAs for stricter protection from extractive or economically driven activities may indeed meet many biological objectives, e.g., integration of fish and wildlife values and watershed and forest health, consistent with the agency's multipurpose agenda. In addition, IRAs may also contribute invaluable benchmarks to gauge ecological changes on managed U.S. Forest Service lands. A representative system of natural habitats, set aside from active management, would allow natural ecological processes, including a full suite of existing native species, to survive free of human activities. Without strict conservation areas that represent all forest habitat types, it will be difficult to make objective assessments on the sustainability of forest management (Noss and Cooperrider 1994, Norton 1999, Noss et al. 1999). Based upon our analyses, we conclude that IRAs support many at-risk species and thereby greatly contribute to the conservation of biodiversity throughout the United States. For some species with only a few remaining populations, the strict and permanent protection of IRAs may represent the final, critical refuge.

ABSTRACT

The Santa Fe municipal watershed provides up to 40% of the city's water and is at high risk of a stand-replacing fire that could threaten the water resource and cause severe ecological damage. Restoration and crown fire hazard reduction in the ponderosa pine (PP) forest is in progress, but the historic role of crown fire in the mixed-conifer/aspen (MC) and spruce-dominated forests is unknown but necessary to guide management here and in similar forests throughout the southwestern United States. The objective of our study was to use dendroecological techniques to reconstruct fire history and fire–climate relationships along an elevation, forest type, and fire regime gradient in the Santa Fe River watershed and provide historical ecological data to guide management. We combined systematic (gridded) sampling of forest age structure with targeted sampling of fire scars, tree-ring growth changes/injuries, and death dates to reconstruct fire occurrence and severity in the 7016 ha study area (elevation 2330–3650 m). Fire scars from 141 trees (at 41 plots) and age structure of 438 trees (from 26 transects) were used to reconstruct 110 unique fire years (1296–2008). The majority (79.0%) of fires burned during the late spring/early summer. Widespread fires that scarred more than 25% of the recording trees were more frequent in PP (mean fire interval $(MFI)_{25\%}$ = 20.8 years) compared to the MC forest (31.6 years). Only 24% of the fires in PP were recorded in the MC forest, but these accounted for a large percent of all MC fires (69%). Fire occurrence was associated with anomalously wet (and usually El Niño) years preceding anomalously dry (and usually La Niña) years both in PP and in the MC forest. Fire in the MC occurred during more severe drought (mean summer Palmer Drought Severity Index; PDSI = −2.59), compared to the adjacent PP forest (PDSI = −1.03). The last fire in the spruce forest (1685) was largely stand replacing (1200 ha, 93% of sampled area), recorded as fire scars at 68% of plots throughout the MC and PP forests, and burned during a severe, regional drought (PDSI = −6.92). The drought–fire relationship reconstructed in all forest types suggests that if droughts become more frequent and severe, as predicted, the probability of large, severe fire occurrence will increase.

1. Introduction

Large areas of forest throughout the southwestern United States (Arizona, New Mexico and adjacent areas) are unnaturally dense due a century of fire exclusion, and are consequently at high risk of historically unprecedented large crown fires (Covington and Moore, 1994; Allen et al., 2002). Given limited resources for treatment, a triage approach must be adopted to identify areas with high resource value or that are located strategically within the larger landscape. Historical ecological data describing the range of variability of disturbance regimes and their climatic controls are vital to guide forest restoration (Swetnam et al., 1999), particularly when facing the additional challenge of a changing climate (Millar et al., 2007).

The upper Santa Fe River watershed, New Mexico is arguably the most at risk, high-profile municipal watershed in the southwestern U.S. Santa Fe is the oldest state capital, founded on the Santa Fe River in the early 17th century (Debuys, 1985). Sitting at 2137 m elevation on the alluvial plane of a steep, forested, montane watershed, Santa Fe is inextricably linked to the ecosystem services (e.g., drinking water) and natural hazards (e.g., fire and floods) associated with the wildland urban interface. Surface water that originates high in the spruce-fir forests of the Pecos Wilderness Area is regulated through a system of reservoirs that provides up to 40% of the city's water supply (Grant, 2002). The population in Santa Fe County has tripled in recent decades (1970–2007; USCB, 2009), overtaxing the already limited water

supply. Like much of the West, there has not been a widespread fire in the ponderosa pine (PP) and mixed-conifer (MC) forests of the watershed for 130 years, increasing the area at high risk of crown fire beyond the spruce-fir forests, where they naturally occur.

Recent, large, crown fires in near by watersheds have produced runoff and erosion events two orders of magnitude greater than pre-fire events (Veenhuis, 2002). This type of event in the Santa Fe watershed could destroy the water supply infrastructure and flood the historic heart of the city. The threat of catastrophic fire sparked years of contentious public debates, which ultimately led to U.S. Congressional earmarks of seven million dollars to fund planning and implementation of crown fire hazard reduction and forest restoration in the lower elevation PP forests (USDA, 2001). However, the ecological role of fire and the consequences of fire exclusion in the upper elevation mesic MC and spruce-fir forest types remain largely unknown, and it is these forests that cover the majority of the area that supplies the main reservoir.

1.1. Gradients: elevation, forest types and fire regimes

Gradients (e.g., elevation and vegetation) are common in terrestrial ecosystems and are a valuable way to study how ecological processes vary across a range of conditions (Whittaker and Niering, 1965; Whittaker, 1967). In the southwestern U.S. fire is a keystone ecological process that has affected vegetation across ecosystem gradients for hundreds to thousands of years (Swetnam and Baisan, 1996; Allen, 2002; Anderson et al., 2008). The size, frequency and severity of fire over time define the fire regime (Agee, 1993). Fire regimes are commonly classified by the extremes of the fire severity gradient (low severity or high severity). Recently, the term *mixed-severity fire regime* has been described as including a range of fire severities across a spatially complex mix of forest patches, including unburned, low, moderate, and high severity fire (Agee, 2005).

At landscape scales (1000–100,000 ha; watersheds to mountain ranges), fire can move across gradients of elevation, forest types and likely, between fire regimes. The PP forest type in the southwestern U.S. is a classic low severity, high frequency fire regime (Swetnam and Baisan, 1996). Subalpine spruce-fir forests in the southern Rocky Mountains exemplify the other extreme: a high severity, low frequency fire regime (Romme and Knight, 1981; Sibold et al., 2006). The steep topography of the southwestern U.S. juxtaposes these two forest types (representing the extremes of the fire severity gradient) in close proximity (<10 km separation) along a continuous elevation gradient with continuous fuels. MC forests are intermediately located between PP and spruce-fir (Dick-Peddie, 1993). Lower elevation, xeric, MC forests historically burned with low severity, but less frequently than PP (Dieterich, 1983; Brown et al., 2001). Some upper elevation, mesic MC forests have evidence of high severity fire (Fule et al., 2003; Margolis et al., 2007; Margolis, 2007). Historically, drought synchronized fire occurrence within and between low and high severity fire regimes regionally (Swetnam and Baisan, 1996; Margolis et al., 2007), but there is limited research examining connectivity between low and high severity fire regimes along a continuous forest gradient in a single, continuous landscape (Fule et al., 2003).

The implications of low and high severity fire regime connectivity are important given the well-documented changes associated with fire exclusion in ecosystems of the southwestern U.S. Over a century of fire exclusion in PP forests of the region has dramatically increased forest density and the risk of large crown fires (Covington et al., 1997; Allen et al., 2002). While there is historical evidence of high severity fire patches in some MC forests (Fule et al., 2003), increased forest density in other MC forests due to fire exclusion has increased the size of forest patches at risk of crown fire (Fule et al., 2003; Cocke et al., 2005; Heinlein et al., 2005; Margolis et al., 2007).

There is comparatively less information about the effects of fire exclusion on forest density, composition, and crown fire risk in the upper elevation spruce-fir forests of the region (Fule et al., 2003; Cocke et al., 2005). It is generally thought that a century of fire exclusion has not had dramatic impacts in these naturally dense forest types (Sibold et al., 2006), because high elevation, high severity forest fire regimes burn at long (centennial-scale) return intervals (Turner and Romme, 1994). Evidence of decreased fire frequency during the fire suppression period, compared to previous centuries has been observed in some subalpine forests of the Southern Rockies (Kipfmueller and Baker, 2000), but not others (Sibold et al., 2006). If forest ecosystems along steep elevation gradients are connected by fire spread across vegetation and fire regime gradients, then a century of fire exclusion in the lower elevation pine-dominated and MC forests is likely to have affected the high elevation, high severity forest fire regimes as well.

The semi-arid climate of the southwestern U.S. is highly variable, with frequent (2–7 years) wet/dry oscillations that are partially driven by multiple ocean-atmosphere oscillations, particularly the El Niño Southern Oscillation (ENSO; Diaz and Markgraf, 2000). Fire–climate analyses indicate that moisture variability largely explains patterns of fire occurrence in tree-ring reconstructed and contemporary records in low- and mid-elevation forests of the southwestern U.S. (Swetnam and Betancourt, 1990; Crimmins and Comrie, 2004). Warmer temperatures in recent decades have increased the length of the fire season, resulting in more large fires throughout the western U.S. (Westerling et al., 2006). The established link between climate variability and fire, coupled with predicted warmer global temperatures (IPCC, 2007) and drier conditions in the southwestern U.S. (Seager et al., 2007) has led to predictions of more large fires in the future (Westerling et al., 2006). Better understanding of the link between climate variability and fire occurrence along the elevation gradient of forest types and fire regimes is necessary to proactively manage our forests with a science-based approach, in the face of climate change.

The goal of the research is to provide essential historical ecological data across a gradient of forest types and fire regimes to guide management in the upper Santa Fe watershed and similar upper montane forest types in the region. Our first objective was to reconstruct fire history (frequency, severity, and size) along an elevation, vegetation and fire regime gradient in the upper Santa Fe Watershed. Our second objective was to reconstruct and compare historic fire–climate relationships between forest types. Our third objective was to test for evidence of direct connectivity of fire regimes along the fire severity gradient from low, to mixed, to high severity.

1.2. Study area

The study area encompasses the upper Santa Fe River watershed (7016 ha), which includes the headwaters located within the U.S. Forest Service Pecos Wilderness Area (Fig. 1). The watershed is located on the west slope of the Sangre de Cristo Mountains, northeast of the city of Santa Fe, NM, near the southern terminus of the Southern Rocky Mountains. The upper watershed has been closed to the public since 1932 to protect the water supply for the city of Santa Fe (USDA, 2001). Elevation ranged from 2237 m at the lowest point in the stream channel to 3847 m on the peaks that rise above tree-line and define the headwaters of the basin. Tree-ring samples were collected from 2328 m to 3650 m.

The climate is semi-arid and continental. Precipitation peaks during summer monsoon convective storms (July–August), and winter snowpack is common except during extreme drought years

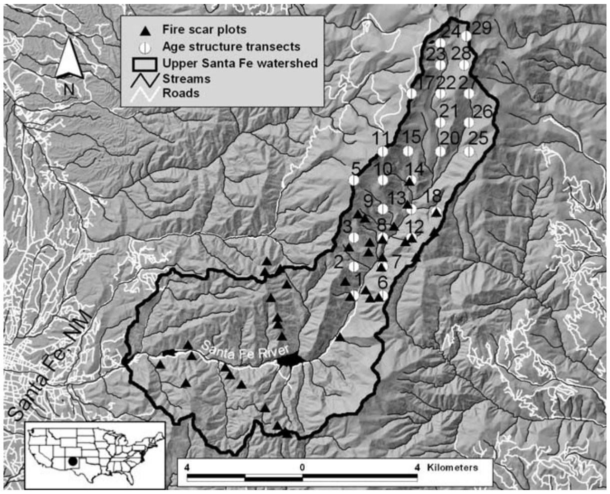

Fig. 1. Location of gridded age structure transects (numbered) and fire scar plots used to reconstruct fire history in the upper Santa Fe watershed, NM. The upper watershed, containing only age structure transects, is spruce-dominated forest. The lower watershed, containing only fire scar plots, is PP. The middle-elevation forest area where both age structure and fire scars overlap is MC.

(e.g., 2002). Temperature (1972–2005) at Santa Fe, NM (2060 m) ranged from an annual average minimum of 2.3 °C to an annual average maximum of 18.2 °C. Total annual average precipitation was 34.8 cm and total annual average snowfall was 44.2 cm (Western Regional Climate Center, www.wrcc.dri.edu). Fire occurrence records were available for 222 fires (1970–2003) from the ranger district containing the watershed and the adjacent district to the east (Española and Pecos/Las Vegas Ranger Districts). The majority (93%) of fires occurred between May and August, peaking in July, but monthly area burned peaks in May and June during the dry foresummer. Eighty percent of all fires were started by lightning (USFS, unpublished data).

Along the elevation gradient, forest types transitioned from PP dominated forests in the lower part of the study area, to MC in the middle elevations, to spruce-fir in the upper elevations. The spruce-fir type was composed of Engelmann spruce (*Picea engelmannii* Parry) and corkbark fir (*Abies lasiocarpa* [Hook] Nutt. var. *arizonica* [Merriam] Lemmon), but Engelmann spruce was dominant in all locations sampled and often present in pure stands. This general upper elevation forest type is hereafter referred to as "spruce-dominated." The MC forest was relatively diverse and species composition varied largely by aspect. The following species were present in various combinations in this forest type, listed in order of abundance of the dominant tree: Douglas-fir (*Pseudotsuga menziesii* [Mirb.] Franco.), ponderosa pine (*Pinus ponderosa* Lawson), southwestern white pine (*Pinus strobiformis* Engelm), quaking aspen (*Populus tremuloides* Michx.), white fir (*Abies concolor* [Gord. and Glend.] Lindl. Ex Hildebr.), and Engelmann spruce. There were no conspicuous, large (>50 ha) stands dominated by quaking aspen that might indicate recent stand-replacing fire patches. The lower section of the study area was dominated by ponderosa pine, with associated species including Colorado pinyon pine (*Pinus edulis* Engelm.), Rocky Mountain juniper (*Juniperus scopulorum* Sarg.), Gambel oak (*Quercus gambelii* Nutt.), Douglas-fir, white fir, and southwestern white pine.

2. Methods

2.1. Tree-ring fire history methods

A combination of tree-ring methods was necessary to reconstruct fire history along the elevation, vegetation and fire regime gradient. Fire scar-based methods (Dieterich and Swetnam, 1984; Swetnam and Baisan, 1996) were used to reconstruct surface fire frequency, seasonality, and extent for the PP and dry MC portions of the watershed where fire scars were present. However, in the upper elevation spruce-dominated and mesic MC forests, fire-scarred trees were rare or non-existent because: (1) high severity, high intensity, stand-replacing crown fires destroy (kill and burn) direct tree-ring evidence of past fires, (2) the thin bark of spruce and fir species is more susceptible to being fatally girdled, even by low-intensity fire, thus leaving no evidence of the most recent fire (e.g., fire scars), and/or (3) long fire return intervals may allow the rare fire-scarred trees to heal over so that open fire scar wounds are not visible.

In forest types where fire scars are not abundant, age structure-based fire history methods are commonly applied (Heinselman, 1973; Agee, 1993; Johnson and Gutsell, 1994). These methods largely rely upon the establishment dates of tree cohorts that regenerate following stand-replacing fire events to date the fire and determine aerial extent of the stand-replacing patches. Thus, in the spruce-dominated forest type we used age structure sampling methods to reconstruct the age of the dominant, presumably oldest trees, thereby estimating the time since the last fire (Kipfmueller and Baker, 1998). Satellite imagery, aerial photography, and field observations were used to identify any potential post-fire forest patches.

Age structure data alone may not be sufficient to determine if the forest patch was a post-stand-replacing fire cohort and ultimately date the fire. Unlike lodgepole pine (*Pinus contorta*) or quaking aspen, spruce and fir trees may take years to decades to regenerate following stand-replacing fire (Antos and Parish, 2002). This is likely due to a combination of variability in seed sources, dispersal, and post-fire weather and climate. The precision of fire dates derived strictly from forest age will not be annual because of lagged regeneration. Decadal precision of fire dates can be sufficient when calculating area-based estimates of fire frequency (e.g., natural fire rotation; Heinselman, 1973), due to the long return intervals (100 years to >400 years) of forest crown fire regimes (Turner and Romme, 1994). Annually precise stand-replacing fire dates may be reconstructed if fire scars, fire-killed trees or injured trees are present in adjacent forest stands, or on the perimeter of unburned patches (Johnson and Gutsell, 1994; Margolis et al., 2007). Annually resolved fire dates are necessary for inter-annual fire–climate analyses, which can provide specific climate information associated with the relatively rare, but important, stand-replacing fire events.

In forest types such as MC, where a combination of low severity and high severity fire occurs (i.e., mixed-severity fire), it is necessary to use a combination of fire scar and age structure-based methods to reconstruct the fire history (Agee, 2005). For example, some stands within the MC zone had no fire scars or potentially fire-killed trees, and stand age was the best evidence of past fire. Alternatively, other stands had abundant fire scars (i.e., evidence of repeated, low severity surface fire) and no clear post stand-replacing fire cohorts.

2.2. Sampling design

In the PP forests of the lower portion of the study area we used a targeted approach to locate and collect fire scars. Targeted fire scar sampling in Southwestern ponderosa pine provides similar estimates of fire frequency compared to systematic sampling, particularly for widespread fires, with the added benefit of providing a longer record (Van Horne and Fule, 2006). Samples were primarily collected at 50 m-radius plots along two transects; a north-facing transect, and a south-facing transect. These transects were located in the middle of the PP zone and followed a series of ridges that extended from the river up to the respective watershed boundaries. From the ridgetop location we searched both slopes that descended from the ridge and adjacent slopes that could be seen from the ridge. Additional plots were located within the PP zone to provide broader spatial coverage of the PP forest fire history. One group of plots was located west (downstream) of the transects in the area surrounding the lower reservoir. An additional plot was located east (upstream) of the transects, above the second reservoir. The resulting spatial patterning of the plots was determined by a combination of our search effort, topography and the presence of fire-scarred material.

In the high elevation spruce-dominated forests, a systematic, gridded age structure sampling approach provided the best evidence of fire history (i.e., "time since last fire"; Johnson and Gutsell, 1994). We generated a 1 km grid beginning with a random location in the study area (Fig. 1). The grid was oriented along cardinal directions to facilitate navigation in the field. Two grid points (24 and 28) initially fell within unforested vegetation types and were relocated 50 m inside the nearest forested area.

In the middle-elevation, MC forest evidence of fire was present as both fire scars and post-fire tree regeneration cohorts. We extended the 1 km-spaced age structure grid into the MC zone, and because fire scars were only present at 5 of 12 MC age structure transects we used a targeted approach to locate and sample fire scars in this forest type. In the MC forest, fire-scarred trees were most abundant on the relatively flat ridges, apparently because of lower fire severity that allowed trees to survive fires that were otherwise stand-replacing on the adjacent steep slopes. We searched and sampled ridges with the goal of obtaining a relatively even spatial distribution of fire scar plots and to maximize the length of the fire history record. The final spatial distribution of the fire scar sample plots was ultimately determined by the location of fire-scarred trees, in part determined by topography and chance, and therefore is not evenly distributed in space.

In the topographically complex mountains of the semi-arid southwestern U.S., elevation and aspect can be important variables mediating vegetation type (e.g., Whittaker and Niering (1965)) and fire regimes (e.g., Iniguez et al. (2008)). To ensure that the distribution of aspect class (N, S, E, W) at our gridded, age structure transects was proportional to the relative abundance of aspect classes in the study area we stratified the sampling grid by aspect class. The percent of sample points in the four primary aspect classes was distributed similar to the percent of land area in each aspect (Table 1), with a slight over-sampling of east-facing slopes and under-sampling of the south-facing slopes.

2.3. Field sampling

Where multiple fire-scarred trees were present we used a plot-based field sampling approach. A plot was sampled where two or more fire-scarred trees were located less than 15 m apart. The plot center was located between the samples. Samples from multiple fire-scarred trees were collected within a 50 m search radius that defined the plot. Collecting multiple trees within a plot increased the probability of recording all fires that actually occurred in that area. This is necessary because trees are imperfect recorders of fire and individual trees may not record all fires (as fire scars) that burned around the tree (Dieterich and Swetnam, 1984). Wedges and cross-sections were collected from fire-scarred logs, stumps and rarely from live trees with a cross-cut saw in the MC forest (within the Pecos Wilderness Area) and with a chainsaw in the PP forests using standard procedures (e.g., Arno and Sneck (1977)).

To determine stand age at the gridded age structure transects in the spruce-dominated and MC zones we sampled the 20 largest (diameter at breast height (dbh)) trees along a 100 m by 20 m belt transect. The transect was centered on the grid point and the long axis was oriented parallel to the contour of the slope (i.e., sideslope). To determine tree age, increment cores were collected as close to the base of the tree as possible (<0.3 m). We angled the borer down to intersect the estimated location of the root crown in an attempt to sample all the years of tree growth. We re-sampled trees until we extracted a core containing rings estimated to be within 10 years of the pith.

2.4. Lab methods

All tree-ring samples were sanded with progressively finer sandpaper until the ring structure was visible and then crossdated using standard dendrochronological procedures (Stokes and Smiley, 1968). For fire scar samples, we determined the calendar year of the scar and the season of fire occurrence by analyzing the relative position of each scar within the annual growth ring: dormant season, early earlywood, middle earlywood, late early-wood, latewood, or unknown (Baisan and Swetnam, 1990). Predominant occurrence of spring or early summer fires in northern New Mexico and the southwestern U.S. is widely supported by fire seasonality data from observed 20th century fires in the region (Barrows, 1978), locally, and from hundreds of tree-ring reconstructed fires (Swetnam and Baisan, 1996). Based on our observations and conventional season of montane fire occurrence in the region, all fire years with fire scars recorded only in the dormant season were assigned to the spring/summer of the next year (ring).

For age structure samples, we estimated the date of the first year of growth (pith) for increment cores that did not contain the pith ring, using a concentric circle pith estimator (Applequist, 1958). Cores that were estimated to be greater than 30 years from the pith ring or that had no curvature in the inner rings were not included in the age structure data. Because cores were collected at a downward angle to intercept the root crown, the error associated with the age to core height was assumed to be within the resolution of the age class bins (10 years) and was not estimated.

A qualitative description of the initial tree-ring growth of cored trees (open, average, or suppressed) was recorded to provide information regarding the growth environment when trees established (Romme and Knight, 1981). Spruce and fir species are shade tolerant and are able to survive in low light conditions under canopies, but the growth rates in these conditions can be very slow (i.e., "suppressed"). Growing conditions for trees germinating in an open forest, such as following a stand-replacing fire, would be more favorable and should be indicated as relatively wide initial ring widths (i.e., open). This information was combined

Table 1
Aspect class of land area and age structure transect grid in the MC and spruce-dominated forests.

Aspect class	Area (ha)	Area (% of total)	Age structure transect (#)	Age structure transect (% of total)
Flat (0% slope)	0.22	0.01	0	0
N (315–45°)	221.11	8.29	3	11.54
E (45–135°)	773.59	28.99	9	34.62
S (135–225°)	852.73	31.95	6	23.08
W (225–315°)	821.03	30.77	8	30.77

with tree ages and fire scar dates to determine if trees were likely part of post stand-replacing fire cohorts.

2.5. Data analysis

The fire scar data were entered into a database and analyzed using FHX2 software (Grissino-Mayer, 2001). Because fire scar return intervals are rarely normally distributed and more commonly fit a Weibull distribution (Grissino-Mayer, 1999), we tested for the fit of the Weibull model (Kolmogorov–Smirnov (K-S) test) and estimated the Weibull Median Probability Interval (WMPI). Central tendency parameters (mean, median and WMPI) of fire frequency were calculated for five ''filtered'' subsets of the composite fire history data for (1) the PP forest and (2) the MC forest. The following filtered subsets of reconstructed fires were used for the analysis: (1) all fires, (2) fires recorded by a minimum of 2 trees, (3) a minimum of 2 trees and >10% of recording trees, 10% scarred, (4) a minimum of 2 trees and >20% of recording trees, 20% scarred and (5) fires recorded by a minimum of 2 trees and >25% of recording trees, 25% scarred. ''Recording trees'' refers to previously fire-scarred samples that have intact wood (i.e., not burned away or missing pieces) and an open wound (not covered by bark) during the time period in question. Many montane conifers have thick bark that protects trees from damage to the cambium by fire. These full-bark trees may not record fires as fire scars, while the same fire is recorded on adjacent trees with pre-existing open ''cat face'' fire scar wounds.

Filtering the fire scar data by the percent of recording trees scarred is used to infer relatively large, spreading fires, as compared to less widespread fires that only scar a relatively small number (percent) of trees (see discussion in Swetnam and Baisan, 2003). Widespread fires are thought to be more ecologically important because of the extent of the effects. Too few fire-scarred trees were present on the landscape and/or collected to confidently allow plot-based fire interval analysis (e.g., Iniguez et al., 2008). In addition, high severity fire in parts of the MC forest killed and burned evidence of prior fires at individual plots, so fire dates from all plots were combined to make a site composite for each forest type (Dieterich, 1980). We also chose not to analyze fire intervals for individual trees (point intervals), because our attempt to extend the record back in time by targeting remnant wood resulted in many samples having an incomplete record due to being burned and/or eroded. This was particularly the case in the MC zone of the wilderness area, where a majority of samples were remnant wood. Given these limitations of a relatively long record, we still are confident that the percent of trees recording fire is a good indicator of widespread vs. localized fires and that the widespread fires that we focus on are the most robust to variability in sampling (Van Horne and Fule, 2006). Because fire intervals vary over time with changes in fuels and climate (e.g., Swetnam (1993)), central tendency statistics (e.g., MFI) oversimplify historic fire regimes. We report additional statistics (e.g., minimum and maximum fire intervals) and interpret these data in terms of fire management to provide a better understanding of the historic range of variability of the fire regime.

To test for differences in historical fire frequency between the PP and MC forests we used the Student's *t*-test to compare MFI, the Folded-*f* test to analyze differences in variance, and the K-S test to analyze differences in distributions (FHX2, Grissino-Mayer, 2001). Because these tests assume that the data are normally distributed, the data are transformed to the standard normal distribution (i.e., mean of zero and a standard deviation of one) before the comparisons (Grissino-Mayer, 2001). To quantify synchrony of burning (i.e., fire spread) between the PP and the MC forests we counted the number of coincident fire years between the two forest types, and calculated the percent of all fire years in each forest type that were synchronous between forest types. As a more robust test of synchrony we used Chi-squared analysis to test for independence between MC fire years and PP fire years (1550–1880) for all filtered subsets of fire years.

We used superposed epoch analysis (SEA; Baisan and Swetnam, 1990) to test for inter-annual relationships between variability in four tree-ring reconstructed measures of climate and fire occurrence in (a) the PP forest and (b) the MC forest. The tree-ring reconstructed climate variables included (1) Palmer Drought Severity Index (PDSI), (2) annual precipitation from El Malpais, NM, (3) an index of El Niño/Southern Oscillation (ENSO), and (4) an index of the Pacific Decadal Oscillation (PDO).

PDSI is a commonly used measure of available moisture (Palmer, 1965). Summer (June–August) PDSI is a good indicator of moisture conditions prior to and during the southwestern U.S. fire season and is highly correlated with variability in historical fire occurrence (Swetnam and Baisan, 2003) and 20th century fire occurrence (Crimmins and Comrie, 2004). A 2.5° gridded tree-ring reconstruction of summer PDSI exists for much of North America and in the southwestern U.S. it extends hundreds of years prior to the 20th century instrumental climate data (Cook et al., 2004). PDSI gridpoint 133 is nearest to our study site and is used in the SEA analysis. A tree-ring based precipitation reconstruction from El Malpais National Monument, in west-central NM (Grissino-Mayer, 1996), was also used as a sub-regional climate variable.

Indices of Pacific Ocean-atmosphere oscillations (e.g., ENSO and PDO) that have been shown to affect climate variability in the southwestern U.S. (Diaz and Markgraf, 2000; Brown and Comrie, 2002) were also used as variables in the SEA analysis. As a proxy index for ENSO we used the tree-ring reconstructed Niño3 index (Cook, 2000) of winter (December–February) sea surface temperature (SST) from the eastern equatorial Pacific Ocean (5°N–5°S, 90°–150°W). Positive (negative) Niño3 index values represent warm (cool) SST's - El Niño (La Niña).

We used the (D'Arrigo et al., 2001) annual PDO index reconstruction derived from temperature sensitive tree-ring sites from coastal Alaska (5) and Oregon (1), and two tree-ring reconstructed PDSI grid points in northern Mexico. Positive (negative) index values of PDO correspond with warm (cold) phases of the primary mode of variability in Pacific Ocean SST's polewards of 20°N (Mantua et al., 1997).

To test whether drier conditions were associated with fire in the MC forest than in PP, we compared mean PDSI during widespread (25% scarred) and ''all fire'' years with a *t*-test. To test whether widespread fires occurred on drier years than ''all fire'' years we compared mean PDSI between fire years for each vegetation type with a *t*-test.

3. Results

3.1. Fire scars—PP

In the PP zone (1600 ha search area) we crossdated a total of 442 fire scars from 76 trees at 20 locations, for a total of 99 unique fire years (Tables 2 and 3). The PP fire scar record covers 709 years (1296–2004), with fire scars recorded from 1331 to 1966 (Fig. 2, Table 2). The period 1550–1880 was chosen for fire interval analysis as the best compromise between record length and sample depth.

The season of fire occurrence was determined for 331 (75%) of the fire scars (Table 4). The remaining fire scars were in poor condition or were in rings too narrow to accurately determine the season. When fire scar season could be determined, the most frequent occurrence (69%) was in the dormant (D) season (i.e., between ring boundaries). All but 3% of the remaining fire scars were recorded in the earlywood (E) portion of the ring and the

Table 4
Fire scar seasonality reconstructed from the relative position of the fire scar in the tree-ring. Period of record: PP, 1296–2006 and MC, 1337–2008.

Scar position	Number of fire scars (PP/MC)	Percent of scars with season determined (PP/MC)
Dormant	229/39	69.2/42.4
Early earlywood	40/27	12.1/29.3
Middle earlywood	35/15	10.6/16.3
Late earlywood	18/11	5.4/12.0
Latewood	9/0	2.7/0.0

majority of those were in the first third of the earlywood (early earlywood, EE). The remaining 3% of the fires were recorded in the latewood (A) portion of the tree-ring. Overall, 81% of the fires in the PP zone were burning in the beginning of the growing season (May or June; D or EE).

The fire frequency of the reconstructed PP fire regime was highly variable through time (Fig. 2), and cannot adequately be described by one metric (e.g., MFI). The fire interval data (1550–1880) were not normally distributed (K-S d-statistic = 0.438, $p < 0.001$) and were fit with the Weibull model (K-S d-statistic = 0.132, $p = 0.144$). Increasingly exclusive filters increased the fire interval central tendency statistics by eliminating the (small) fires recorded by only a few trees, such that the WMPI increased from 3.8 years (all fires) to 18.8 years (25% scarred; Table 5). MFI was similar and ranged from 4.3 years (all fires) to 20.8 years (25% scarred). Thus, somewhere within the 1600 ha PP search area there was a fire recorded by at least one tree approximately every four years, on average, and relatively widespread fires scarring more than 25% of the trees occurred approximately every 18–21 years, on average. The minimum fire interval ranged from 1 year (all fires) to 7 years (25% scarred). The maximum fire interval ranged from 16 years (all fires) to a fire-free period of 63 years (1779–1842, 25% scarred). No widespread fires (25% scarred) occurred in the 20th century.

3.2. Fire scars—MC

In the mixed–conifer/aspen forests (1200 ha search area) we crossdated a total of 139 fire scars from 65 trees at 21 locations, for a total of 35 unique fire years (Tables 2 and 3). The MC fire scar record covers 672 years (1337–2008) with fire scars recorded between 1399 and 1879 (Fig. 2, Table 2). The period from 1495 to 1880 was chosen for fire interval analysis.

The season of fire occurrence was determined for 92 (66%) of the fire scars (Table 4). Based on the observed dominance of earlywood fires and the absence of latewood fires we used the same convention as in the ponderosa zone to assign fires only recorded in the dormant season to the spring/summer of the next year ($n = 7$). The majority (72%) of the fire scars dated to the season in the MC zone were burning in the spring or early summer (May or June; D or EE).

The MC fire interval data (1495–1880) were fit with the Weibull model (K-S d-statistic = 0.103, $p = 0.897$). The WMPI ranged from 10.3 years (all fires) to 27.8 years (25% scarred, Table 5). MFI was similar and ranged from 12.4 years (all fires) to 31.6 years (25% scarred). Minimum fire intervals ranged from 1 year for all fires, to 6 years for widespread (25% scarred) fires. Maximum fire intervals ranged from 31 years for all fires, to 94 years for widespread fires. No widespread fires (25% scarred) occurred in the 20th century. Further comparisons of fire intervals among the 5 filtered datasets and between vegetation types are discussed later in the paper.

Table 5
Fire interval analysis statistics for the PP (1550–1880) and the MC forests (1495–1880) for five filtered subsets of fire years (e.g., 20% = fires recorded by >20% of the recording trees).

Filter	Intervals (#) PP/MC	Mean fire interval (years) PP/MC	Median fire interval (years) PP/MC	Weibull median probability interval (years) PP/MC	Minimum interval (years) PP/MC	Maximum interval (years) PP/MC
All fires	76/31	$4.3^{+}/12.4^{+}$	4.0/12.0	3.8/10.3	1/1	16/31
>2 Trees	48/18	$6.8^{+}/21.3^{+}$	5.0/16.5	5.8/18.9	1/6	20/71
10%	34/18	$9.1^{+}/21.3^{+}$	7.0/16.5	8.0/18.9	1/6	25/71
20%	17/14	$17.1^{+}/27.4^{+}$	15.0/22.5	15.0/24.4	7/6	63/94
25%	14/11	20.8/31.6	15.5/25.0	18.8/27.8	7/6	63/94

$^{+}$ Indicates significantly different ($p < 0.05$) MFI between PP and MC (Student's t-test).

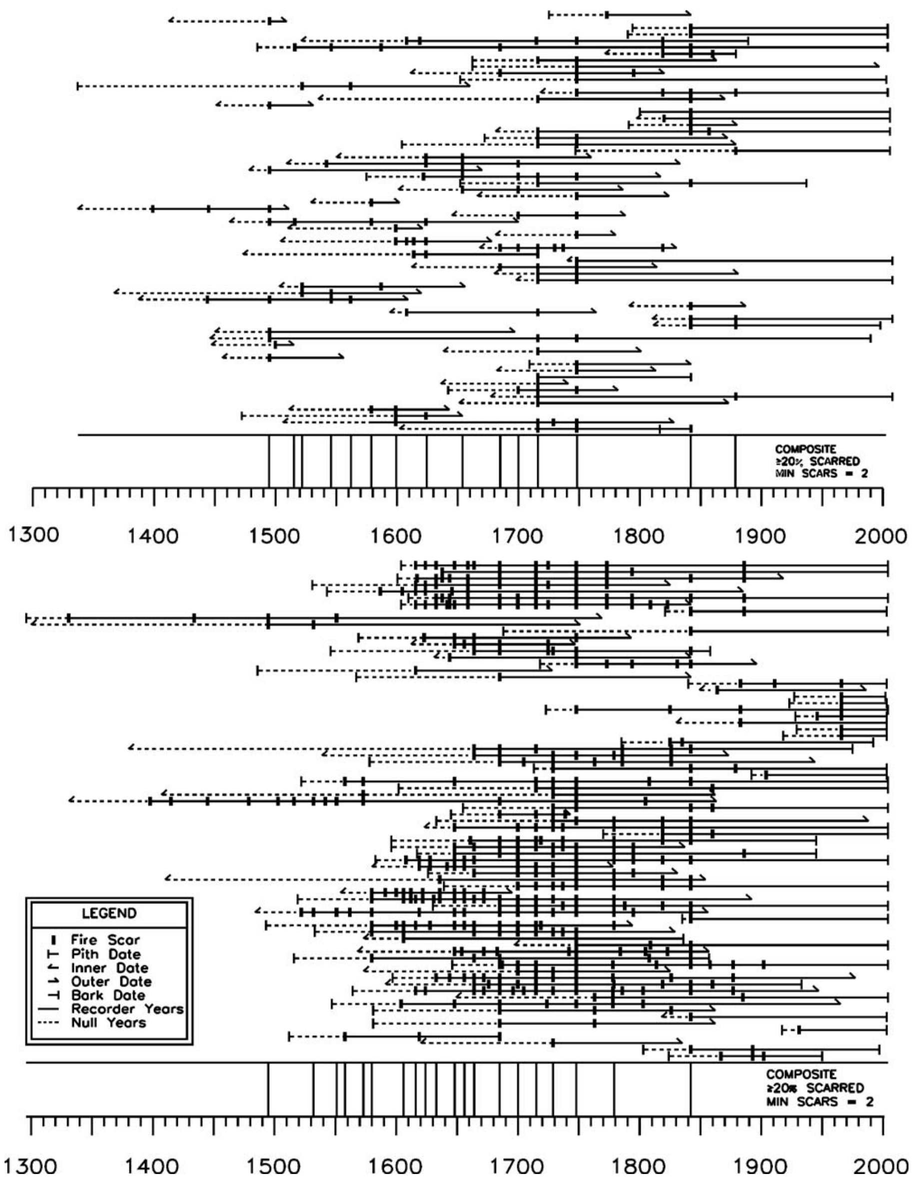

Fig. 2. Historical fire occurrence recorded by fire scars (1296–2004) in the PP forest (bottom) and MC forest (top) of the Santa Fe watershed. Each horizontal line is a tree and each vertical line is a dendrochronologically crossdated fire scar. The fire occurrence composite (bottom of each fire chart) indicates "widespread" fires recorded by a minimum of 2 trees and at least 20% of the trees recording fire.

3.3. Fire scars—spruce-dominated forest

No fire scars or any other direct evidence of fire (e.g., charred wood) were encountered at or between the age structure transects in the spruce-fir zone (1200 ha search area). Fire history in this vegetation type is presented in the age structure section.

3.4. PP vs. MC

The number of fire scars and individual fire years in the PP zone was approximately three times greater than that in the MC forest (Table 2). Historic fire intervals (1550–1880) in the PP zone were significantly shorter than in the MC forest for four of the five filtered subsets of fire years (all fires, ≥2 trees scarred, 10% scarred, and 20% scarred, Table 5). Although the MFI in the MC zone for the 25% scarred class (31.6 years) was approximately 10 years longer than in the ponderosa zone (20.8 years), the values were not statistically different (Student's *t*-test with equal variance, *t*-statistic = -1.780, $p = 0.092$).

Twenty-four fire years were synchronous between the two forest types (Table 3). Multiple synchronous fire years occurred every century from the 1400s to the 1800s. The number of synchronous fire years was greater than that would be expected by chance for all fire years ($\chi^2 = 39.22$, $p < 0.005$) and widespread (25% scarred) fire years ($\chi^2 = 29.15$, $p < 0.005$, with Yates correction for continuity). Sixty nine percent of all fires in the MC forest were also recorded in the PP zone. Only 24% of all fires in the PP forest were recorded in the MC zone.

3.5. Age structure

All of the age structure transects were located in the MC and spruce-dominated forest. Age structure transects were classified as spruce-dominated ($n = 14$) if the plurality of dominant trees was

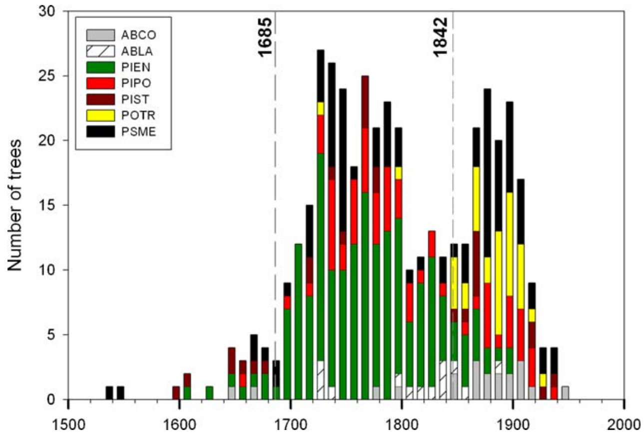

Fig. 3. Age structure and species composition of the dominant trees from the MC and the spruce-dominated forests. Data are from all age structure transects, in 10-year classes (plotted on the last year of the decade), and presented as estimated pith dates. Quaking aspen (POTR) was sub-dominant, but was sampled as a potential indicator of high severity fire. The last widespread fires with a stand-replacing component in the spruce-dominated (1685) and the MC forests (1842) are indicated as dashed lines.

Engelmann spruce. The remaining transects were classified as MC ($n = 12$). We collected 594 cores from 488 trees at 26 age structure transects (Fig. 1). We were not able to collect cores from all 20 dominant trees at 5 transects due to decomposed wood near the tree center and inclement weather. We were able to estimate pith dates for 438 (90%) of the sampled trees. Cores from the remaining 10% of the trees had no curvature in the inner rings or were estimated to be greater than 30 years from the pith so the number of rings to pith could not be estimated. The major cause for inadequate cores for pith estimation was decomposed wood near pith.

The collective age structure of dominant trees at all 26 transects in the MC and spruce-dominant forest has two recruitment peaks (i.e., a bi-modal distribution, Fig. 3). Less than 3% of the dominant trees established prior to 1650. A change in recruitment occurred in the late 1600s, increasing from a local minima of three trees (1681–1690) to the mode of 27 trees only 40 years later (1721–1730). This recruitment peak is dominated by Engelmann spruce. A second major tree recruitment pulse occurred in the mid-1800s. This younger recruitment peak is dominated by MC species. The recruitment peaks follow the last widespread fires in the MC (1842) and the spruce-dominated forests (1685) and there are relatively few trees dating to the decades prior to these two widespread fires.

The age structure at the individual transects illustrates both commonality and variability within and between the MC and the spruce-dominated forests (Figs. 4 and 5). The youngest MC stands all established after 1850 (1, 2, 6, 7) and were located nearest to the PP zone. The two oldest MC stands established circa 1600 (14, 18) and were located on rocky, relatively fire-protected sites near the upper MC/spruce ecotone. The youngest spruce-dominated stand began regenerating in the 1760s and the oldest trees date to the 1530s. The average age of the dominant trees in the spruce-dominated stands (mean [median] estimated pith date = 1769 [1763]) was approximately 60–100 years greater than in the MC forest (1829 [1861]).

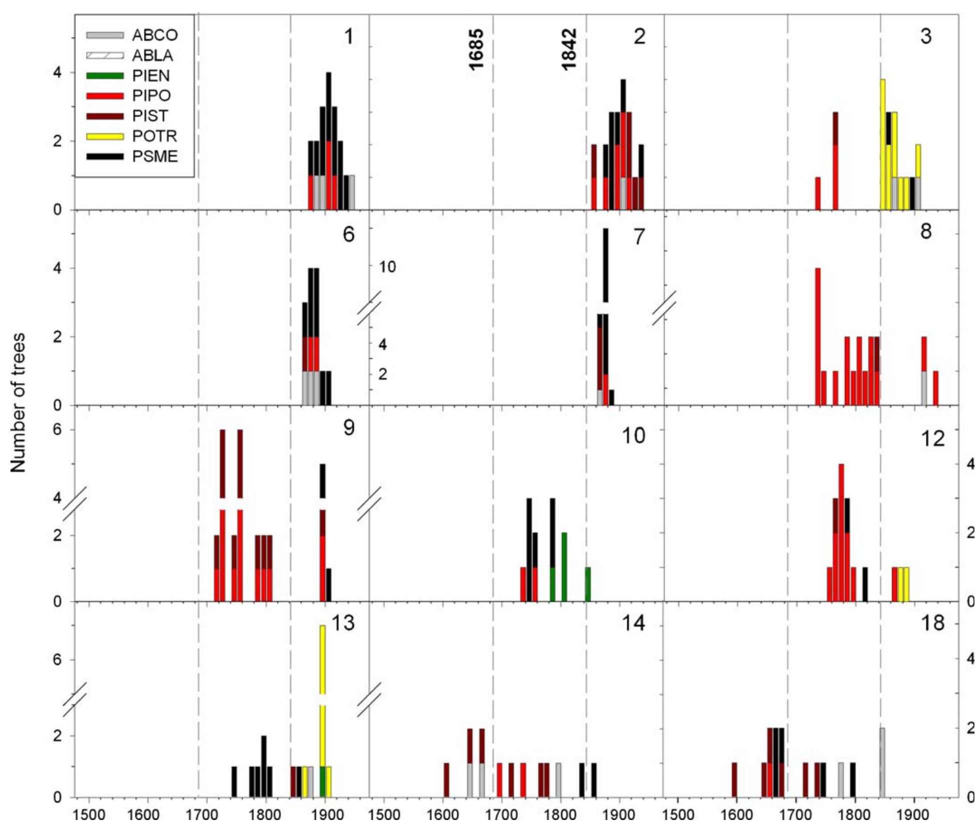

Fig. 4. Age structure and species composition of the dominant trees at individual age structure transects (e.g., 1) from the MC forest. Tree age data (estimated pith dates) are in 10-year classes. Note different scale for transects 7, 9, and 13.

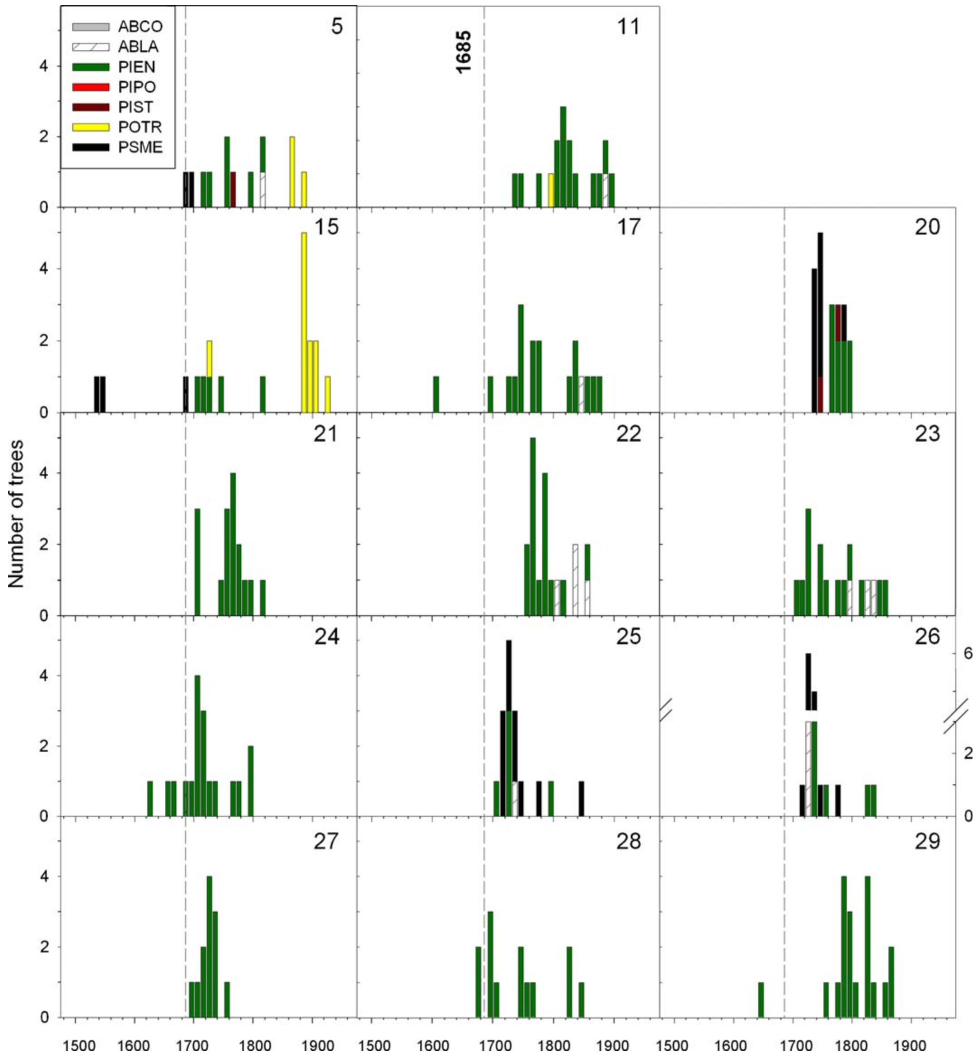

Fig. 5. Age structure and species composition of the dominant trees at individual age structure transects (e.g., 11) from the spruce (co-) dominated forest. Tree age data (estimated pith dates) are in 10-year classes. The lack of trees pre-dating the 1685 fire at 9 of the 14 transects suggests that this fire was largely stand-replacing in the upper, spruce-dominated portion of the watershed. Four of the five transects with trees surviving the fire (15, 17, 24, 28) had growth changes or injuries (i.e., traumatic resin ducts) in the tree-rings in 1685 (see Fig. 6).

3.6. *Evidence of stand-replacing fire*

The 1685 fire was recorded as fire scars by 57% ($n = 35$) of the recording fire-scarred trees at 68% ($n = 19$) of the recording fire scar plots throughout the MC and PP zones. Nine of the 14 spruce-dominated age structure transects and 10 of the 12 MC transects had no living trees that pre-date 1685. Four out of the five spruce-dominated transects that pre-date 1685 (15, 17, 24, and 28) had trees with growth changes or injuries/resin ducts in the tree-rings in 1685 (e.g., Fig. 6). The combination of age structure, growth changes/injuries, and widespread fire scar evidence indicates that the 1685 fire was relatively large and stand-replacing in the upper elevation forest.

The interpolated area of the 1685 fire within the upper Santa Fe watershed based on the spatial distribution of tree-ring evidence was 4730 ha. Approximately 25% of the reconstructed fire area was stand-replacing (1200 ha), all within the spruce-dominated zone (Fig. 7). It is likely that some of the younger forest stands below the spruce-dominated zone also burned with stand-replacing severity in 1685, but subsequent fires killed and burned any evidence of prior post-fire cohorts. We were conservative when reconstructing fire area and included these younger age structure transects as "not recording." The gaps between polygons in the reconstructed 1685 fire area are likely due to this lost record of fire.

Other fires that were widespread throughout the watershed (i.e., recorded by >50% of recording fire scar plots in the MC and PP forests, 1748, 1842; Fig. 2) were not recorded in the spruce-dominated forest. Age structure transects with many trees that

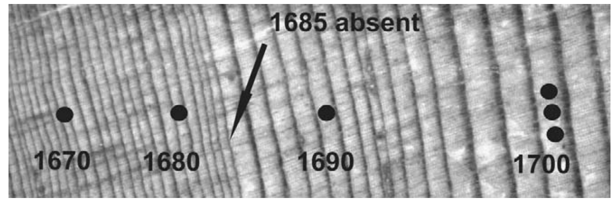

Fig. 6. Tree-ring growth release in a Douglass-fir core inferred to be a result of reduced competition due to tree mortality following the 1685 high severity fire.

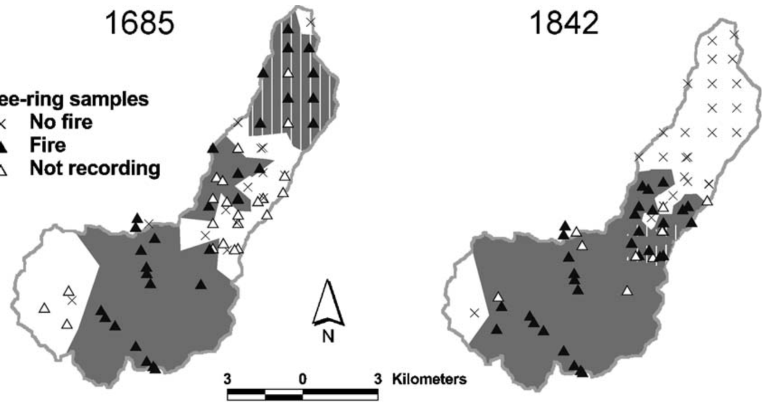

Fig. 7. Reconstructed fire area (gray) derived from thiesen polygon interpolation of tree-ring fire history data (fire scars, death dates, growth changes/injuries, and forest age structure). Areas with vertical white lines indicate stand-replacing fire patches.

pre-date these fires suggest that although these fires were widespread in the mid-elevation MC and lower pine forests, climate and/or fuel conditions were not suitable for fire spread into the mesic upper elevation spruce-dominated forest. It is possible however, that some widespread fires (e.g., 1716) may have burned with localized stand-replacing severity in the lower spruce-dominated forest and may explain the lack of trees in the early 1700s at some transects (e.g., 20).

3.7. Mixed-severity fire

There was evidence of mixed-severity fire in the MC zone. We use the term "mixed-severity" to indicate that some forest stands experienced high severity, stand-replacing fire (recorded as a tree recruitment pulse with no surviving trees) and other, adjacent stands experienced low-severity surface fire (recorded as fire scars). The landscape structure in the lower MC zone is such that north- and south-facing slopes are located on opposite sides of ridges. The youngest stands in the watershed (transects 1, 2, 6 and 7; Figs. 1 and 4) were on the more productive north- and east-facing slopes in this zone, near the ecotone with PP. These stands established in the mid-to-late 19th century and had the highest percentages of trees with "open" inner-ring growth (85–95%).

The 1842 fire was recorded as fire scars by 82% ($n = 24$) of the recording plots and 57% ($n = 42$) of the recording fire-scarred trees in the MC and PP forests. In addition to the four transects with no trees surviving the 1842 fire, three transects (3, 9, and 12) had growth changes or injuries/resin ducts in the tree-rings in 1842. Transect three had an aspen recruitment pulse beginning immediately following 1842 and the dominant PP trees that survived the fire had multi-year growth suppressions in the tree-rings beginning in 1843. The fire scar plot located less than 200 m southwest of age structure transect six had no samples post-dating 1842 and one of the fire-scarred trees had a bark-ring date of 1841.

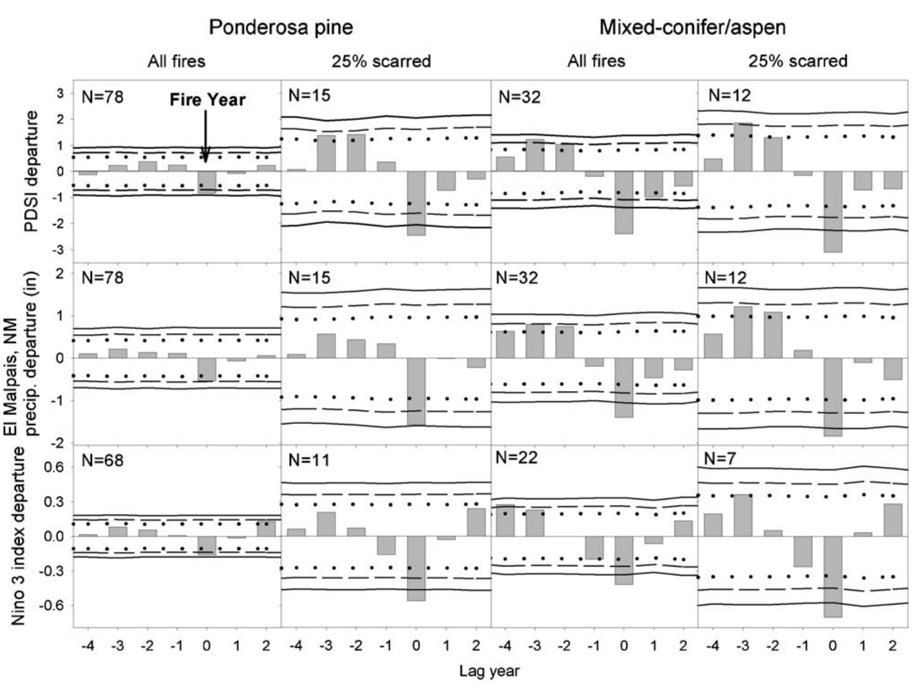

Fig. 8. Superposed epoch analysis for the PP and MC forests illustrating departure from the mean of reconstructed climate indices (PDSI, El Malpais, NM precipitation, and Niño3 index) for all fires and widespread (25% scarred) fires. Dotted, dashed and solid lines represent 95, 99, and 99.9% confidence intervals derived from 1000 Monte Carlo simulations; *n*, number of fire years.

The proximity of high severity (age structure) and low-severity (fire scar and tree-ring growth change) evidence within the lower MC zone indicates that the 1842 fire burned with mixed-severity within this forest type. Based on the multiple lines of fire evidence presented above, the reconstructed 1842 fire area within the upper Santa Fe watershed was 4642 ha (Fig. 7). The reconstructed stand-replacing fire area was 182 ha, consisting of multiple patches ranging from 34 ha to 110 ha.

3.8. Fire–climate

The results of the SEA indicate that all four filtered subsets of fire scar data (all fires, 10% scarred [not shown], 20% scarred [not shown], and 25% scarred) from both the PP and MC forests were significantly associated with negative (dry) departures during the fire year from mean summer PDSI and El Malpais, NM precipitation (Fig. 8). Fire occurrence in both forest types was also associated with positive (wet) departures from mean summer PDSI two to three years prior to the fire year. Fire occurrence was also associated with positive (wet) departures from mean annual precipitation at El Malpais, NM two to four years prior to the fire year in the MC forest. All sets of fire scar data in both forest types were associated with negative (cool ocean phase—La Niña) SST departures from the mean Niño3 index during the fire year. All fires and widespread (25% scarred) fires in the MC forest and 10% scarred fires in the PP forest (not shown) were associated with positive (warm ocean phase—El Niño) SST departures three to four years prior to the fire year. Fire occurrence in both forest types was not associated with inter-annual variations in PDO (results not shown). The period of analysis was the same used in the fire interval analyses, except when the reconstructed climate series was limiting (i.e., earliest date for reconstructed Niño3 index, 1600 and PDO index, 1700).

Although the results of the SEA indicate surprisingly similar inter-annual fire–climate relationships between the MC and the PP forest types, there were some differences. Mean summer PDSI associated with all fires in the MC forest (-2.59) was significantly drier than in the PP (-1.03; $t = 3.428$, $p < 0.001$, t-test with equal variance; SPSS 16.0). Widespread fire years (25% scarred) in the mixed/conifer aspen forests occurred on drier years (mean PDSI = -3.22) than in the PP forest (-2.57), but the difference was not statistically significant ($t = 0.798$, $p = 0.432$). Widespread fires occurred during drier years on average compared to all fires in the PP forest ($t = 2.498$, $p = 0.014$). The same was true in the MC forest, but the difference was not significant ($t = 0.896$, $p = 0.375$). The PDSI during the one reconstructed stand-replacing fire (1685) in the spruce-fir zone was -6.92.

4. Discussion

Fire in the upper Santa Fe River watershed historically spread between forest types and fire regimes. Low severity fires burned frequently in the PP forests. During sufficiently dry conditions fire spread up the watershed into the MC forests and burned with mixed-severity. During an extreme drought (1685), fire continued to spread into the highest elevation spruce-dominated forests and burned primarily with high severity. The connectivity of forests through fire, the removal of this important process, and historical evidence of large (100–1200 ha) stand-replacing fire patches in MC and spruce-dominated forests have important implications for both fire and water management in the upper Santa Fe watershed and similar forests throughout the region.

4.1. Human influence on the fire regime

Santa Fe was settled by the Spanish earlier than other locations in the southwestern U.S. (1600s), making this site unique. The most striking feature of the Santa Fe watershed fire scar record is the lack of widespread fire since the mid-to-late 19th century (Fig. 2). Fires stopped earlier (i.e., last widespread fire in the PP and MC, 1842) compared to the general pattern of circa 1900 fire exclusion in the southwestern U.S. (Swetnam and Baisan, 1996, 2003). The start of fire exclusion at a particular site has been linked to the timing of intensive land use practices (e.g., grazing and fuel wood collecting) by the Spanish and Anglo-American settlers (Savage and Swetnam, 1990; Baisan and Swetnam, 1997). Sheep herding in the vicinity of Santa Fe began in the 1600s, became a stable industry regionally by the mid-1700s, and peak numbers in the pre-American Civil War era were recorded in the 1820s and 1830s (Baxter, 1987). This early, intensive land use may have created a pattern of anomalously early fire exclusion (e.g., early 1700s, Sandia Mountains, NM; Baisan and Swetnam, 1997) on the east side of the Rio Grande valley along the Camino Real Spanish travel and settlement route. A long gap between widespread fires in the PP and MC forest in the Santa Fe watershed beginning in the 1700s may indicate initial effects of early grazing, but may also have a climatic explanation.

In specific locations in the southwestern U.S. the fire scar record has revealed periods of anomalously high fire frequency (e.g., repeated 1-year fire intervals) or a change in the seasonality of fire occurrence, indicating possible human ignitions (e.g., Chiricahua Mountains, Arizona; Seklecki et al. (1996)). Very few (<2%) latewood fires were recorded in the Santa Fe watershed and there was not evidence of anomalously high fire frequency, despite the long record of settlement. The high percentage of lightning-caused fires (80%, $n = 178$, 1970–2003) in the local area supports the general premise that sufficient lightning ignitions occur in the southwestern U.S. to account for the reconstructed frequency of fire occurrence (Allen, 2002).

4.2. Spruce-fir fire history

Very little fire history and/or age structure data exist for old-growth spruce-fir forests of Arizona and New Mexico. Fule et al. (2003) reconstructed a mixed-severity fire regime with surprisingly frequent small fires ($MFI_{all\ fires} = 2.6$ years) and less frequent widespread fires ($MFI_{25\%} = 31.0$ years) in a relatively low elevation (<2800 m) spruce-fir forest that contained a mix of species (including PP) on the north rim of the Grand Canyon, AZ. A higher elevation spruce-fir forest (average elevation 3200 m) in the San Francisco Peaks, AZ, has not burned catastrophically for over 200 years based on the age of the oldest trees (Cocke et al., 2005). Other high elevation (>3000 m) pure spruce-fir forests in the southern sky island region (Pinaleño Mountains, AZ, and Mogollon Mountains in the Gila Wilderness, NM) had not experienced significant stand-replacing disturbance for at least 300 years prior to the recent crown fires beginning in the late 1990s (Grissino-Mayer et al., 1995; Margolis, 2007). Multiple lines of tree-ring evidence suggest that the Pinaleño spruce-fir stand regenerated after a stand-replacing fire in 1685 (Grissino-Mayer et al., 1995; Margolis, 2007; Swetnam et al., 2009), the same year as the upper Santa Fe watershed. Drought conditions in 1685 were remarkably severe and widespread throughout the southwestern U.S. (Cook et al., 2004). This climate event synchronized these rare stand-replacing fire events, and potentially others, hundreds of kilometers apart.

4.3. Comparing the PP and MC fire regimes

Historical MFI was significantly shorter in PP compared to the higher elevation MC forest in four of the five filtered subsets of fire years (Table 5). Widespread fires in the MC forest occurred on average at intervals that were 10 years (50%) longer than in PP

(Table 5; PP $MFI_{25\%} = 20.8$ years, MC $MFI_{25\%} = 31.6$ years). The difference in fire frequency might be partially explained by a larger area in the PP zone (PP, 1600 ha vs. MC, 1200 ha), different sampling intensity (PP, 76 trees: MC, 65 trees) or the spatial distribution of samples. However, these sampling differences are relatively small and with sufficient sample numbers, 25% scarred MFI is robust to differences in sampling (Van Horne and Fule, 2006) and thus likely does not account for the magnitude of observed fire frequency differences. Regionally, MC forests burned less frequently than pine-dominant forests based on comparisons from dozens of Southwestern fire history studies (Swetnam and Baisan, 1996; Heinlein et al., 2005). $MFI_{25\%}$ of widespread fires at six other MC sites in New Mexico ranged from 16.0 years to 26.4 years (Swetnam and Baisan, 1996), which is shorter than the Santa Fe watershed (MC $MFI_{25\%} = 31.6$ years). The relatively long MFI could be a result of settlement and land-use (e.g., grazing) by the Spanish beginning in the 1600s (Debuys, 1985), which could have reduced fine fuels and consequently fire occurrence in the watershed earlier than in other locations (e.g., Savage and Swetnam, 1990; Baisan and Swetnam, 1997).

An inverse relationship between fire frequency and elevation exists broadly across the montane forests of the western U.S. (Martin, 1982) and at individual sites (Caprio and Swetnam, 1995; Brown et al., 2001)), but site-specific topographic factors may weaken the relationship in some locations (Brown et al., 2001). A hypothesized mechanism for this pattern relates to increased moisture in the higher elevation forests and consequently less frequent occurrence of drought conditions severe enough to dry fuels sufficiently to sustain fire spread. Our results indicate that, on average, fires in the MC forest occurred during drier conditions compared to the adjoining lower elevation PP, providing quantitative support for this hypothesis (Fig. 8). Specifically, the grassy understory of the drier, relatively open PP forest was more likely to carry fire, even if fuels in the mesic mixed-conifer zone were not primed by drought for widespread fire.

4.4. Fire–climate relationships

The relationship between fire occurrence in MC and PP forests and drought during the fire year is intuitive and commonly observed in fire history reconstructions across fuel types in the southwestern U.S. (Fig. 8; Swetnam and Baisan, 1996). The relationship between fire occurrence and wet conditions in prior years is less intuitive, but also well replicated in pine-dominant forests of the southwestern U.S. from fire history studies (Baisan and Swetnam, 1990; Swetnam and Baisan, 1996) and the instrumental record (Crimmins and Comrie, 2004; Baisan and Swetnam, 1990) hypothesize that wet years increase fine fuels (e.g., grass and pine needles) that carry fire, which are burned during subsequent dry years.

This antecedent wet-year relationship is not present in high elevation sub-alpine forests and upper montane seral MC forests of the Southern Rockies (e.g., Sibold et al., 2006; Margolis et al., 2007). A similar drought-only fire–climate relationship exists at multiple MC fire history sites in the region (Swetnam and Baisan, 1996; Touchan et al., 1996). These more mesic, higher elevation forest types are generally not fuel-limited, but require more severe drought for fire occurrence than lower elevation forests.

Based on this prior research, the relationship between fire occurrence and antecedent wet years in the MC forests of the Santa Fe watershed was somewhat surprising (Fig. 8). This result suggests that variability in fine fuels may have been important for fire occurrence (i.e., the system was fuel-limited). But how can a fire regime with a 20- to 30-year mean return interval for widespread fires be fuel-limited? Twenty years in a MC forest should be sufficient to produce enough fuel to sustain fire spread, even in the semi-arid southwestern U.S. It is possible that due to the topographic heterogeneity of the landscape (opposing north and south-facing slopes), wet conditions followed by drought were needed to produce sufficient fuel on the drier south aspects to connect the more productive forest patches and allow fire to burn across aspect and forest types. Grazing could amplify the aspect-driven fuel discontinuity by further reducing fuels on the drier, grassy, south-facing slopes.

A second factor that may explain the wet lags in the MC SEA results is the connectivity of the MC forest to the adjacent, large, frequent burning PP forest. The PP forest in the Santa Fe watershed, similar to others throughout the southwestern U.S., had an herbaceous understory that fueled the frequent fires. As expected, historical fire occurrence in the Santa Fe watershed PP forest was associated with prior wet years that replenished this herbaceous fuel layer (Fig. 8). Prevailing wind direction and the tendency for fire to move upslope would push fires from the PP into the MC forest. Based on our analysis of fire synchrony, 24% of the PP fires spread to the MC forests, but these accounted for a large proportion (69%) of all fires in the MC forest (Table 3). Thus, if fires in PP were in part fueled by prior wet years, and it was sufficiently dry during the fire year, fires would continue to spread up the "fireshed" into the MC forest. The connectivity between forest types would indirectly link fire occurrence in the MC zone to antecedent wet years.

4.5. Landscape scale connectivity of fire regimes

By reconstructing fire history along an elevation, vegetation and fire regime gradient we were able to reconstruct evidence of the transition of fire regimes (and individual fires) from surface fire, to mixed-severity fire (e.g., 1842 fire), to widespread stand-replacing fire (e.g., 1685 fire) in a single watershed. We present multiple lines of evidence of connectivity between forest types and fire regimes through fire as a continuous process that moves across artificially drawn fire regime and vegetation boundaries (Caprio and Swetnam, 1995; Fule et al., 2003). An important implication of this connectivity is that by altering the fire regime in one location (forest type) there may be effects in other forest types. The disruption of the surface fire regime in the mid-elevation, pine-dominated forest throughout the southwestern U.S. (Swetnam and Baisan, 1996, 2003) may not only have serious consequences for that vegetation type (Allen et al., 2002), but is also likely to have effects all along vegetation/elevational gradients. In the Santa Fe watershed, early fire exclusion in PP (i.e., last widespread fire, 1842) from grazing followed by active fire suppression removed an important source of fires for the MC and the spruce-dominated forests. As a result, fire frequency was dramatically reduced in the upper elevation MC forest (Fig. 2).

4.6. Mixed-conifer/aspen forest change due to fire exclusion

Over 120 years of fire exclusion in the MC forest has contributed to changes in structure and composition similar to what occurred regionally and locally in PP and MC forests (Fig. 9). We present age structure data from two fire sensitive species (white fir and quaking aspen) as examples of changes in species composition in the MC forest that occurred coincidently with fire exclusion. Seventy-five percent of the dominant white fir in the MC zone recruited since the last widespread fire (1842; Figs. 3–5). Young white fir has thin bark, making them particularly sensitive to even low-intensity surface fire. In the absence of fire these trees survived to occupy a dominant canopy position, and because they are shade tolerant, they have continued to recruit in the understory, creating ladder fuels, and increasing crown fire hazard. This pattern has been documented in PP dominated systems (Allen

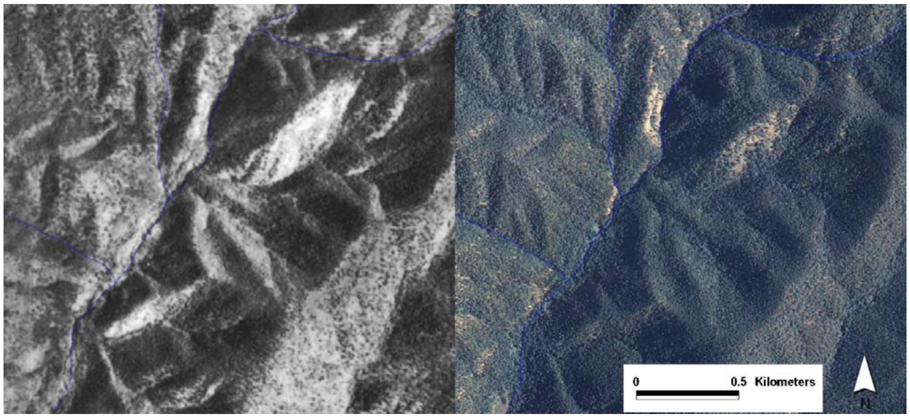

Fig. 9. Comparison of aerial photos (1935 on the left, 2005 on the right) from the MC forest of the Santa Fe watershed indicating a dramatic increase in forest cover on south- and southeast-facing slopes. Images encompass age structure plots 8, 12, and 7. Photos from the U.S.F.S. Santa Fe National Forest, courtesy of Julie Luetzelschwab.

et al., 2002) and other southwestern U.S. MC forests (Mast and Wolf, 2006).

Fire was historically an important determinant of quaking aspen mortality and natality in many upper elevation forests across the western U.S. (Kulakowski et al., 2006; Margolis, 2007; Margolis et al., 2007) and the cessation of fire has been identified as one cause of widespread stand-deterioration throughout its range (Bartos and Campbell, 1998; Kashian et al., 2007). In the Santa Fe watershed, only one (2.5%) quaking aspen stem pre-dated the last widespread fire (1842, Figs. 3–5). Quaking aspen recruitment pulses occurred at three transects following the last fire (3, 13, and 15). Conifers survived the fire at these locations, indicating mixed-severity fire effects by species (i.e., quaking aspen were top-killed and re-sprouted while the overstory conifers survived). This evidence of fire killing and regenerating quaking aspen stems at multiple locations throughout the MC forest illustrates the substantial effect of fire (occurrence and exclusion) on quaking aspen age structure.

4.7. Spruce-fir forest: potential for fire exclusion effects

In the high elevation spruce-fir forests of the region, limited research has assessed the potential for changes related to fire exclusion (Fule et al., 2003; Cocke et al., 2005). Cocke et al. (2005) recorded increased density in spruce-fir since 1876, but this is consistent with natural succession in this forest type. Because *Picea* and *Abies* species are shade tolerant and fires are infrequent, these forests naturally increase in density through time. Different approaches (e.g., examining effects of fire interval length on successional pathways) may be necessary to evaluate potential effects of fire exclusion in this forest type.

Changes in the length of fire-free intervals, even if they were naturally long, may affect successional pathways and forest composition (Romme and Knight, 1981; Kipfmueller and Kupfer, 2005). For example, Romme and Knight (1981) found that sites with naturally longer fire-free intervals and more rapid succession were dominated by spruce-fir forests, compared to sites with more frequent fire and slower succession, which were dominated by lodgepole pine. In the southwestern U.S., quaking aspen is the upper elevation tree species most likely to be sensitive to changes in the length of fire intervals. Seral quaking aspen in the upper montane forests of the region depend on stand-replacing fire for widespread regeneration and long-term perpetuation of the stand (Margolis et al., 2007). Following fire in these seral stands, the aspen-conifer successional pathway proceeds and shade tolerant conifer species regenerate under the canopy, eventually overtopping and shading out the aspen stems in the absence of fire (Dick-Peddie, 1993). Lengthening fire-free intervals in seral aspen stands beyond the life of the above-ground stems and the below-ground clonal root resources could potentially remove aspen from the site, affecting the long-term forest composition.

We hypothesize that although fire intervals were naturally long in high elevation forests of the southern Rocky Mountains, because fire historically spread between forest types, fire exclusion in the lower elevation forests has likely affected some high elevation forests. Future research should be designed to test for changes (e.g., altered successional pathways) resulting from fire exclusion. Upper elevation spruce-fir forests are naturally dense, so although forest density has been an indicator of change in PP and MC forests, it is not likely the best variable to test for change in the spruce-fir zone.

4.8. Will Santa Fe flood?

Large patches of high severity fire (>100 ha) historically occurred on some north-facing slopes in the MC forests of the Santa Fe watershed. The dramatic increase in forest density and canopy cover in these forests, evident from repeat photos (Fig. 9), has very likely increased the size of forest patches at risk of high severity fire. Areas that historically burned with mixed-severity (i.e., 100 ha patches of high severity fire adjacent to equally large low-severity patches) now are likely to burn as larger, contiguous high severity patches. This increased area of forest at risk of stand-replacing fire could subsequently result in a larger, historically unprecedented post-fire hydrologic response in this vital municipal watershed (e.g., Veenhuis, 2002).

One approach to evaluating post-fire flood risk would be to use a combination of our historical fire reconstructions and a hydrological model. The 1685 fire was the worst-case scenario in the spruce-dominated forest; 93% of the sampled spruce forest burned with stand-replacing severity (~1200 ha). The reconstructed spatial extent and location of low and high severity fire patches from this fire and others (e.g., 1842) could be used to populate a GIS-based hydrologic model such as The Automated Geospatial Watershed Assessment Tool (Goodrich et al., 2006). Alternatively, fire behavior and fire spread models (e.g., FARSITE) could be used to estimate the range of high severity patch sizes under current forest conditions for comparison with reconstructed patch size. The different fire scenarios (modeled and reconstructed) could then be used to populate the hydrologic model. Modeled post-fire runoff and erosion output would provide the best possible answer to the big question in the Santa Fe watershed: what will happen to the water supply when the forest burns?

5. Conclusions

Historical fire in the upper Santa Fe River watershed burned across gradients of elevation, forest types and fire severity. Widespread fires that burned up to 80% of the MC forest area occurred on average at intervals 10 years longer ($MFI_{25\%}$ = 31.6 years) than in the adjacent, lower elevation PP forest ($MFI_{25\%}$ = 20.8 years). The historical MC fire regime is best described as mixed-severity, where patches of stand-replacing fire greater than 100 ha were located adjacent to stands with evidence of repeated surface fire. The upper elevation spruce-dominated forest last burned in 1685 in a climate-driven stand-replacing fire that affected greater than 93% (1200 ha) of the sampled spruce forest and at least 68% of the MC and PP forests (total fire area, 4730 ha). This history of fire that includes natural stand-replacing patches in the upper elevation forests presents challenges for fire management in the watershed. Restoring the aspect-driven heterogeneity of fuels in the MC forest is both ecologically sound and would reduce the area at risk of crown that could threaten the water supply. Given the natural occurrence of large (>1000 ha) stand-replacing fire patches in the spruce-fir zone of the Pecos Wilderness Area, where fire hazard reduction treatment options are limited and would be ecologically unsound, hydrologic models should be used to develop a contingency plan for a large, high severity fire.

Climate variability has strongly influenced fire regimes for centuries in the montane forests of the southwestern U.S. (Swetnam and Betancourt, 1990; Swetnam and Baisan, 1996) and more broadly across western North America (Kitzberger et al., 2007). Fire synchrony between the MC and the PP forest during 24 individual fire years (69% of all MC fires) indicates both top-down control of fire occurrence by climate and connectivity between forest types and fire regimes. More severe drought was required on average for the higher elevation MC forest to burn (sometimes with mixed-severity), compared to the lower PP forest. The worst single-year drought in over 700 years (1685) was associated with the last major fire in the upper elevation spruce-dominated forests of the Santa Fe watershed and synchronized high severity fire in the upper elevations of multiple, distant mountain ranges. This evidence of a direct relationship between drought severity, fire occurrence, and fire severity in MC and spruce-dominated forests suggests that if temperatures continue to increase (IPCC, 2007) and droughts become more frequent and severe as predicted (Seager et al., 2007), the probability of large and severe fire occurrence will increase (Westerling et al., 2006). This emphasizes the urgency for creative and science-based fire and watershed planning and management in this and other fire prone, vitally important watersheds across the West.

Drought, multi-seasonal climate, and wildfire in northern New Mexico

E. Q. Margolis[1] · C. A. Woodhouse[2,3] · T. W. Swetnam[3]

Received: 22 August 2016 / Accepted: 21 March 2017 / Published online: 25 April 2017

Abstract Wildfire is increasingly a concern in the USA, where 10 million acres burned in 2015. Climate is a primary driver of wildfire, and understanding fire-climate relationships is crucial for informing fire management and modeling the effects of climate change on fire. In the southwestern USA, fire-climate relationships have been informed by tree-ring data that extend centuries prior to the onset of fire exclusion in the late 1800s. Variability in cool-season precipitation has been linked to fire occurrence, but the effects of the summer North American monsoon on fire are less understood, as are the effects of climate on fire seasonality. We use a new set of reconstructions for cool-season (October–April) and monsoon-season (July–August) moisture conditions along with a large new fire scar dataset to examine relationships between multi-seasonal climate variability, fire extent, and fire seasonality in the Jemez Mountains, New Mexico (1599–1899 CE). Results suggest that large fires burning in all seasons are strongly influenced by the current year cool-season moisture, but fires burning mid-summer to fall are also influenced by monsoon moisture. Wet conditions several years prior to the fire year during the cool season, and to a lesser extent during the monsoon season, are also important for spring through late-summer fires. Persistent cool-season drought longer than 3 years may inhibit fires due to the lack of moisture to replenish surface fuels. This suggests that fuels may become increasingly limiting for fire occurrence in semi-arid regions that are projected to become drier with climate change.

1 Introduction

Over the past decade, wildfires have made headlines due to their increasing size, severity, and cost. Warming temperatures, drought, and earlier snowmelt—all consistent with projected future climate in the southwestern USA—have been linked to an increasing number of large fires (Dennison et al. 2014; Westerling 2016). The legacy of late nineteenth and twentieth century land use and forest management has also played an important role by increasing fuels that have led to recent megafires (10,000 ha to >100,000 ha), particularly in dry conifer forests (Stephens et al. 2014). Natural climate variability, in addition to human influences, has long been a primary driver of variability in wildfire occurrence, severity, and seasonality (Littell et al. 2016; Swetnam et al. 2016). Climate change will likely alter fire regimes globally, but the mechanisms and the directions of the effects are complex and will vary geographically (Moritz et al. 2012).

Understanding the relationships between climate variability and wildfire by analyzing instrumental and paleoecological data (e.g., tree rings or sediment charcoal) is increasingly valuable for fire management and modeling future fire regimes. Robust relationships have been established in North America between variability in instrumental period (twentieth and twenty-first century) and paleo (pre-twentieth century) fire records and a suite of climate variables, climate patterns, and ocean-atmosphere oscillations (Swetnam and Betancourt 1990; Westerling et al. 2006; Kitzberger et al. 2007; Marlon et al. 2012; Williams et al. 2015). However, fire-climate relationships are spatially and temporally complex, with significant variability within and among regions in fire and moisture seasonality, and lagging relationships that drive fire (Swetnam and Betancourt 1998; Littell et al. 2009; Keeley and Syphard 2016). To date, there is limited understanding of the impacts of the seasonality of moisture and persistent drought on wildfire size and seasonality.

The relationships between cool-season moisture and fire over past centuries (circa 1600–1900 CE) have long been established in the southwestern USA using data from fire-scarred trees (for background on fire scars, see Text S1). A pattern of one or two wet cool seasons followed by cool-season drought is consistently associated with fire occurrence in dry conifer forests of the region (Swetnam and Betancourt 1990; Swetnam and Betancourt 1998). In contrast, the role of summer moisture, delivered through the North American monsoon (NAM) and accounting for up to 50% of the annual precipitation in the southwestern USA, has not been well investigated. Limited research indicates a potential influence of the NAM on fire through increased fine fuels from prior wet monsoons (Crimmins and Comrie 2004; Text S2), or the possibility of monsoon drought leading to more monsoon-season fires (Grissino-Mayer and Swetnam 2000). Until recently, there have been no tree-ring proxies of summer moisture, but a large new network of partial ring-width chronologies now enables the reconstruction of both cool- and monsoon-season moisture in the southwestern USA (Griffin et al. 2013; Text S3).

In this study, we compile the largest known collection of fire scar data for a single mountain range and develop new reconstructions of cool- and monsoon-season moisture to investigate relationships between historical fire regimes and multi-seasonal climate in northern New Mexico. Our main research questions are (1) How do monsoon- and cool-season moisture variability affect fire occurrence, extent, and seasonality? and (2) What is the relationship between fire and prolonged drought? Our goal is to improve the understanding of fire-climate relationships in the past to help inform how climate change may impact fire regimes in the future.

2 Study area and data

The Jemez Mountains are located in northern New Mexico within NAM region 3 (Gochis et al. 2009; Fig. 1). Approximately 44% of the annual precipitation falls in the cool season (October–April) and 43% in the monsoon season (July–September). The warmest and driest months of the year are May and June, when the largest fires occur. Multiple large fires have burned in the Jemez Mountains in recent years, including the 2011 Las Conchas fire (63,400 ha). Vegetation in the Jemez Mountains ranges from grasslands at the lower forest border (~2000 m a.s.l.), to ponderosa pine and mixed conifer forests, to montane meadows and spruce forests at the highest elevations (~3000 m a.s.l.). The majority of the landscape was historically dry conifer forest that included ponderosa pine. The region has extensive networks of fire-scarred and climatically sensitive trees, making it an ideal location for tree-ring fire-climate analyses (Swetnam et al. 2016).

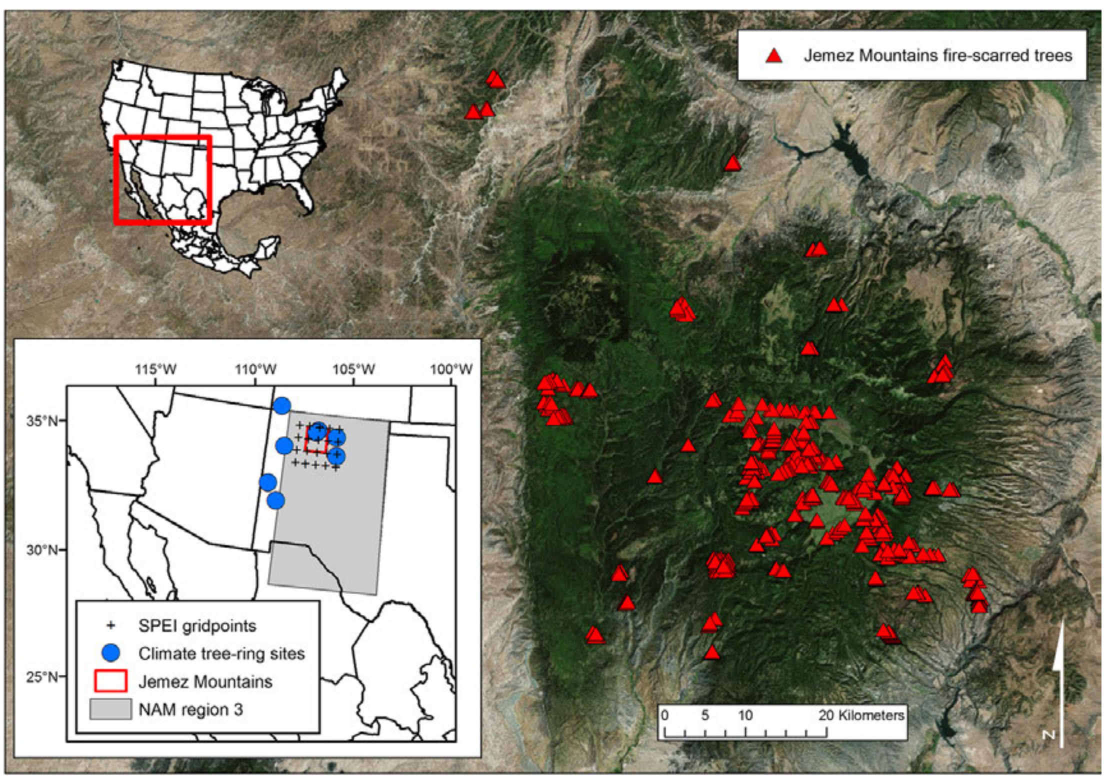

Fig. 1 Study area in southwestern North America focused on the North American monsoon (NAM) region 3. Inset map indicates the location of the climate-sensitive tree-ring sites, the standardized precipitation-evapotranspiration index (SPEI) gridpoints used in the climate reconstructions, the Jemez Mountains, and NAM region 3. The aerial photo is of the Jemez Mountains in New Mexico, which contain a network of 1343 fire-scarred trees

2.1 Tree-ring climate reconstructions

To reconstruct cool- and monsoon-season moisture, we used existing earlywood and adjusted latewood chronologies from 23 sites in New Mexico and southern Colorado located within and adjacent to the Jemez Mountains and NAM region 3 (Text S3). Adjusted latewood chronologies have the dependence of latewood growth on earlywood removed statistically (Griffin et al. 2011). We reconstructed the standardized precipitation-evapotranspiration index (SPEI), because fire is influenced by the combined effects of temperature and moisture that are integrated into SPEI (Williams et al. 2015). SPEI data were obtained from the Global SPEI Database, which uses monthly precipitation and potential evapotranspiration at a 0.5 degree spatial resolution. A regional time series was generated based on the average of 20 grid points centered on the Jemez study area (Text S3, Fig. 1). Monthly SPEI was averaged for the cool (October–April) and monsoon (July–August) seasons.

Reconstruction models were developed by calibrating earlywood chronologies with October–April SPEI and adjusted latewood chronologies with July–August SPEI separately, using stepwise regression (1896–2007). Models explained 67 and 52% of the total variance for October–April and July–August SPEI, respectively. Models met the assumptions of linear regression, and cross-validation statistics indicate reasonable skill. Details of regression results are in supplemental materials (Text S3, Table S1, Fig. S1). The October–April SPEI reconstruction extends 1594–2007 and July–August SPEI, 1599–2008. The relationship between the seasonal SPEI variables is preserved, for the most part, in the reconstructions. There is no relationship between the instrumental cool- and monsoon-season SPEI ($r = -0.09$, $p > 0.05$), but there is a weak correlation between the reconstructed cool- and monsoon-season SPEI in the instrumental period ($r = 0.23$, $p < 0.05$). Over the full common reconstruction period, 1599–2007, the cool and monsoon-season SPEI are uncorrelated ($r = 0.09$, $p > 0.05$).

2.2 Tree-ring fire history reconstructions

The tree-ring fire scar data were compiled from existing collections in the Jemez Mountains. The data cover approximately 300,000 ha of historically dry conifer forests that used to burn predominantly with low-severity fire. This network, the largest in North America for a single mountain range, is a compilation of 19 studies conducted over 40 years (Text S4). A total of 8588 fire scars from 1295 trees were dated to the year (1599—1899). Fire seasonality was determined for 77% of the scars ($n = 6581$) from the position of the scar within the annual ring. Categories for scar positions and their seasonal timing include: dormant (D—early spring); early, mid, and late earlywood (E, M, L—late spring through mid-summer); and latewood (A—late summer and fall). Most fire years historically had scars in multiple fire seasons (Fig. 2 and S2). Details of the fire scar seasonality methods are described in the supplementary materials (Text S1).

Fire scar data were compiled and analyzed with the “burnr” fire history package in R (Malevich et al. 2015; R Core Team 2015). Percent of recording trees scarred was used as a proxy for relative fire size (e.g., Farris et al. 2010). Fires recorded by a single tree were not included in the analysis. After 1899, the number of fires in the Jemez Mountains declines precipitously due to increased human land use, so the common period for the fire and climate data is 1599–1899. Native Americans influenced fire regimes through the mid-1600s in the southwest Jemez Mountains (Swetnam et al. 2016), which could affect fire-climate relationships in the early part of the record.

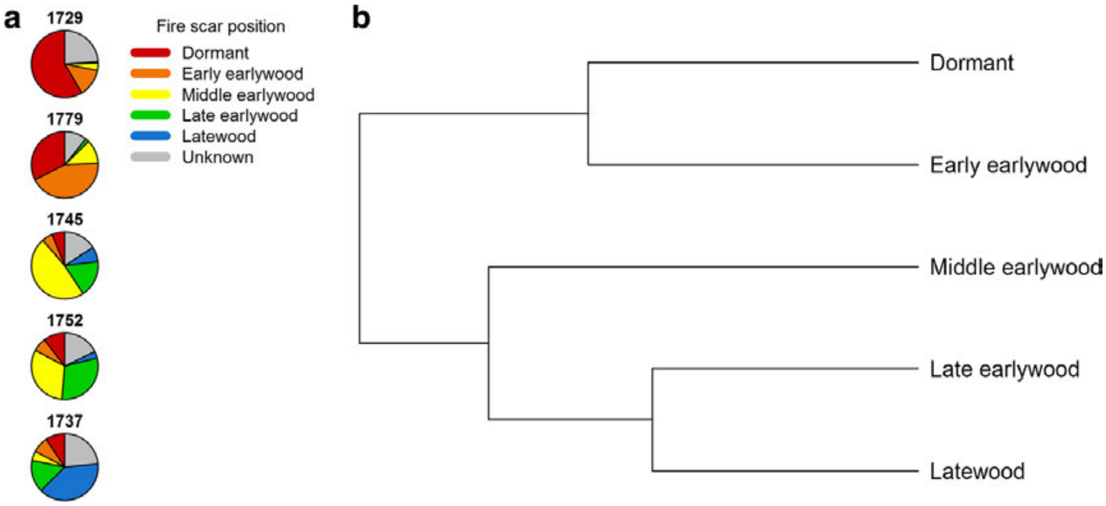

Fig. 2 **a** The proportion of trees scarred by fire in the Jemez Mountains in each fire scar position, or season, for five large fire years. The selected years have the largest number of fire scars in the spring dormant (1729) through late summer/fall latewood (1737) fire seasons in the 1700s. Note the inter- and intra-annual variability in the distribution of fire seasonality. **b** Cluster dendrogram of large, 95th percentile fire years by fire-scar position (n = 16 years for each scar position). Note the grouping of dormant and early earlywood (DE) fire years and middle earlywood, late earlywood and latewood fire years (MLA)

Analyses focused on the extreme fire years. Extreme large and small fire years were determined by the 95th and 5th percentile rank of the percent of recording trees scarred in a year (Table S2). Extreme fire years were first determined for all fires (combining all fire seasons, including unknown seasonality), and then for each of the five individual fire scar seasonalities (spring through fall). A total of 16 fire years fell within the 95th percentile (Fig. S2). The 5th percentile years were all years when no fires occurred.

3 Analysis methods

3.1 Multi-seasonal fire-climate analysis

We used superposed epoch analysis (SEA) to test whether fire occurrence and fire seasonality were associated with cool- and monsoon-season SPEI anomalies (Swetnam 1993). SEA is a compositing approach that uses block re-sampling and bootstrap simulations to evaluate the significance of the concurrence between fire event years and wet or dry conditions in the event year or lagged years. We examined 7-year blocks of cool- or monsoon-season SPEI spanning 4 years before, and 2 years after the fire year (year zero). We first used SEA to test whether cool- and monsoon-season SPEI anomalies were associated with all extreme large fire years and no fire years, and then for SPEI associations with the separate individual fire seasons.

To determine associations among the different fire scar positions, as well as relationships between fire-scar positions and seasonal climate, we used hierarchical cluster analysis of extreme large fire years for all five individual fire scar positions (hclust; R Core Team 2015). The analysis includes all possible combinations, not just adjacent scar positions. The groups that resulted from the cluster analysis were used as a framework for combining multiple fire scar positions for analyzing the relationships between sequences of cool- and monsoon-season moisture and the related fire scar positions, as well as the drought-fire analysis.

3.2 Drought-fire analysis

Reconstructed cool- and monsoon-season SPEI series were first analyzed to investigate characteristics of seasonal drought. This included the number and length of droughts (single and consecutive years with negative SPEI values) and comparisons of these metrics between cool- and monsoon-season droughts. The relationships between droughts and large fire years in the early (D and E) and mid-to-late (M, L, and A) fire seasons—as grouped by the cluster analysis—were then examined to determine (1) the length of droughts in which the large fires occurred and (2) the year in the drought that large fires occurred. On the basis of the SEA results, early-season fires were evaluated with cool-season droughts, and mid- to late-season fires were evaluated with both cool- and monsoon-season droughts.

We also assessed whether the driest decades of the cool- and monsoon-season SPEI reconstructions were associated with increased fire. Here, we relax the threshold for fires to include those with at least 2.5% of trees scarred (74th percentile, $n = 79$ fire years for early-season fires and 85th percentile, $n = 46$ fire years for mid- to late-season fires). Decadal dry periods were identified as the five driest non-overlapping decades for each climate season. Decades with the highest fire activity for early and mid- to late-season fires were defined as the five non-overlapping decades with the largest sum of the percent of recording trees scarred. These decadal measures of climate and fire were compared visually to assess the correspondence between the most active fire periods and the driest periods.

4 Results

4.1 Cool-season climate associated with large fire years

The SEA analysis for the largest fire years, regardless of fire season, highlights the importance of cool-season drought during the fire year (Fig. 3a, top row). The largest fire years were also associated with wet cool seasons 2 and 3 years prior to the fire year. No significant associations were found between all large fires and monsoon-season moisture, although a similar pattern of dry conditions during the fire year preceded by wet years is suggested (Fig. 3b, top row). Years without fire were associated with wet cool seasons in the fire year, but not with monsoon moisture.

When the largest fire years for each fire season are analyzed, several different fire-climate relationships are revealed. The SEA results indicate that early season (D and E) fires are most strongly associated with cool-season drought during the fire year, with the strength of the association decreasing by mid-summer through fall (Fig. 3a). Similarly, the importance of prior wet cool seasons associated with large fire occurrence decreases through the fire season; spring (D) fires are associated with two prior wet cool seasons 2 and 3 years before the fire year; early- to mid-summer fires (E, M, and L) are associated with one wet cool season 2 or 3 years prior to the fire year; and late-summer and fall (A) fires have no significant relationship with prior wet cool seasons.

4.2 Monsoon-season climate associated with large fire years

Monsoon-season drought during the fire year is significantly associated with large late season (L and A) fire occurrence (Fig. 3b). There is a suggestion of a similar relationship with the

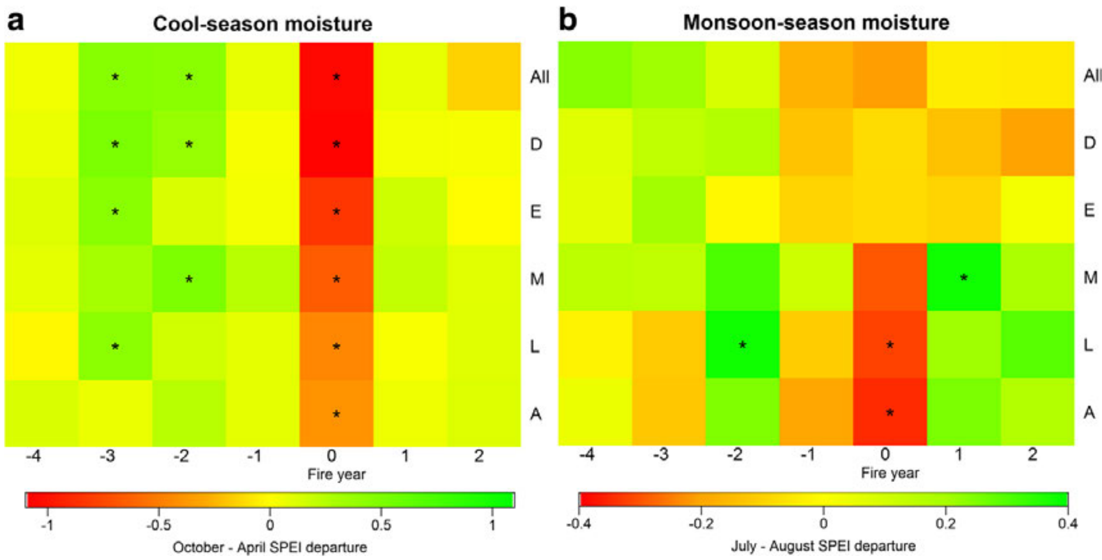

Fig. 3 Superposed epoch analysis of **a** cool-season moisture and **b** monsoon-season moisture by fire-scar position for large, 95th percentile fire years in the Jemez Mountains (n = 16 fire years for each seasonality, 1599–1899). All = all fire scar positions, D = dormant, E = early earlywood, M = middle earlywood, L = late earlywood, and A = latewood. SPEI = standardized precipitation-evapotranspiration index. *Asterisks* in cells denote significant departures from mean SPEI based on bootstrap simulations ($p < 0.05$)

monsoon and mid-season (M) fires. Since late-season fires are also associated with cool-season drought during the fire year, joint drought in the cool and monsoon seasons appears important for widespread late-season fires. Wet conditions in the cool and monsoon seasons 2 or 3 years prior to the fire year also appear to be important in this sequence favoring late-season fires. There is no significant association between monsoon moisture and D or E fires.

4.3 Fire seasonality patterns

The cluster analysis of the fire-scar seasonality of large fire years supports results from the SEA. There were two main groups of fire scar positions: (1) dormant and early earlywood (DE) and (2) middle earlywood, late earlywood, and latewood (MLA) (Fig. 2b). The patterns of fire-climate relationships from the SEA suggest a similar grouping of M, L, and A fires, particularly in association with monsoon moisture (Fig. 3b). This implies different climatic controls on spring and early summer (DE) fires compared with the mid-summer to fall (MLA) fires. Large early-season fires, by virtue of their timing, are strongly linked to cool-season drought, and they rarely continue to burn throughout the summer (Fig. 2 and S2). Whereas the largest MLA fires burn through the summer under dry monsoon conditions and consequently are associated with drought in both the cool and monsoon seasons. Mid-summer (M) fires are most likely to continue burning through the late summer and fall (L or A scars), but only during dry monsoons (e.g., differing fire-scar position distributions of the 1729 dormant fire year compared to the 1745 middle earlywood fire year, Fig. 2 and S2).

4.4 Relationships between persistent drought and fire

Results from the SEA and cluster analysis suggest that a sequence of both wet and dry years in the cool and monsoon seasons lead to large fires. Thus, a short-term drought might be most favorable for fire, while persistent (multi-year) droughts that do not include intervening wet

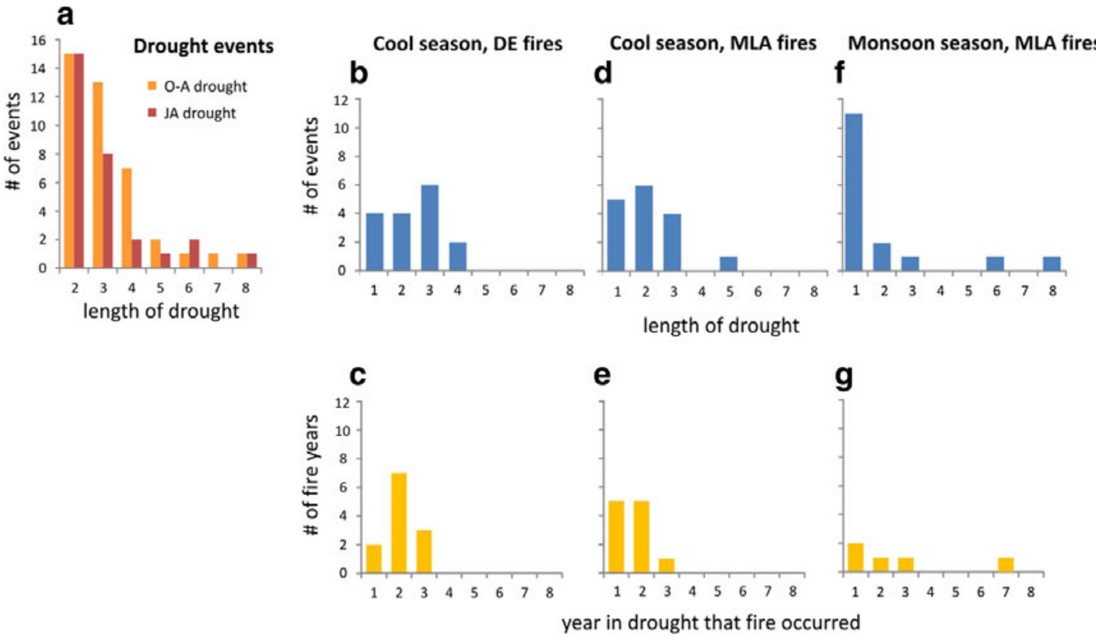

Fig. 4 **a** Numbers and length of droughts (consecutive years of negative SPEI) for October–April (*orange*) and July–August (*brown*) SPEI, 1599–1899. **b**, **d**, and **f** Lengths of the droughts in which the largest fire years occurred, and numbers of fire years corresponding to each drought length for cool season DE fires, cool season MLA fires, and monsoon season MLA fires. **c**, **e**, and **g** The year within the drought in which the fire occurred

conditions could inhibit large fires. The SPEI drought analysis revealed differences in the distributions of drought lengths between the cool and monsoon seasons (Fig. 4a). Single dry years are more common in the monsoon and multi-year droughts occur more frequently in the cool season. There were 25 cool-season droughts of 3 years or more, compared to 14 for the monsoon (Table S3). The longest cool-season droughts lasted up to 8 years. In order to explore the relationship between fire occurrence and drought length, we examined when large fires occurred relative to multi-year cool- and monsoon-season droughts.

Although there are cool-season droughts lasting 5 to 8 years, none of the largest early-season (DE) fires occur during these persistent droughts (Fig. 4). Of the 16 largest early season fire years, ten occurred within a 2- to 3-year cool-season drought, and two within a 4-year cool-season drought (Fig. 4b). The remaining four large early season fire years occurred during single-year cool-season droughts. Within a multi-year cool-season drought, fires only occurred in the first 3 years and primarily in the second year of the drought (Fig. 4c). This result generally supports the SEA, which indicates that conditions most strongly linked to large early-season fires include a wet year 2 or 3 years prior to the fire year, but not the year prior to the fire year.

Relationships between persistent cool-season droughts and the largest mid- to late-season fires (MLA) are similar to the early-season fires. Most of the mid- to late-season fires occur during droughts of 2 or 3 years (Fig. 4d). Almost all large mid- to late-season fires occur in the first 2 years of a cool-season drought (Fig. 4e).

Similarly, persistent monsoon-season drought was not related to large fire occurrence. Only 31% (5 of 16) of the large mid- to late-season fire years occurred during persistent monsoon droughts (Fig. 4f). These monsoon droughts lasted 2 to 8 years. All but one of these large fires occurred within the first 3 years of the persistent drought (Fig. 4g). Results for the monsoon droughts may reflect the fact that, compared to the cool season, monsoon droughts are more likely to occur as single years (Fig. 4a).

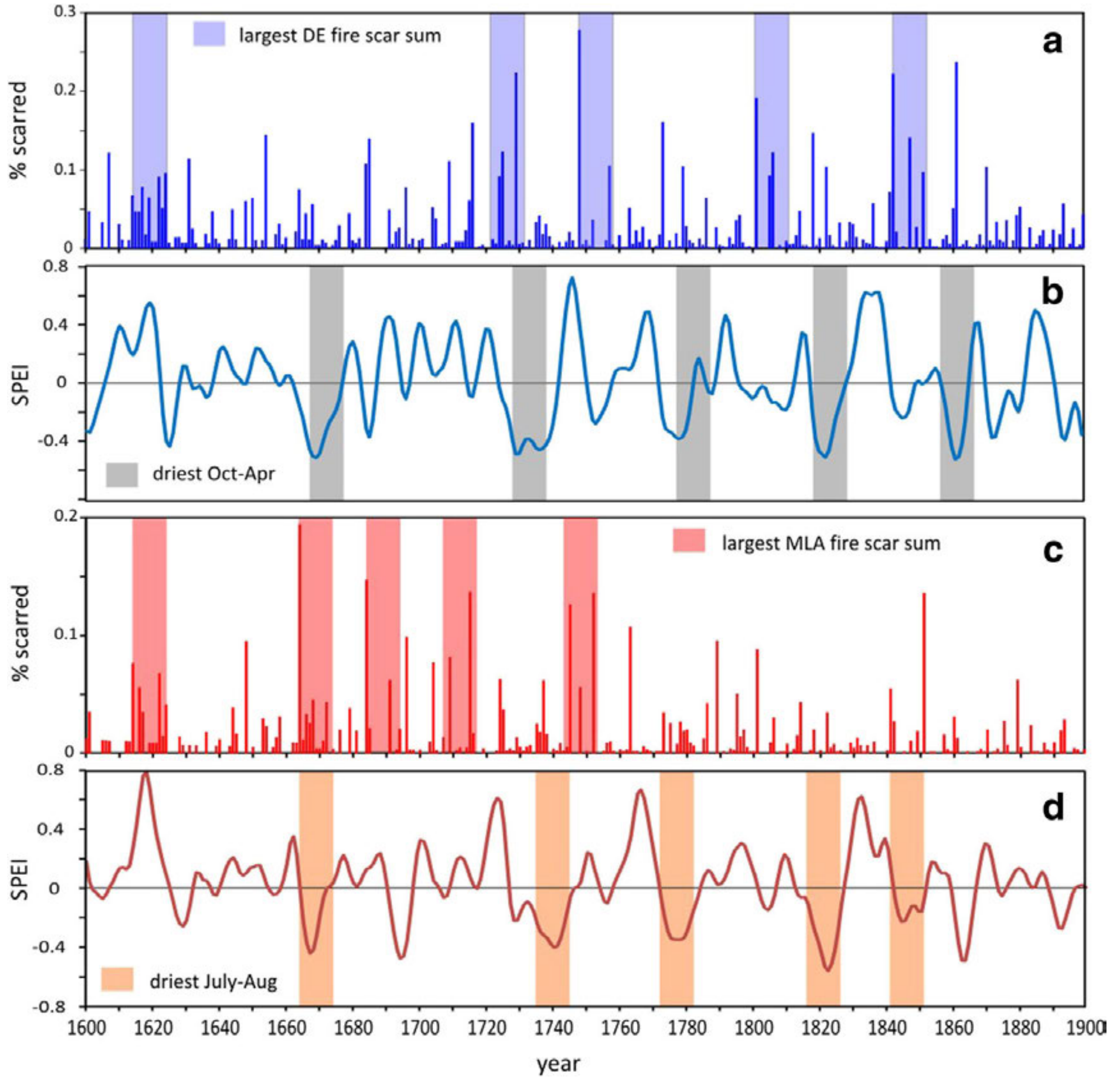

Fig. 5 **a** Percent of recording trees scarred by early-season (DE) fires in *dark blue bars*. *Light blue vertical bars* are the five non-overlapping decades with the largest sums of percent DE scarred trees. **b** October–April SPEI smoothed with a 10-year spline; *vertical bars* are the five non-overlapping decades with the lowest SPEI values. **c** Percent of recording trees scarred by mid- to late-season (MLA) fires in *dark red bars*. *Light red vertical bars* are the five non-overlapping decades with the largest sums of percent MLA scarred trees. **d** July–August SPEI smoothed with a 10-year spline; *vertical bars* are the five non-overlapping decades with the lowest SPEI values

When the driest decades of both SPEI seasons were assessed, they were not consistently related to decades of high fire occurrence. For early season (DE) fires, the five decades with the largest sum of percent trees scarred—periods of widespread fire—had little correspondence with the driest decades of cool-season moisture (Fig. 5a, b). Since both cool- and monsoon-season drought appear to influence mid- to late-season fires (Fig. 3), we compared dry decades for both seasons with high MLA fire decades. These dry periods are distributed across three centuries (Fig. 5b, d), whereas the decades with the largest MLA fire scar sums are concentrated in the first half of the record (Fig. 5c). As with DE fires, there is little correspondence between the decades with the most widespread MLA fires and the driest decades of cool-season SPEI. The one exception is the mid-1660s to mid-1670s (Fig. 5b, c). However, when looking at monsoon moisture, two of the five driest decades do overlap with high mid- to late-season fire scar sums. The mid-1660s is unique, with widespread mid- to late-season fires coinciding with some of the driest decades in both seasons. This period includes the year with the highest percent of trees scarred in the mid-to-late fire season, 1664.

5 Discussion

5.1 Multi-seasonal climate associated with large fire years

The largest early-season fires tend to occur when wet cool seasons are followed by cool-season drought. Years without fires occur after wet cool seasons, with no influence from climate in prior years. These results emphasize the historical importance of cool-season moisture for promoting conditions conducive to large fires in the dry conifer forests of the Jemez (Touchan et al. 1996), the southwestern USA (Swetnam and Betancourt 1998), and the western USA (Swetnam et al. 2016). Modern studies confirm the importance of cool-season wet-dry oscillations in the cool season for fire occurrence across the western USA, but highlight regional differences. Cool-season drought is an important predictor of twentieth century area burned in northern or mountainous ecoprovinces across the western USA, whereas wet cool seasons in prior years are also important in drier ecoprovinces (Westerling et al. 2003; Littell et al. 2009).

Our results are the first documented effects of the NAM on fire occurrence prior to the twentieth century. Monsoon moisture has the greatest effect on mid- to late-season (M, L, and A) fires. The monsoon must be dry for these mid- to late-summer and fall fires to be widespread, as hypothesized by Grissino-Mayer and Swetnam (2000). Large late-season fires may also depend on cool-season conditions, such that dual-season drought preceded by dual-season wet conditions are important for large late-season fire occurrence. Modern studies indicate that prior-year NAM moisture was associated with fires in Arizona and the Great Basin (Westerling et al. 2003; Crimmins and Comrie 2004; Littell et al. 2009). In these studies, wet summers 1 and 2 years prior to the fire likely increased fine fuels, such as grasses, that were important for fire spread.

The intra-annual distribution of fire seasonality derived from tree-ring fire scars provides additional insights into the effects of the monsoon on fire seasonality. The largest early-season fires appear to burn until the onset of the monsoon (Fig. 2 and S2). This is consistent with modern fires in the region, many of which are extinguished by monsoon moisture. Historically, many of the largest late summer and fall fires appear to have occurred when dry monsoons allowed relatively small early-season fires to continue to burn into the summer and fall. This is indicated by all of the largest late summer and fall fires having some proportion of trees scarred in the early (DE) fire seasons (see distribution of fire scar positions for large latewood fires in Fig. 2 and S2). It is also possible that some large late-season fires may have ignited during a dry monsoon season. Multiple ignitions over the fire season could confound these interpretations.

5.2 Persistent drought and fire

Analysis of cool- and monsoon-season droughts and fire occurrence indicates that, overall, fires most often occur during the first or second year of multi-year droughts. Long droughts do not appear to promote large fires in the later years of the drought. The occurrence of all but one large fire in the first 3 years of a drought is not surprising (Fig. 4c, e, and g), but reinforces the importance of short droughts for fires in the region. This is further supported by the sequence of climate conditions leading to fires, which include a wet cool season several years prior to the fire. Because of the key role of wet cool seasons 2 and 3 years prior to a large fire year, and to a lesser degree in the monsoon season, prolonged drought may actually limit the occurrence of large fires in dry conifer forests. Once these dry forests burn, they need moisture to replenish surface fuels before the area can burn again.

The decades with the driest cool seasons were not consistently related to periods of high fire occurrence. These dry decades do not provide the necessary periodic wet conditions that precede the biggest fire years. Fitch and Meyer (2016) also found that extended dry periods in the Jemez Mountains, going back multiple millennia, did not necessarily correspond with increased fire activity, likely due to fuel limitations. While extremely dry winters are a necessary component for the most widespread fires, regardless of fire seasonality, if dry conditions persist beyond several years, the chances of widespread fire likely diminish. This result of persistent drought reducing fire occurrence in a fuel-limited ecosystem supports observations of the importance of biomass variability for modeling fire regimes globally and their response to climate change (Krawchuk et al. 2009).

Overall, these results suggest that the strongest climatic controls over fire regimes in the Jemez Mountains were seasonal and inter-annual to sub-decadal in scale. Decadal fire-climate relations were generally weak. This suggests that fine fuel biomass production (grasses, tree needles, and cones), which can respond to these short time-scale variations in climate, was likely the most important mechanism of climatic influence. It is probably not coincidental that the El Niño-Southern Oscillation (the key synoptic climate control over wet-dry oscillations in the southwestern USA), the phenological cycle of ponderosa pine (*Pinus ponderosa*) needle and cone production, and the frequency of surface fires, all typically occur over time scales of about 2 to 7 years (Maguire 1956; Swetnam and Betancourt 1990). That is, natural wet-dry oscillations might readily entrain inherent (and evolved) vegetative and reproductive cycles of flammable fuel production, which in turn promote synchronized, extensive surface fires.

5.3 Insights from the past for future fire regimes

Projecting fire response to climate change in semi-arid, biomass-limited regions is challenging, and future fire regimes will likely vary temporally in accordance with biomass availability. Climate-driven changes in vegetation will further confound forecasts of future fire regimes. Williams et al. (2015) suggest that future increased drought and moisture stress will increase fire occurrence in the southwestern USA, until fuel becomes limiting. Our results suggest that in the semi-arid southwestern USA, fuel was historically limiting in dry conifer forests and that persistent cool-season drought actually reduced fire occurrence. This differs from wetter, more productive mixed-conifer, aspen, and spruce-fir forests that are not fuel limited and where prior wet years are not associated with fire occurrence, only severe drought during the fire year (Swetnam and Betancourt 1998; Margolis and Swetnam 2013). Fine and heavy fuel loads in dry conifer forests have increased significantly over the last century due to fire exclusion (Fulé et al. 1997), although mega-fires in recent decades are beginning to reduce these overabundant fuels in portions of the landscape (Stephens et al. 2014). As warming continues to increase drought stress and increase large fire occurrence, some of the drier ecosystems in the region may move back toward being fuel-limited, with consequences for forecasting future fire regimes.

A major uncertainty for future fire regimes in fuel-limited systems is future moisture variability. Forecasting future precipitation is particularly complex in the southwestern USA, because of the two seasons of moisture. Projected extended drying in the region, due to reduced cool-season moisture (e.g., Seager and Vecchi 2010) would likely continue to increase fire occurrence in coming decades. However, as biomass becomes limiting, fire occurrence could ultimately decrease in dry forests and woodlands where fine-fuels are important for fire spread. A transition to a shortened or a weak NAM (e.g., Cook and Seager 2013) could extend the fire season in the southwestern USA through the summer and into the fall, which is currently rare, but consistent with the tree-ring record. Failed monsoons could represent the scenario with the greatest fire occurrence in the near term, before moisture stress from increased temperature supersedes any potential increases in precipitation (e.g., Williams et al. 2013), and biomass becomes increasingly limiting to fire occurrence.

6 Conclusions

We present the first in-depth, landscape-scale analysis of historical multi-seasonal climatic controls of fire size and seasonality using tree rings. Our findings suggest different seasonal climate controls on early season and mid- to late-season fires, but in both cases, sequences of wet and dry conditions are critical for preconditioning forests to burn. Dry conditions in the year of the fire—dry in the cool season for early-season fires, and dry in the monsoon season for late-season fires—are critical. Equally important are wet conditions, particularly in the cool season, 2 to 3 years preceding the fire year. The importance of this sequence of wet and dry years has key implications for relationships between fire activity and drought, and our results indicate persistent drought is not associated with the largest fires or periods of high fire activity in this region.

Our results suggest that as moisture stress increases in the southwestern USA due to warming (Seager et al. 2007; Williams et al. 2013), large fire occurrence may decrease in some fuel-limited ecosystems. Many model projections of global fire response to climate change use multi-decadal climate "normals" and lack inter-annual or intra-annual climate variability (e.g., Krawchuk et al. 2009; Moritz et al. 2012). We demonstrate that inter- and intra-annual climate variability is an important control for large fire occurrence and fire seasonality in a semi-arid, monsoon-affected region of southwestern North America. Accurate projections of inter- and intra-annual moisture variability will likely be important to accurately model future fire in the southwestern USA, particularly due to the bimodal precipitation regime and a likely future increase in biomass limitations on fire occurrence (i.e., requiring wet conditions to produce fuels to burn). In the future, in semi-arid regions such as the southwestern USA, prolonged droughts driven by warming could decrease fire activity due to biomass limitations.

ABSTRACT

The recent occurrence of large fires with a substantial stand-replacing component in the southwestern United States (e.g., Cerro Grande, 2000; Rodeo-Chedeski, 2002; Aspen, 2003; Horseshoe 2, Las Conchas, and Wallow, 2011) has raised questions about the historical role of stand-replacing fire in the region. We reconstructed fire dates and stand-replacing fire patch sizes using four lines of tree-ring evidence at four upper montane forest sites (>2600 m) in the Madrean Sky Islands and Mogollon Plateau of Arizona and New Mexico, USA. The four lines of tree-ring evidence include: (1) quaking aspen (*Populus tremuloides*) and spruce-fir age structure, (2) conifer death dates, (3) traumatic resin ducts and ring-width changes, and (4) conifer fire scars. Pre-1905 fire regimes in the upper montane forest sites were variable, with drier, south-facing portions of some sites recording frequent, low-severity fire (mean fire interval of all fires ranging from 5 yr to 11 yr among sites), others burning with stand-replacing severity, and others with no evidence of fire for >300 yr. Reconstructed fires at three of the four sites (Pinaleño Mountains, San Francisco Peaks, and Gila Wilderness) had stand-replacing fire patches >200 ha, with maximum patch sizes ranging from 286 ha in mixed conifer-aspen forests to 521 ha in spruce-fir forests. These data suggest that recent stand-replacing fire patches as large as 200 ha to 500 ha burning in upper elevation (>2600 m) mixed conifer-aspen and spruce-fir forests may be within the historical range of variability.

Keywords: fire history, mixed conifer, quaking aspen, spruce-fir, tree ring

INTRODUCTION

The number and duration of large fires in the western United States has increased in recent decades due in part to increasing temperatures (Westerling *et al.* 2006). In the southwestern US (Arizona, New Mexico, and proximate areas), many of the recent large fires included large (100 ha to >1000 ha) high-severity fire patches, which raises questions about the historical role of stand-replacing fire in the region. Many of the recent stand-replacing fire patches in the southwestern US have occurred in the overstocked, mid-elevation ponderosa pine (*Pinus ponderosa* C. Lawson) and dry mixed conifer forests, where extensive stand-replacing fires are unreported in the documentary records prior to *circa* 1950 (Cooper 1960, Allen *et al.* 2002). However, in the upper elevation (>2600 m) mixed conifer-aspen and spruce-fir forests, historical photographs and tree-ring data from seral quaking aspen (*Populus tremuloides* Michx.) stands provide direct evidence that fires with large (100 ha to >1000 ha) stand-replacing patches occurred in parts of the region as recently as the early twentieth century (Abolt 1997, Romme *et al.* 2001, Margolis *et al.* 2007).

Relatively little is known about pre-EuroAmerican settlement fire regimes (size, severity, frequency, and seasonality) of upper elevation forests in the southwestern US (Grissino-Mayer *et al.* 1995, Fulé *et al.* 2003, Margolis *et al.* 2007, Margolis and Balmat 2009). Extensive fire histories from upper montane and subalpine forests of southern Wyoming, Colorado, and northern New Mexico indicate that infrequent (>100 yr intervals) stand-replacing fire is a dominant disturbance in upper elevation forests of the southern Rocky Mountains (Kipfmueller and Baker 2000, Sibold *et al.* 2006, Margolis *et al.* 2007). Thus, it is logical to hypothesize that upper elevation mixed conifer-aspen and spruce-fir forests of the southwestern US outside of the southern Rocky Mountains potentially had a historical fire regime that included infrequent, relatively large (>100 ha) patches of stand-replacing fire.

Reconstructing Stand-Replacing Fire

Age-structure-based methods for reconstructing fire history were developed in coniferous subalpine and boreal forests of North America where stand-replacing fire regimes are dominant (Clements 1910, Heinselman 1973, Agee 1993, Johnson and Gutsell 1994). By definition, stand-replacing fires leave few or no surviving trees to record direct evidence of those fires within the highest burn severity patches (but note that fire-scarred survivors can sometimes be found on the edges of such patches; e.g., Margolis *et al.* 2007). Post-fire tree cohorts, assumed to have established soon after the fire, are the most common type of evidence used to date and map stand-replacing burns. In the Rocky Mountains, the assumption that there is typically rapid recruitment of a post-fire cohort (i.e., <5 yr) within stand-replacing burn patches is well supported in the case of quaking aspen, because it has evolved mechanisms for rapid regeneration, and has been commonly observed to do so following fires (Clements 1910, Patton and Avant 1970). Post-fire cohort evidence (dates and mapped perimeters) can be combined with the relatively rare direct conifer evidence of fire (e.g., fire scars, tree death dates, ring-width changes or traumatic resin ducts) to reconstruct annually resolved stand-replacing fire dates (Johnson and Gutsell 1994, Margolis *et al.* 2007).

In the current study, we separate the upper elevation forest into mixed conifer-aspen (2600 m to 3100 m) and spruce-fir (>3100 m) because of differing fire ecology, and potentially different fire regimes and use of differing fire history methods. Age-structure-based fire history methods in mixed conifer-aspen forests have been applied in a few studies in the southwestern US, primarily focusing on quaking aspen regeneration dates as a proxy for stand-replacing fire (Abolt 1997, Romme *et al.* 2001, Margolis *et al.* 2007). Romme *et al.* (2001) reconstructed a 140-year stand-replacing fire rotation period from aspen stand age in the La Plata Mountains of southwestern Colorado. They noted that the lack of fire-scarred trees in aspen stands was a limitation to dating past fires. Abolt (1997) used coincident aspen pith dates and conifer fire scars from lower elevations to date stand-replacing fire patches in mixed conifer forests of the Mogollon Mountains of southwestern New Mexico. Margolis *et al.* (2007) combined four lines of tree-ring evidence (aspen age structure, conifer fire scars, conifer death dates, and conifer injury dates) to reconstruct synchronous, drought-related stand-replacing fire dates and patch sizes from aspen stands embedded in upper montane mixed conifer and spruce-fir forests at a network of twelve sites in the upper Rio Grande Basin (New Mexico and Colorado). These studies indicate that, because of the unique fire ecology of quaking aspen (i.e., high sensitivity to being killed by fire and ability to re-sprout), the age structure from seral aspen stands is a potential indicator of historical stand-replacing fire in upper elevation forests in the southwestern US.

Fewer studies have evaluated the effectiveness of age-structure-based fire history methods in southwestern US spruce-fir forests. In the Pinaleño Mountains, Arizona, Grissino-Mayer *et al.* (1995) used intensive, but spatially limited, age structure sampling in spruce-fir forests, combined with lower elevation fire scars, to hypothesize that the spruce-fir zone regenerated following a stand-replacing fire. Due to limited spatial coverage of the sampling, stand-replacing fire area was not estimated. Fulé *et al.* (2003) used fire scars, tree age and species, and spatial patterns of forest stands to reconstruct fire-initiated tree groups at the plot scale (20 m × 50 m), which likely originated after severe eighteenth century fires in high-elevation forests (including aspen and spruce-fir) on the north rim of the Grand Canyon, Arizona. They were not able to identify distinct fire-created stands in the study area from aerial photos or satellite data, which differs from the stand-replacing fire history methods used in the Rocky Mountains. In the Santa Fe Watershed, New Mexico, Margolis and Balmat (2009) combined a systematic spatial grid sampling of spruce-fir age structure with conifer ring-width growth changes and conifer fire scars to conclude that approximately 90 % of the spruce-fir zone (1200 ha) regenerated following stand-replacing fire. These studies provide evidence of past stand-replacing fires in spruce-fir forests in the southwestern US, but leave questions about patch sizes, variability between sites, and the ability to apply fire history methods from other regions and forest types.

Fire Patch Size and Severity

Fire patch size and severity have strong influences on the ecological effects of fire on terrestrial and aquatic systems. Stand-replacing fire patch size is a key determinant of post-fire vegetation composition and structure (Agee 1993, Turner *et al.* 1994, Turner and Romme 1994). Following the extensive (>250 000 ha) fires in Yellowstone National Park, Wyoming, in 1988, the size and severity of burn patches were shown to affect overall plant cover, tree seedling recruitment, and herbaceous recruitment (Turner *et al.* 1994). High-severity fires remove overstory vegetation and ground cover that dramatically affects watersheds and water resources by altering the important processes of evapotranspiration, interception, surface flow, and subsurface flow (Swanson 1981). The size of high-severity fire patches is important in determining the probability of fire-induced flooding or debris flows (Pearthree and Wohl 1991, Cannon and Reneau 2000). Recent, large stand-replacing fires in the southwestern US have produced runoff and erosion events as much as two orders of magnitude greater than pre-fire conditions (Veenhuis 2002).

High-severity (stand-replacing) fire patches are usually part of a "mosaic" of burn severities, within fire perimeters that include moderate- and low-severity surface fire patches, as well as unburned patches (Turner and Romme 1994). For example, less than half of the 1988 Yellowstone fires burned with high severity (Turner *et al.* 1994). Reconstructing the complex spatial patterns and wide range of burn severities of pre-twentieth century fires at high resolution (i.e., less than a few hectares) is not possible. However, the largest stand-replacing fire patches often leave a persistent and identifiable legacy in the form of tree ages and, less commonly, as conifer death dates, conifer fire scars, and tree-ring growth patterns in conifers injured by the fire. From these legacies, stand-replacing fire patch sizes and dates can be reconstructed and compared with recent fires even if overall size (extent) of the entire fire is unknown.

Research Objectives

Our primary objective was to use dendroecological methods to expand the upper elevation stand-replacing fire history network of Margolis *et al.* (2007) to four new sites in mixed conifer-aspen forests (2600 m to 3100 m elevation) in the Mogollon Plateau and Madrean Sky Island regions of the southwestern US, focusing on quaking aspen as a potential indicator of the dating and patch size of past stand-replacing fires. The secondary objective was to test the utility of using spruce-fir forest age structure to expand the reconstruction of stand-replacing fires above the local elevation range of quaking aspen (>3100 m) at two test sites. We did not attempt to reconstruct a complete inventory of all historical stand-replacing fire patches at these four sites; rather, we mapped and dated the largest and potentially most ecologically significant patches.

METHODS

Study Area

To expand the existing southwestern US network of upper elevation stand-replacing fire history sites of Margolis *et al.* (2007) beyond the upper Rio Grande Basin, we selected two sites on the Mogollon Plateau and two sites from the Madrean Sky Islands (Figure 1, Table 1). The sites were selected based on the presence of the largest seral aspen stands, which potentially represented historical stand-replacing fire patches. We used the regional gap analysis program vegetation map, USDA National Forest vegetation maps, black and white and color infrared digital ortho-rectified quarter-quadrangle photographs (DOQQs) and field surveys to map and verify the largest aspen patches on the Mogollon Plateau and Madrean Sky Islands on US Forest Service land. We set the minimum aspen patch size threshold at 5 ha to eliminate smaller patches. We targeted seral aspen stands embedded within conifers to eliminate self-replacing aspen and aspen within high-elevation parklands that likely experienced frequent surface fires (Jones and DeByle 1985).

The largest potential post-stand-replacing fire aspen patches on the Mogollon Plateau were in the San Francisco Peaks (SFP) and the Mogollon Mountains (Gila Wilderness, GIL; Table 1 and Figure 2). On the Mogollon Plateau, we chose GIL as our test site for age-structure-based fire history methods in spruce-fir (>3100 m) because the patches were smaller than at SFP and required less sampling. In the Sky Islands, the Chiricahua Mountains (CHI) and the Pinaleño Mountains (PIN) had the largest potential historical post-stand-replacing fire aspen patches (Figure 2). At PIN, aspen was not present in homogeneous patches; rather, aspen stems were scattered throughout the mixed conifer forest, potentially representing older stand-replacing fire patches that had infilled with conifers. The PIN contains the only spruce-fir forest in the Sky Islands, which we used as the second test site for spruce-fir fire history methods.

Mean elevation of the study sites was 2982 m and tree-ring samples were collected between 2694 m and 3257 m (Table 1). All sites are managed as US Forest Service wilderness areas except PIN, which is closed to the public to protect the endangered Mount Graham red squirrel (*Tamiasciurus hudsonicus grahamensis*). We did not see evidence of logging (e.g.,

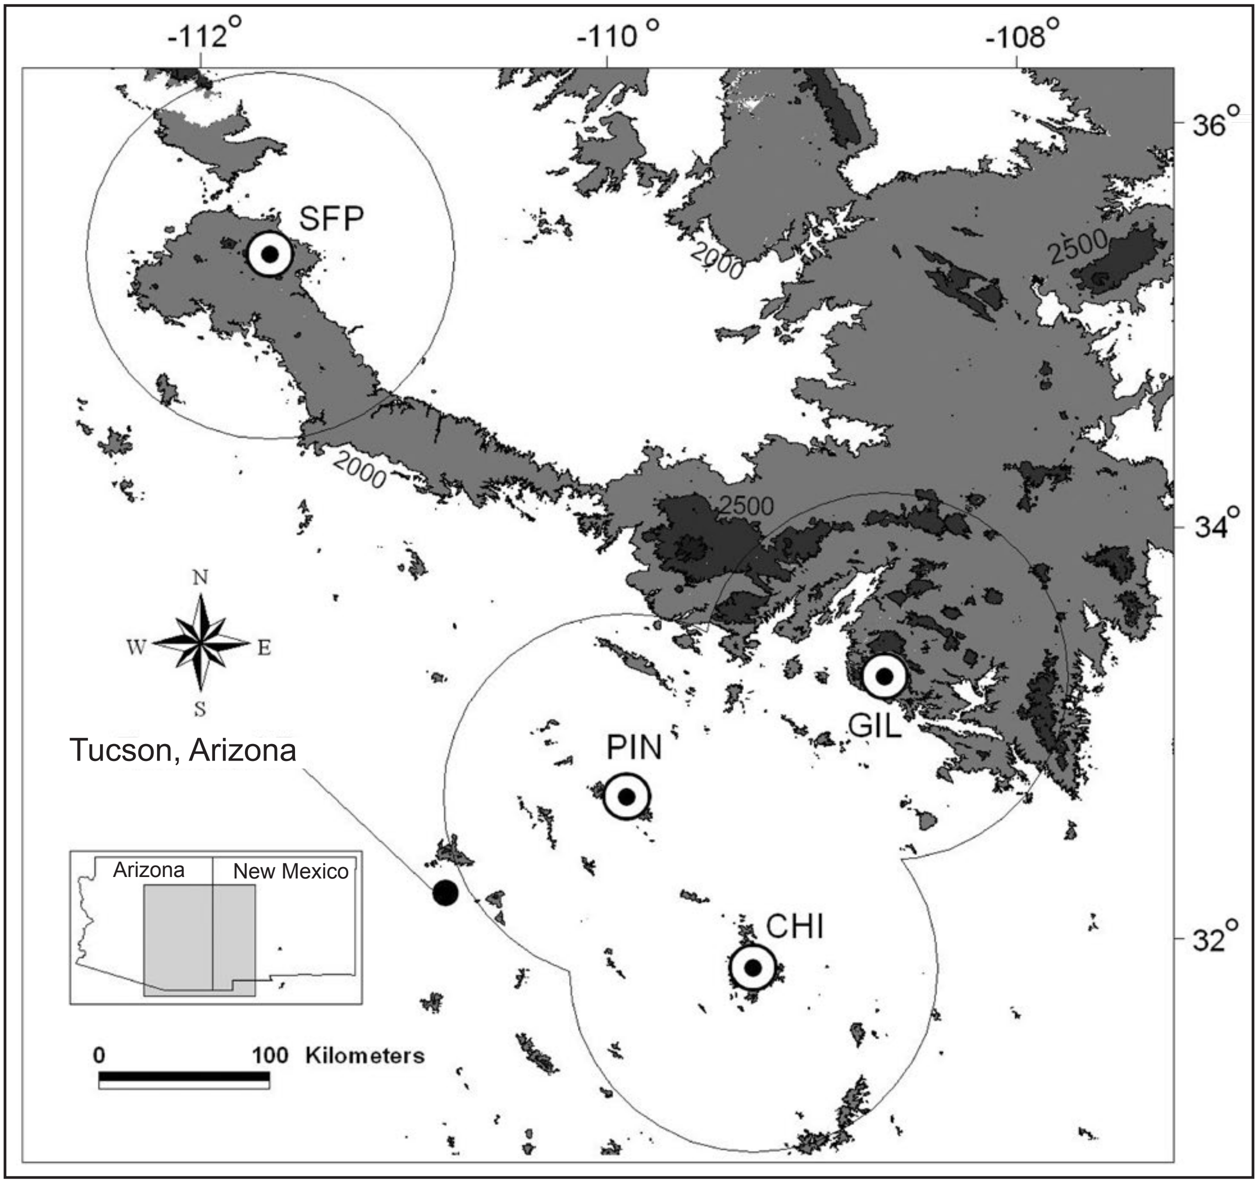

Figure 1. Map of site locations (e.g., SFP) in the Mogollon Plateau and the Madrean Sky Islands of Arizona and New Mexico, USA. Shading indicates major topographic features >2000 m in elevation at 500 m intervals. Large circles indicate the 100 km search radius around the fire history sites used to select recent fires (1984 to 2008) to quantify the size of recent stand-replacing fire patches.

Table 1. Site information for four upper elevation fire history sites from the Mogollon Plateau and Madrean Sky Islands, USA.

Site ID	Site name	Vegetation type[a]	Sampled aspen area (ha)	Sampled spruce-fir area (ha)[b]	Number of plots	Mean sample elevation (m)
CHI	Chiricahua Mountains	MC/S	139	--	26	2856
GIL	Mogollon Mountains	MC/SF	744	1639	32	3060
PIN	Pinaleño Mountains	MC/SF	0*	521	33	3057
SFP	San Francisco Peaks	MC/SF	990	--	25	2954

[a] MC = mixed conifer-aspen, SF = spruce-fir, S = spruce
[b] Spruce-fir was only mapped and sampled at two test sites (GIL and PIN).
* Distinctive seral aspen patches greater than 5 ha were not present.

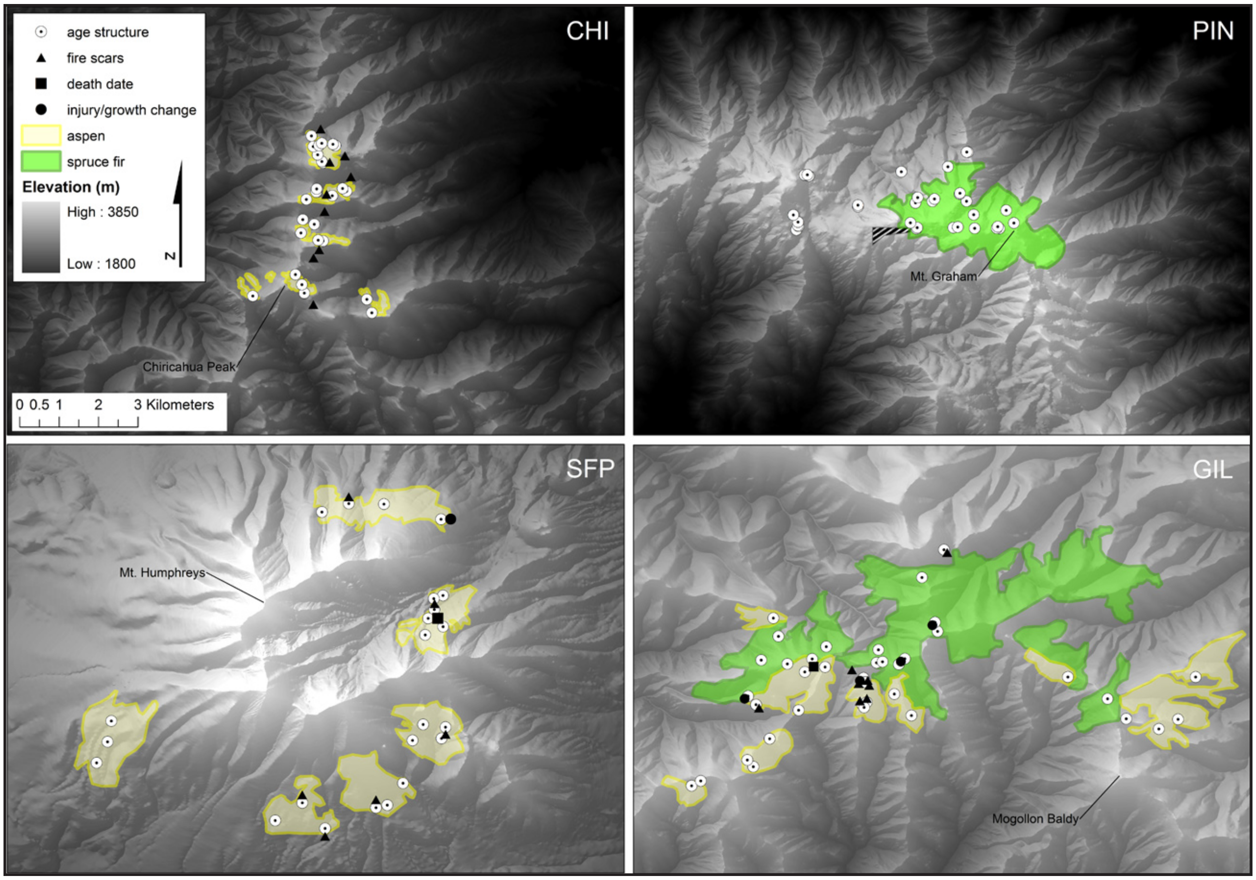

Figure 2. Tree-ring sample locations and analyzed aspen and spruce-fir stands at the study sites in the Chiricahua Mountains (CHI), Pinaleño Mountains (PIN), San Francisco Peaks (SFP), and Gila Wilderness (GIL) of the Mogollon Mountains. Hatched polygon at PIN indicates fire scar sample area from Grissino-Mayer *et al.* (1995).

stumps or skid trails) within the sampled stands. Fire exclusion resulting from late nineteenth century grazing followed by twentieth century fire suppression occurred at all sites, similar to most montane forests in the southwestern US (Dieterich 1980, Bahre 1985, Swetnam and Baisan 1996, Allen *et al.* 2002).

The general climate of the study area is continental with a bimodal precipitation regime. All sites receive an average of 40% to 50% of annual precipitation from summer (July to September) monsoon convective thunderstorms (1910 to 2009; http://www.prism.oregonstate.edu/). Average annual precipitation was similar amongst sites, ranging from 800 mm to 950 mm. Average annual maximum temperature ranged from 12.5 °C to 17 °C and minimum temperature ranged from 0° C to –4.5° C (1910 to 2009; http://www.prism.oregonstate.edu/). All sites receive winter snow, but snowpack varies widely from year to year depending on the winter storm track. The majority of area that burns in the study area occurs during a consistently dry and warm pre-monsoon period that begins in April or May and lasts through June (Barrows 1978). The potential severity and length of the fire season in the high-elevation forests of the region is largely a function of the snowpack and residual moisture that persists into the early summer pre-monsoon period.

The sampled seral quaking aspen stands at all four sites were located adjacent to mixed conifer or spruce-fir forests. The following conifer tree species were observed within and adjacent to the aspen stands, listed in descending order of occurrence: Engelmann spruce (*Picea engelmannii* Parry ex Engelm.), Douglas-fir (*Pseudotsuga menziesii* [Mirb.] Franco), southwestern white pine (*Pinus strobiformis* Engelm.), white fir (*Abies concolor* [Gord. & Glend.] Lindl. Ex Hildebr.), subalpine fir (*Abies lasiocarpa* [Hook.] Nutt.), ponderosa pine, and Rocky Mountain bristlecone pine (*Pinus aristata* Engelm.).

Although all sites contained quaking aspen, there were differences between and within sites. Aspen patches in the two Sky Island sites were smaller than on the Mogollon Plateau (Table 1, Figure 2). This pattern can be partially explained by less land area in the aspen zone (2600 m to 3100 m) at the Sky Island sites (2927 ha in CHI, and 5945 ha in PIN) compared to Mogollon sites (7088 ha in SFP, and 7645 ha in GIL). Within-site differences in vegetation that could affect fire regimes were driven by aspect, with south-facing slopes containing drier, more open forests, and north-facing slopes generally supporting more mesic, denser forests.

Stand-Replacing Fire History Methods—Mixed Conifer-Aspen Forest

Our general sampling methods follow Margolis *et al.* (2007), in which large quaking aspen patches embedded in mesic mixed conifer and spruce-fir forests of the upper Rio Grande Basin were mapped and tree-ring dated with multiple lines of evidence to reconstruct stand-replacing fire patch sizes and dates. The four lines of evidence included 1) quaking aspen age structure, 2) conifer death dates, 3) conifer traumatic resin ducts or ring-width changes, and 4) conifer fire scars. All conifer death dates were bark-ring dates. Bark-ring dates indicate that either bark or other evidence of an intact outer ring (e.g., insect galleries) was present on the samples—this ensures that the outer ring dates are actual tree death dates.

Age structure plots were randomly located within each mapped aspen patch at a minimum density of three to four plots per 100 ha (e.g., SFP in Figure 2). Aspen patches were visually surveyed in the field to ensure plot locations were representative of the stand. Additional plots were added in the field at locations with conifer evidence of fire to verify stand boundaries, or to age potentially older trees (fire survivors) indicated by anomalously large diameter.

Aspen age structure plots had a 10 m fixed radius. Within the plots, we cored the two aspen stems with the greatest diameter at breast height (dbh). Trees were cored at <0.3 m core height until the pith was present in one sample at the plot. In a post-stand-replacing fire aspen stand, sampling two stems per plots at multiple plots within a patch has been shown to be sufficient to determine stand age (Margolis *et al.* 2007). This is because of the immediate asexual regeneration response of aspen following aboveground stem mortality, which creates a distinct recruitment pulse and a single-tiered, even-aged stand (Barnes 1966, Patton and Avant 1970). In upper montane seral aspen stands, subsequent regeneration is relatively rare and the dominant post-fire cohort is easily identified as the stems with largest dbh (Margolis *et al.* 2007). A more intensive sampling design would be necessary to fully describe a multi-cohort age structure, but this was not our goal. Post-fire quaking aspen regeneration can grow up to 1 m in the first year of growth (Jones 1975); thus, <0.3 m core height seems adequate to capture the first year of the aspen regeneration pulse (Margolis *et al.* 2007).

We searched within aspen patches and along the patch boundaries for conifers with potential direct evidence of fire (e.g., fire scars, conifer death dates, and ring-width changes and injuries). Cross sections and partial cross sections were collected with handsaws from remnant conifer logs, living trees, and standing dead snags with intact outer rings. Increment cores were collected from potentially injured live conifers without basal scars. Potential evidence of fire injury included char, scars on the undersides of branches, elevated crown base height, and unilateral loss of branches. Fire scars were not collected at PIN due to the existing fire scar collection located within our study site (Grissino-Mayer *et al.* 1995).

All tree-ring samples were prepared and crossdated according to standard dendrochronological procedure (Stokes and Smiley 1968). To estimate the date of the first year of growth (pith) for age structure increment cores that did not contain the pith ring, we used a concentric circle pith estimator (Applequist 1958). Dates from the four lines of tree-ring evidence were plotted together to determine fire dates (from conifer fire scars, death dates, and tree-ring growth changes and injuries) and stand-replacing fire patches (from age structure of aspen patches).

A mapped aspen patch was determined to represent the minimum extent of a previous stand-replacing burn patch if: 1) the oldest aspen estimated pith dates were associated with (≤5 years following) a fire event recorded by conifer death dates from within the patch or fire scars on surviving trees along the periphery of the patch, and 2) estimated aspen pith dates were part of a site-level (i.e., multi-patch) aspen recruitment pulse. The rarity and poor spatial coverage of fire-scarred trees at some sites (e.g., $n = 6$) prevented the use of percent-scarred filters to categorize and compare relatively widespread versus local fires between sites (Swetnam and Baisan 2003). Instead, we categorized fires recorded by ≥5 conifer samples at a site (e.g., conifer death dates, growth changes or traumatic resin ducts, and fire scars) as likely being more widespread than fires recorded by fewer trees.

Testing Fire History Methods in Spruce-Fir Forest

Within our study area, potential post-stand-replacing fire quaking aspen patches were generally found between 2600 m and 3100 m, and forests above 3100 m were generally dominated by spruce and fir. Pure spruce-fir forests with no living aspen stems would not be expected to contain quaking aspen regeneration following fire, so above 3100 m in this region, past stand-replacing fire patch size and dates cannot be estimated using post-fire aspen patches. We tested the utility of age structure fire history methods in spruce-fir forests at two sites, PIN and GIL. These sites were chosen because the relatively small size of the spruce-fir patches was more manageable for testing the efficacy of the methods. Therefore, the extensive spruce-fir stands at SFP were not sampled.

Aerial photographs and field observations were used to map spruce-fir patches and identify differences in texture, density, color, or differences in tree height, potentially representing fire boundaries (Johnson and Larsen 1991, Agee 1993, Johnson and Gutsell 1994). We were not able to identify any evidence of potential fire boundaries (e.g., discrete changes in canopy height) within the spruce-fir stands at PIN or GIL. Therefore, we treated each spruce-fir stand as a single potential stand-replacing fire patch.

In contrast to the predominance of asexual reproduction in aspen, spruce and fir trees recruit from seed, so the initial post-fire cohort can lag behind the fire date and may be distributed over decades (e.g., Antos and Parish 2002). Subsequent cohorts of these shade-tolerant conifers are able to regenerate under the canopy of the initial post-fire cohort. This multiple-aged structure makes the initial post-fire cohort in spruce-fir more difficult to identify with age or size structure data. We collected age structure samples using similar methods for dating aspen patches (see above), but with two differences to account for the differing fire ecology. First, we doubled the number of trees cored at each plot to include the four trees of largest dbh in order to account for the potentially complex age structure. Conifers were cored as low on the bole as possible and angled down to intersect the root crown and capture the earliest years of growth.

The second difference from the aspen age structure methodology was in the criterion to qualify as a stand-replacing fire patch. A spruce-fir patch was determined to be a post-stand-replacing fire patch if the oldest estimated conifer pith dates were ≤10 years following a fire recorded by conifer death dates from within the patch or by fire scars on the periphery of the patch. We increased the cut-off criteria to 10 yr (compared to 5 yr for aspen) to account for potentially lagged seedling recruitment (compared to immediate asexual regeneration in aspen). A 10-year lag window is likely conservative, given reports of greater than 50-year lags for subalpine forest regeneration following stand-replacing fire (Stahelin 1943). Because of relatively high fire frequency recorded by fire scars in some of the mixed conifer forests immediately below the spruce-fir stands, we determined that a 10-year lag would help to avoid spurious matches between fire scar dates and age structure that could be interpreted as stand-replacing fire dates. All tree-ring samples were collected in 2003 and 2004.

Historical Stand-Replacing Fire Patch Size

The aspen and spruce-fir patches that were dated to historical stand-replacing fires were used to derive minimum estimates of historical stand-replacing fire patch sizes. Patch area was calculated with a geographic information system (GIS). This data set provides the first estimate of historical stand-replacing burn patch sizes within two elevation and vegetation ranges at our study sites, including: 1) the aspen zone (2600 m to 3100 m) and 2) the spruce-fir zone (>3100 m).

RESULTS

Tree-ring dates from 178 aspen stems and 139 conifers were used to reconstruct upper montane fire history, including stand-replacing fire patch dates and sizes (Tables 2 and 3, Figures 3-6). Annually dated, direct conifer evidence of fire (e.g., fire scars and tree death dates) was used to reconstruct 77 new fires in addition to the existing fire dates (from Grissino-Mayer *et al.* 1995) for PIN. Across the four sites, 100 fires occurring on 87 unique fire dates were analyzed (1623 to 1904; Table 3). Twenty five percent of the fires (n = 25) were recorded by ≥5 conifers (including fire scars) at a site. An average of 59% of all sampled aspen regenerated within five years after fire, ranging from 27% to 89% among sites. Three fires (1685 in PIN, 1879 in SFP, and 1904 in GIL) met our criteria for stand-replacing fire within mapped aspen or spruce-fir patches (Figures 4-6). Evidence of stand-replacing fire included aspen and conifer recruitment pulses, coincident conifer death and fire scar dates, and a lack of trees that survived (pre-date) the fire.

Table 2. Number of trees with crossdated tree-ring samples used to reconstruct fire history in the Mogollon Plateau and Madrean Sky Islands, USA.

Site ID	Aspen age structure	Conifer age structure	Conifer fire scar	Conifer death date	Conifer growth change or injury	Total
CHI	44	0	26	0	6	76

* Fire scar data from Grissino-Mayer *et al.* 1995 (PIN).

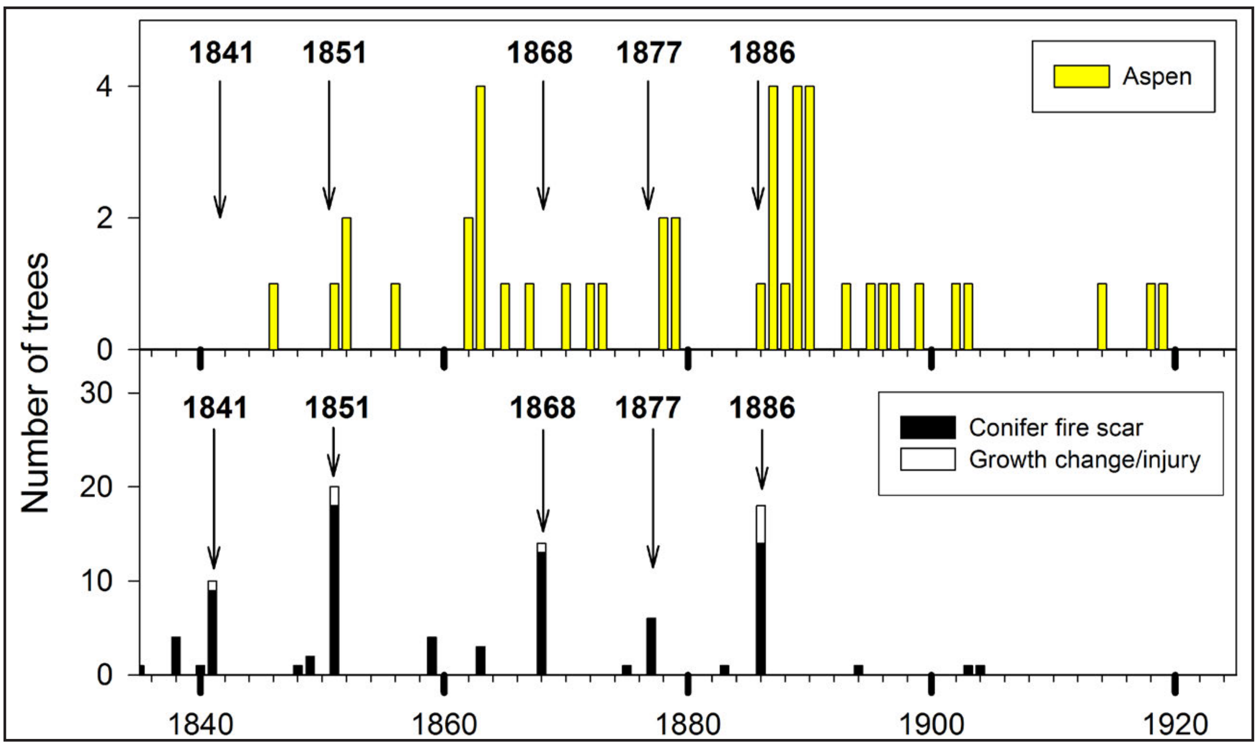

Figure 3. Chiricahua Mountains (CHI) estimated aspen pith dates (top) and direct conifer evidence of fire (bottom) in 1-year classes used to reconstruct fire history in the upper elevation forests. Years (e.g., 1886) indicate annually dated fire events recorded by ≥5 conifer trees, including fire scars.

Chiricahua Mountains

Eight small quaking aspen patches were mapped at CHI, totaling 139 ha (Table 1, Figure 2). No single post-stand-replacing fire quaking aspen cohort was present at CHI, but 89% of the aspen stems regenerated within five years after a fire (Figure 3). Surface fires recorded by conifers on south-facing slopes adjacent to the aspen stands were relatively

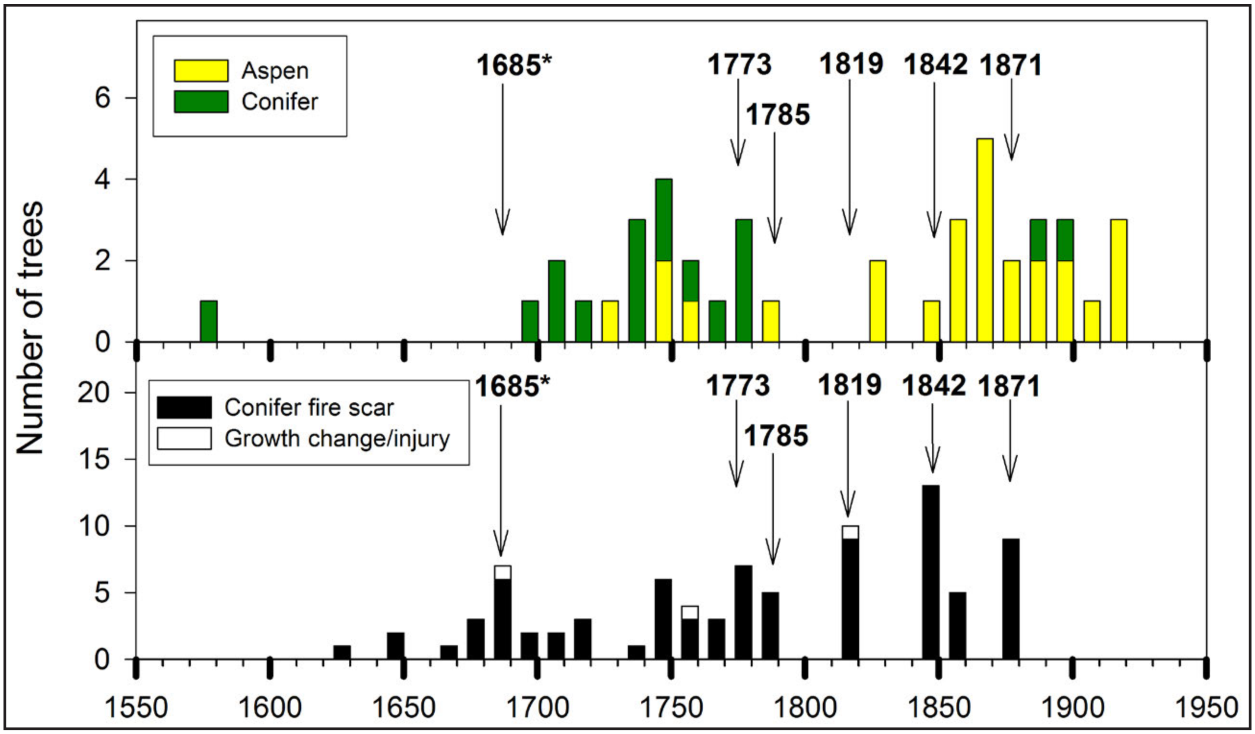

Figure 4. Pinaleño Mountains (PIN) estimated pith dates (top) and direct conifer evidence of fire (bottom) in 10-year classes used to reconstruct fire history in the upper elevation forests. Years (e.g., 1685) indicate annually dated fire events recorded by ≥5 conifer trees, including fire scars. * Indicates stand-replacing fire date. Fire scar data from Grissino-Mayer *et al.* (1995).

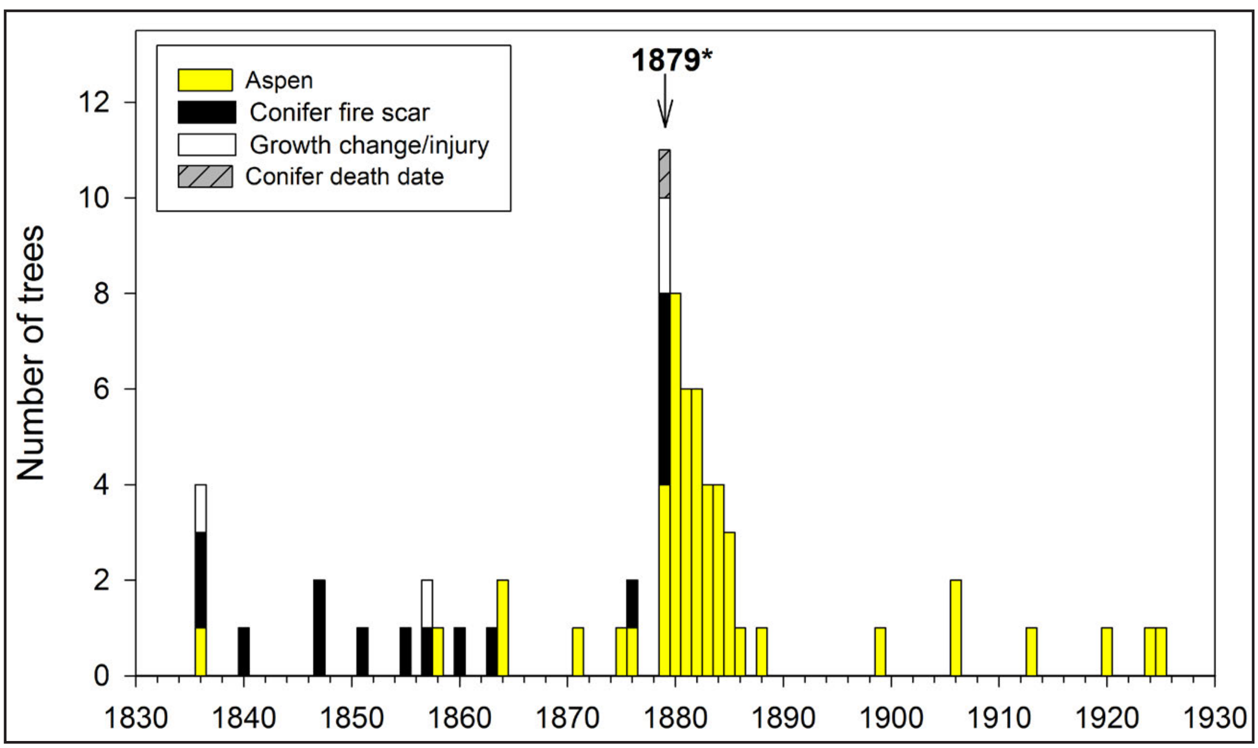

Figure 5. San Francisco Peaks (SFP) estimated aspen pith dates and direct conifer evidence of fire in 1-year classes used to reconstruct fire history in the upper montane forests. Years (e.g., 1879) indicate annually dated fire events recorded by ≥5 conifer trees, including fire scars. * Indicates stand-replacing fire date.

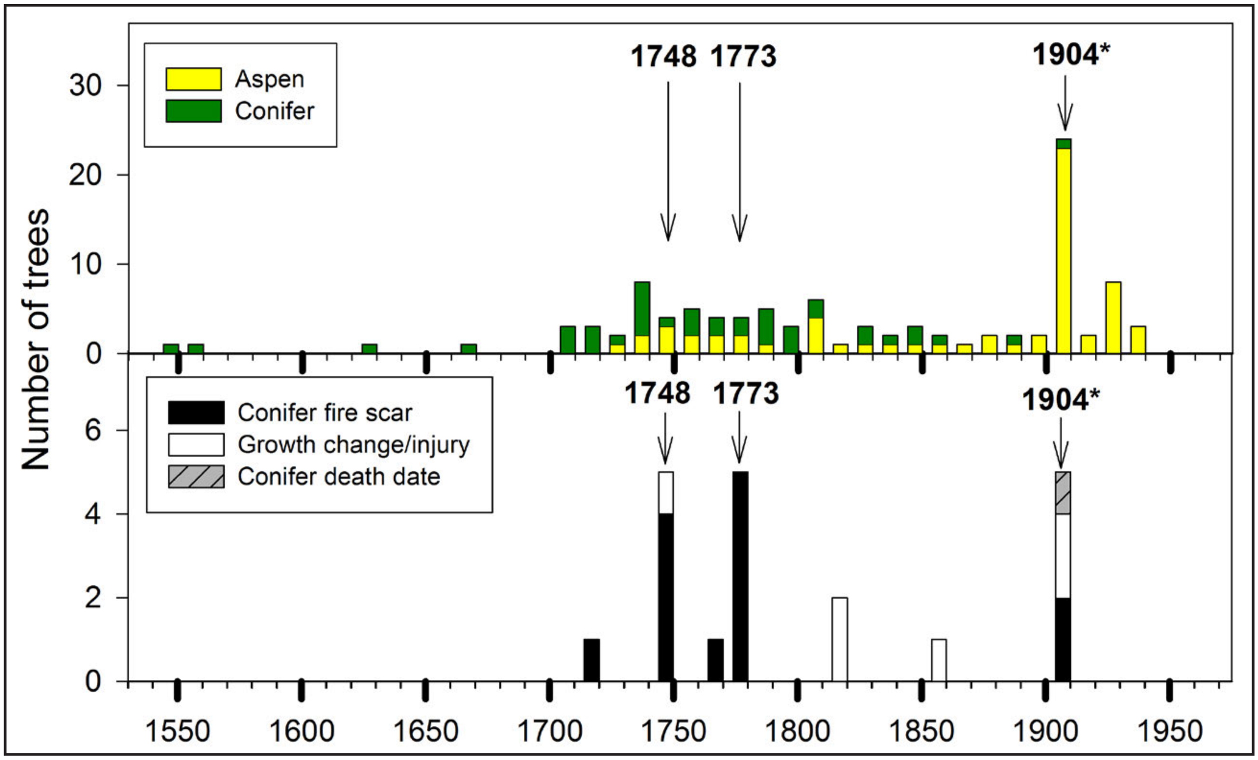

Figure 6. Mogollon Mountains (GIL) estimated pith dates (top) and direct conifer evidence of fire (bottom) in 10-year classes used to reconstruct fire history in the upper montane forests. Years (e.g., 1904) indicate annually dated fire events recorded by ≥5 trees, including fire scars. * Indicates stand-replacing fire dates.

frequent prior to *circa* 1900 (mean fire interval from 1654 to 1904 for all fires was 4.5 yr; Table 3).

The mapped aspen patches at CHI were not post-stand-replacing fire patches based on our criteria. The age structure of the dominant aspen within each patch was multi-aged, with some trees surviving (pre-dating) multiple fire events. For example, aspen from the 1886 post-fire cohort were scattered throughout multiple patches, but were often located adjacent to older aspen stems (e.g., 1851 post-fire regeneration) that survived the 1886 fire.

Pinaleño Mountains

The combined age structure of the multiple, small aspen groups (5 to 10 stems) scattered throughout the mixed conifer forest showed no evidence of a single, widespread, post-fire cohort (Figure 4). Only 27% of the dominant aspen at PIN regenerated within 5 years after a fire. Many aspen pre-dated (survived) fires recorded by multiple conifers as fire scars (e.g., 1871 fire), with the oldest living aspen dating to 1724 (estimated pith date).

Without post-fire aspen cohorts or large contiguous patches of seral, post-fire quaking aspen at PIN, the spruce-fir stand was the best potential evidence of past stand-replacing fire. The oldest tree (Engelmann spruce; 1692 estimated pith date) in the spruce-fir stand regenerated within 10 years after the 1685 fire that scarred all recording trees in the adjacent mixed conifer-aspen zone (Figure 4). The one tree that pre-dated the 1685 fire was a Douglas-fir located on the edge of the spruce-fir zone. These data met our criteria for stand-replacing fire in the spruce-fir zone at PIN in 1685.

San Francisco Peaks

Seventy-one percent of the dominant aspen at SFP regenerated within five years after a fire. Multiple lines of tree-ring evidence indicate that the 1879 fire was stand-replacing in some of the mapped patches (Figure 5). A distinct and immediate aspen recruitment pulse began in 1879, accounting for 63% of the sampled aspen. This site-level aspen age structure, dominated by a single post-fire aspen cohort, was different from the two Sky Island sites that had no dominant aspen cohort (CHI and PIN, Figures 3 and 4). The few aspen at SFP that pre-date 1879 were from the southeastern part of the site where there was no fire-scar evidence of the 1879 fire (Figures 2 and 5). In total, tree-ring evidence of the 1879 fire was present in all but one aspen patch.

The seral, post-stand-replacing fire aspen patches at SFP were located on the north-facing slopes and had the largest mean reconstructed stand-replacing fire patch size of all of the sites (145 ha). The drier, south-facing slopes contained conifers with multiple fire scars within the aspen stands. The ten fires recorded between 1836 and 1879 were all recorded by fire-scarred conifers on the south slope (Figures 2 and 5). This frequent fire regime ($MFI_{All\ fires}$ = 4.8 yr) that scarred, but did not kill, conifers within the south-facing aspen stands differed from the post-stand-replacing fire aspen patches, with no surviving conifers, on the north-facing slopes at SFP.

Mogollon Mountains (Gila Wilderness)

The aspen age structure at GIL was dominated by a post-1904 fire recruitment pulse (Figure 6). No sampled trees from within the mapped aspen patches survived the 1904 fire. These homogenous, even-aged aspen patches contained fire-killed Douglas-fir that died in 1904. Based on this evidence, all mapped aspen patches at GIL (totaling 744 ha) were determined to be stand-replacing fire patches from the 1904 fire. The aspen stems that predated the 1904 fire were located in the spruce-fir stands as scattered, co-dominant stems, some of which were >250 years old. A synchronous recruitment pulse was not evident from these old aspen. Overall, 42% of the sampled aspen at GIL regenerated within five years after a fire.

No direct evidence of fire (e.g., charred wood or fire scars) was observed within the spruce-fir stands at GIL. Relatively continuous conifer regeneration was recorded in the decades from 1700 to 1910, and the oldest individual (Engelmann spruce) in the spruce-fir patches dated to 1707. Multiple spruce trees were older than the oldest crossdated fire scar (1716) recorded adjacent to the spruce-fir patches (Figure 6). Therefore, the sampled age structure did not meet our criteria to be a post-fire recruitment cohort. There was no evidence that the 1904 fire, which our results suggest burned with stand-replacing severity in adjacent mixed conifer-aspen forests, burned into the spruce-fir zone.

Historical Stand-Replacing Fire Patch Size

We derived historical stand-replacing fire patch size estimates from the 10 tree-ring dated post-stand-replacing fire aspen patches (1879 to 1904) and the one post-stand-replacing fire spruce-fir patch (1685 fire; Table 4). Fires at three of the four sites (GIL, PIN, and SFP) had stand-replacing fire patches >200 ha. The maximum reconstructed historical stand-replacing fire patch size was 286 ha in the mixed conifer-aspen zone (2600 m to 3100 m) and 521 ha in the spruce-fir zone (>3100 m; Table 4).

DISCUSSION

Historical Stand-Replacing Fire

We found evidence of historical stand-replacing fire in upper elevation forests

Table 4. Historical and recent stand-replacing fire patch area statistics. Historical burn patch areas derived from combined tree-ring reconstructed aspen and spruce-fir stand-replacing fire patches. Recent burn patch area derived from fire severity maps (1984 to 2008, n = 352 fires). The conservative estimate of recent stand-replacing fire patch size includes only high-severity patches (H), and a more inclusive estimate includes high- and moderate-severity patches (H+M). Recent data only include patches >30 ha, equal to the smallest reconstructed historical stand-replacing fire patch.

	Historical burn patches		Recent burn patches					
	2600 m to 3100 m	>3100 m	2600 m to 3100 m		>3100 m		All elevations	
	Aspen	Spruce-fir	H	H+M	H	H+M	H	H+M
Count	10	1	64	85	1	2	204	675
Mean (ha)	110	521	129	206	33	110	136	233
Median (ha)	63	521	80	86	33	110	65	74
Standard deviation (ha)	89	--	134	300	--	70	204	500
Minimum (ha)	30	521	32	31	33	60	32	31
Maximum (ha)	286	521	637	1540	33	159	1929	5136
Sum (ha)	1104	521	8251	17507	33	219	27810	157482

(>2600 m) at three of the four sites. Fires with multiple large (>100 ha) stand-replacing fire patches were tree-ring dated at the two Mogollon Plateau sites using quaking aspen age structure and associated direct conifer evidence of fire (1904 in GIL and 1879 in SFP). Aldo Leopold (1922), while on a fire assignment in the Gila Wilderness, referenced a 1904 fire in the Mogollon Mountains. Abolt (1997) identified a widespread fire with a stand-replacing component in 1904 in the Mogollon Mountains from tree-rings and historical documents. In the San Francisco Peaks, Heinlein *et al.* (2005) recorded a fire in 1879 in lower elevation ponderosa pine-mixed conifer forests using fire scars, but does not report evidence of stand replacement. Historical photographs taken in 1910 at SFP show standing dead and downed trees in the spruce-fir and mixed conifer-aspen zones that likely resulted from a fire with large (estimated >500 ha) stand-replacing patches in the late nineteenth century (http://www.rmrs.nau.edu/imagedb/viewrec.shtml?id=22141&colid=fv).

We were able to associate spruce-fir age structure with direct conifer evidence of fire (i.e., fire scars) at one of the spruce-fir fire history test sites (PIN). The age structure data we collected, and prior sampling of more than 290 trees by Grissino-Mayer *et al.* (1995) from the large (521 ha) spruce-fir stand at PIN, support the hypothesis of a stand-replacing fire in 1685 (Swetnam *et al.* 2009, but see Stromberg and Patten 1991). Margolis and Balmat (2009) reconstructed a 1200 ha stand-replacing fire patch in the spruce-fir forests of the Santa Fe Watershed, New Mexico, also in 1685. This year was extremely dry (−5.0 reconstructed Palmer Drought Severity Index: Cook *et al.* 2004) and a common fire year throughout the southwestern US (Swetnam and Baisan 2003). Thus, it is plausible that the typically mesic spruce-fir zone at PIN could have been dry enough in 1685 to burn.

Frequent Fire and Quaking Aspen

We did not find evidence of past stand-replacing fire in the sampled aspen stands at CHI. Although 89 % of the aspen stems at this site regenerated within five years after reconstructed fires, the mapped aspen patches were multi-aged. This indicates that some aspen stems survived multiple fires, while other aspen in the same patch were top-killed by the same fires and then regenerated by sprouting.

We found direct evidence of repeated low-severity fire (e.g., conifers with multiple fire scars) adjacent to aspen stands at CHI and within the mixed conifer-aspen forests of PIN. Frequent fire occurred at these two upper montane Sky Island sites prior to *circa* 1900: MFI-$PIN_{All\ fires}$ = 10.9 yr (1685 to 1871), approximately 150 ha sample area (Grissino-Mayer *et al.* 1995), and MFI-$CHI_{All\ fires}$ = 4.4 yr (1654 to 1904), approximately 250 ha sample area. This history of frequent fire may have prevented sufficient fuel accumulation to sustain stand-replacing fire. This suggests that the cessation of fire for over 120 years due to late nineteenth century grazing and twentieth century fire suppression may be a cause of fuel structure changes and buildup that contributed to the recent occurrence of stand-replacing fires in the mixed conifer-aspen forests at these Sky Island sites (Swetnam *et al.* 2009).

Similar evidence of frequent low-severity fire (i.e., logs and living conifers with multiple scars) was present within and adjacent to the aspen stands on the south slope of SFP (Figures 2 and 5). The lower borders of these aspen stands are connected with ponderosa pine-mixed conifer forests that historically burned with frequent low-severity fire (e.g., Heinlein *et al.* 2005). Based on this evidence of repeated surface fire in aspen on south aspects at SFP, it is likely that the present stand structure, dominated by >20 m tall, mature aspen stems (>120 years old) may be in part an artifact of fire exclusion. These fire-sensitive aspen stems would have been historically exposed to frequent fire, thus the same stands likely looked very different in the nineteenth century. One hypothesis is that they were smaller diameter aspen "thickets" that were top-killed and regenerated after each fire (Maini 1960, Allen 1989). Alternatively, some larger diameter stems at the center of the stand may have been protected from being girdled by fire, creating a multi-cohort age and stand structure. Binkley *et al.* (2006) proposed a similar hypothesis of altered quaking aspen stand-structure in response to twentieth century fire exclusion on the Kaibab Plateau in north-central Arizona. The following hypothesis should be tested with future research: the age and stand structures of quaking aspen that historically experienced frequent fire have shifted from young or multi-aged, dense stands, to the current open structure dominated by a single mature cohort, largely due to >120 years of fire exclusion.

Spruce-Fir Fire History Challenges

The lack of burn boundaries within the spruce-fir stands at our two test sites (PIN and GIL) differs from higher latitude, Rocky Mountain landscapes where old stand-replacing fire patch boundaries are visible as obvious stand-height and structural differences that are used to map and date historical crown fires (e.g., Kipfmueller and Baker 2000, Sibold *et al.* 2006). Fulé *et al.* (2003) reported a similar lack of fire-related patch boundaries identifiable with remote sensing data in mixed conifer, aspen, and spruce-fir forests of the north rim of the Grand Canyon, Arizona. The lack of old fire boundaries within the spruce-fir zone of the current study, and on the north rim of the Grand Canyon may suggest that, in these spruce-fir forests, large crown fire patches were not as common within recent centuries as they were in the Rocky Mountains.

The inconclusive evidence of stand-replacing fire in the spruce-fir zone at GIL was possibly due to an insufficient number of tree ages to determine the complex and relatively old (>300 yr) age structure, and the relative scarcity of old (pre-1700 AD) fire scar material in this high-elevation forest type (Figure 6). Age-structure transects with a higher density of samples may be necessary to determine patch age in old (>300 years old) southwestern US spruce-fir forests. Repeated, sample-intensive age structure transects distributed throughout the mapped stands may be the best method to confidently evaluate the age structure of old spruce-fir forests in this region (e.g., Margolis and Balmat 2009). The number of trees sampled for age structure could be adjusted based on the estimated age of the stand (e.g., <150 yr old, > 250 yr old) so that only the oldest stands would require intensive sampling to overcome these challenges.

Multiple mapping and age-structure sampling methods should be tested on known and potential post-fire spruce-fir stands. The subalpine forests of the upper Rio Grande Basin or at SFP could be used to select test sites because there are large spruce-fir stands adjacent to large, post-fire aspen patches from historically documented nineteenth century fires (e.g., Santa Fe Ski Basin, New Mexico). Dating and mapping these sub-alpine conifer stands is the best available method to improve the accuracy of estimates of historical stand-replacing fire area in the highest elevations (>3100 m) in the southwestern US. These data are necessary to estimate fire frequency statistics (e.g., fire cycle or natural fire rotation) of the stand-replacing fire regimes in the upper montane mesic mixed conifer-aspen and spruce-fir forests of the region.

Historical Stand-Replacing Burn Patch Size

The occurrence of historical stand-replacing fire patches >200 ha at three of the four upper elevation sites suggest that recent large (200 ha to 500 ha) stand-replacing patches are within the historical range of variability in upper elevation forests (>2600 m) of the southwestern US outside of the southern Rocky Mountains. Based on our reconstructions, stand-replacing fire patches as large as 286 ha historically occurred in the mixed conifer-aspen zone, and patches as large as 521 ha historically occurred in the spruce-fir zone. Within these upper elevation forests, it is possible that older, larger stand-replacing fire patches were burned over by the late nineteenth century fires, or that such patches were re-colonized by mixed conifer species instead of aspen. We did not observe obvious even-aged mixed conifer stands with abundant fire-killed, remnant conifer logs or snags at our study sites that might indicate evidence of past stand-replacing fire. However, extensive (>500 ha) mixed conifer and spruce-fir patches exist in the region and could be systematically sampled to determine whether they regenerated following stand-replacing fire.

The largest historical stand-replacing fire patch we reconstructed was in the spruce-fir zone at PIN (521 ha). Historical photographs at SFP, discovered after our sampling was completed, illustrate large late-nineteenth century stand-replacing fire patches (estimated >500 ha) in the spruce-fir zone (http://www.rmrs.nau.edu/imagedb/viewrec.shtml?id=22141&colid=fv). In the southern Rocky Mountains of New Mexico, Margolis and Balmat (2009) reconstructed a 1200 ha stand-replacing fire patch in spruce-fir forest. Thus, documentary and tree-ring evidence at multiple sites in the southwestern US indicates the potential for large (500 ha to >1000 ha) stand-replacing fire patches in spruce-fir forest.

Recent Stand-Replacing Burn Patch Size

All four of our study sites have recently burned with high-severity patches. As an ancillary investigation to summarize the recent (1984 to 2008) fires, we quantified patch sizes of 352 fires >404 ha with high- or moderate-severity patches within 100 km of the four fire history study sites (Figure 1, http://www.mtbs.gov/index.html). We stratified the recent burn severity patch size data by elevation and vegetation type and fire severity to produce six subsets: 1) high severity with no elevation limit, 2) high plus moderate severity with no elevation limit, 3) high severity 2600 m to 3100 m, 4) high plus moderate severity 2600 m to 3100 m, 5) high severity >3100 m, and 6) high plus moderate severity >3100 m. The elevation ranges are the same used to categorize the upper elevation fire reconstructions. The subset with no elevation limit includes lower elevation, pine-dominant oak or shrub vegetation. Recent patch sizes were limited to ≥30 ha, equal to the minimum reconstructed stand-replacing fire patch size. Data from all sites were pooled. We were most interested in the largest patches since they arguably have the greatest ecological effects.

Significant direct and delayed mortality from crown scorch and insect attack has been documented in moderate-severity burn patches in recent fires (McHugh and Kolb 2003). Based on an assumption that a substantial percentage of the trees in moderate-severity burn patches die, high- and moderate-severity patches were combined in one subset of the data. We posit that the actual area of fire-related tree mortality (i.e., stand replacement) was probably somewhere between the "high severity" and "high plus moderate severity" patch size estimates.

The largest recent stand-replacing fire patch size with no elevation limit was 1929 ha (high severity) and 5136 ha (high plus moderate severity), with 37 patches >1000 ha (2 high severity and 35 high plus moderate severity; Table 4). In the mixed conifer-aspen zone (2600 m to 3100 m), the largest recent high-severity patch was 637 ha, and the largest high-plus moderate-severity patch was 1540 ha. Above 3100 m, in the spruce-fir zone, the largest recent high-severity patch was 33 ha, and the largest high- plus moderate-severity patch was 159 ha.

Direct comparison between recent and historical stand-replacing fire patch sizes are challenging. Due to reasons discussed above, our historical estimates are likely conservative estimates of stand-replacing patch size. Thus, we cannot confidently test whether the largest recent high- or moderate-severity patches are larger than have occurred in past fires. However, given these limitations, the data suggest that recent high- (or moderate-) severity patches that are smaller than the historical estimates (maximum reconstructed patch size, 286 ha in mixed conifer-aspen forest and 521 ha in spruce-fir forest) are likely within the historic range of variability.

In summary, historical fire regimes at multiple upper elevation (>2600 m) mixed conifer-aspen and spruce-fir sites on the Mogollon Plateau and Madrean Sky Islands included large (>200 ha) stand-replacing fire patches. Aspen recruitment was historically associated with fire, with an average of 59% of the dominant aspen stems regenerating within five years after fire (ranging from 27% to 89% among sites). In the drier portions of the mixed conifer-aspen sites, the cessation of historically frequent fires for the last 130 years has likely altered the current aspen age and stand structures. Tree-ring and photographic evidence of historical stand-replacing fire in the spruce-fir zone indicates that recent fires that burned with high severity in this forest type at the study sites (e.g., 2004 Nuttall Fire at PIN) are rare events, but not unprecedented. Based on the reconstructed estimate, recent stand-replacing fire patches as large as 286 ha in the mixed conifer-aspen zone and 521 ha in the spruce-fir zone may be within the historic range of variability and should be expected in future fires, particularly when considering predictions of a warmer and drier climate in the southwestern US (e.g., Seager *et al.* 2007).

ACKNOWLEDGMENTS

This project was funded by Cooperative Agreement No. 99CRAG0024 between the US Geological Survey, through the USGS Biological Resources Division, Global Change Program, and the University of Arizona Laboratory of Tree-Ring Research. Thanks to M. Zummwalt, J. Iniguez, R. Adams, A. Fitzwater, C. Farris, R. Franklin, M. Villarreal, C. Baisan, and K. Morino for help with data collection, sample preparation, sample dating, and participation in discussions of the ideas presented. We would also like to thank Dr. Peter Z. Fulé and three anonymous reviewers who provided valuable comments on this manuscript.

EXECUTIVE SUMMARY

Wildfires are a fact of life for westerners. They mark the beginning of the spring season and have been a keystone architect of biodiverse ecosystems for millennia. While wildfires are not eco-catastrophes, they are a health concern, evoke public fear-of-fire exploited by decision makers seeking to push through anti-environmental policies, and generate conflicts over the best ways to coexist with this force of Nature that is not going away (nor should it), no matter how hard we try. This white paper summarizes some of the latest science around top-line wildfire issues, including areas of scientific agreement, disagreement, and ways to coexist with wildfire. It is a synopsis of current literature written for a lay audience and focused on six major fire topics:

1. Are wildfires ecological catastrophes?
2. Are acres burning increasing in forested areas?
3. Is high severity fire within large fire complexes (so called "mega-fires") increasing?
4. What's driving the recent increase in burned acres?
5. Does "active management" reduce wildfire occurrence or intensity?
6. Will more wildfire suppression spending make us safer?

Key findings

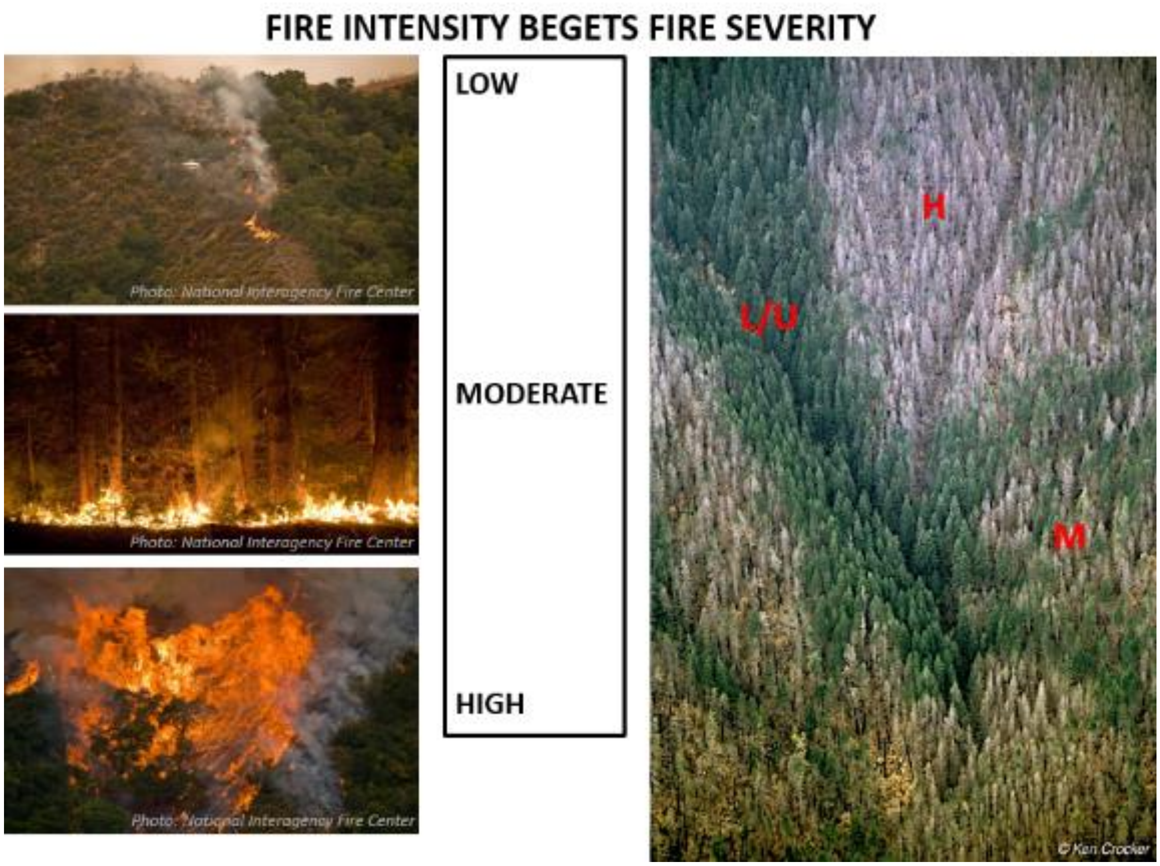
- Large wildland fire complexes, including patches of high severity fire, generate critical ecological pulses of dead trees (biological legacies) that are associated with extraordinary levels of biodiversity under-appreciated by most.
- Using long historical timelines, wildfire acres are currently at historical lows, but have been increasing in recent decades due mainly to three factors: (1) climate change; (2) human-caused fire ignitions (including suppression firing operations such as burnout and backfires); and (3) conversion of fire-resilient native forests to flammable plantations that experience relatively more high fire severity fire.
- Throwing more money at fire suppression will not abate fire concerns as more and more homes are built in indefensible places and are not designed or built with fire-resistant materials.
- Post-fire logging and associated activities (including roads) are unequivocally damaging to fire-rejuvenated forests and related aquatic ecosystems.
- Thinning small trees and prescribed burning can lower fire intensity at the stand level if done properly but this has significant limitations and ecological consequences given the scale of the perceived need and a changing climate.
- The most effective pathway to fire coexistence is to: (1) limit ex-urban sprawl through land-use zoning; (2) lower existing home ignition factors by working from the home-out with vegetation management and home retrofitting (defensible space), instead of the wildlands-in

(logging); (3) thin small trees and prescribe burn in ecologically appropriate settings (e.g., flammable plantations) while prioritizing wildland fire use in most forests away from homes; (4) store more carbon in ecosystems by protecting public forests and incentivizing carbon stewardship on non-federal lands; and (5) shift to a low-carbon economy as quickly as possible. Anything else will not achieve desired results to scale.

Issue 1: Are Wildfires "Catastrophic" or "Disastrous" Events?

Background

Large landscape wildfires are most often referred to as catastrophic "mass fires" or "megafires." Demonizing wildfires has placed this natural process in the same conversation as hurricanes and floods. Such disaster-speak and presumed logging remedies are now inculcated in the "Wildfire **Disaster** Funding Act" (emphasis added) recently passed by Congress as part of federal omnibus appropriations that also included rollbacks to forest protections. But what really goes on after a wildfire may be surprising in terms of the high biodiversity and rejuvenation capacity of forests after large fires, including severe ones.



In general, fire effects are the result of heat energy released during a fire (fire intensity – left photos) and resulting effects on ecosystems (fire severity, right). Most large fires (right) produce a mosaic of burn severity effects on vegetation (H-high severity, M-moderate, U-unburned, L-low). Fire-mediated landscape heterogeneity is habitat for a diverse assortment of species distributed across the successional gradient (new to old forests) and has been referred to as "pyrodiversity begets biodiversity" (see below)[1]. Note – in some cases a fast-moving high-intensity "running" surface fire can produce low severity effects, while a slow-moving low intensity "creeping" fire can produce high severity effects (e.g., smoldering piles of slash or logs).

Issue 2: Are Total Wildfire Acres Burning Increasing (independent of severity)?

Background

Nearly every fire season, the news media and politicians announce another "unprecedented" wildfire season. Such proclamations are incorrectly based on comparisons of contemporary wildfire acres to a recent historical timeline. This has been widely criticized in the scientific literature as the "shifting baseline perspective" (i.e., when a baseline is shifted to a more recent historical time period)[2]. Importantly, in the early part of the 20th century during a warm climatic cycle (Pacific Decadal Oscillation - PDO), wildfire acres were at least five times more abundant than today. A mid-century cool down accompanied by industrial fire suppression resulted in a substantial decline in acres burning[3]. The current warm period is associated with a recent increase in both acres burning and fire suppression (see below). In other words, wildfire activity tracks broad-scale climatic phenomenon (top-down drivers) that also influence fire suppression efficacy.

*Estimated from Medler 2015, Baker 2015, Marlon et al. 2012, Stephens et al. 2007

Figure interpretation caveats: prior to 1984, standardized datasets are difficult to obtain. Contemporary wildfires also have a strong back-burning influence not prevalent in historical times–i.e., errors in estimation exist on both ends of the wildfire acreage continuum. However, historical accounts (including General Land Office records and pollen-sediment core analyses) confirm very active fire seasons in the early part of the 20th century and before[4] (Figure compliments of John Muir Project).

Areas of Agreement

Fewer wildfire acres burning in forests today compared to the early 20th century has resulted in what many are calling a wildland fire deficit[5], which may seem as a surprise given fire hyperbole. The main exception to this deficit is southern California chaparral and shrub-steppe communities (too much human-caused fire is leading to ecosystem type conversions).

Areas of Disagreement

Current science debate is focused mainly on what is the best way for putting fire (i.e., “the right fire” “good fire”) back on the landscape in order to restore wildland fire-forest relationships.

[5] Parks, S.A. et al. 2015. Wildland fire deficit and surplus in the western United States, 1984-2012. Ecosphere 6:275. 13 pp.

Many claim that this cannot be done safely without massive thinning to reduce "fuels"[6], others state that we need to get to coexistence with wildland fire as the amount of thinning needed is prohibitively costly[7], and has significant consequences to ecosystems (see below). Still others want more of the "right kind" of fire in the "right places"– meaning less high severity fire, despite ecological importance of this type in low to mid elevation pine and mixed conifer forests (i.e., even predominately low severity ponderosa pine systems have a component of high severity) throughout the West.

Issue 3: Is High Severity Fire Within Wildland Fire Complexes Increasing?

Background

High severity fires that kill most of the trees in older forests are associated with extraordinary levels of biodiversity not present in low severity burns due mainly to the abundance of biological legacies (e.g., snags and down logs, shrubs)[8]. This fact is now widely accepted by the scientific community; however, the amount and spatial distribution of high severity fire patches within wildland fire complexes remains in question as to whether ecosystem thresholds are being crossed in large fires.

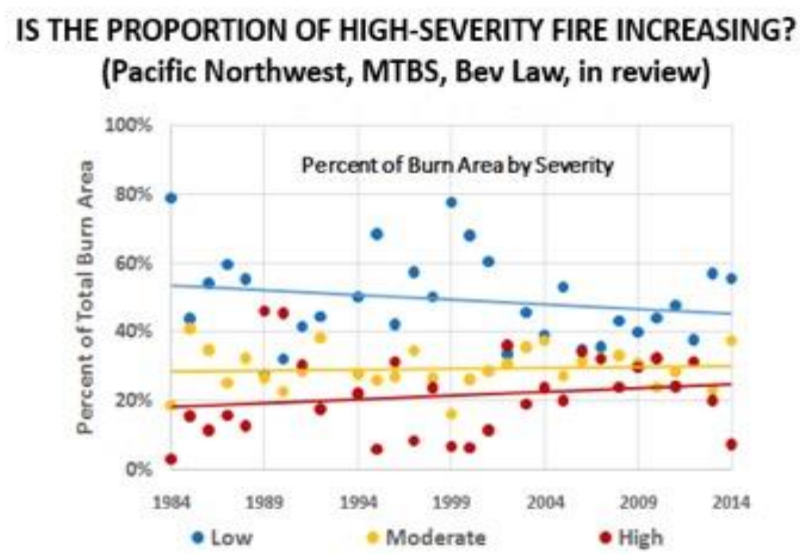
High Severity Fire Patches Become Biodiverse Snag Forests

Complex early seral forest after 12 years of natural conifer regeneration, native shrub patches, and deciduous trees (C. Hansen, Eldorado Starr Fire, Sierra).

Areas of Agreement

Nearly all studies have detected no statistically significant trend in high severity acres or proportion of high severity fire within large fire complexes (Colorado is an exception and there is debate in the Sierra)[9].



This figure shows no discernable increase in percent of various fire severities in the Pacific Northwest over a three-decade period (compliments of Bev Law, Oregon State University). Data prior to 1984 are not available for fire severity comparisons.

[9] Keyser, A., and A. LeRoy Westerling. 2017. Climate drives inter-annual variability in probability of high severity fire occurrence in the western United States.

Areas of Disagreement

Concern has now shifted to whether the size of high severity patches is increasing, believed to be a product of 21st century "mega-fires," and whether this is leading to type conversions (forests to shrubs)[10]. High severity patch data obtained from hundreds of forest fires across the West show no statistical increase in patch sizes in recent decades (DellaSala et al. in peer review). This is important as the patch size debate is used to make claims about "mega-fires" and to justify large-scale thinning, post-fire logging, and tree planting based on perceptions of inadequate tree recruitment or lack of forest resilience to fires. However, most high severity patches have high levels of internal heterogeneity that include small patches of live trees or nearby low-moderate burn areas as seed sources (in review).

Issue 4: What's Driving Recent Increases in Wildfire Acres Burning?

Background and Areas of Agreement

Recent increases in wildfire acres burning (see above PDO figure) can be traced to three main factors acting in concert: (1) a warming PDO from climate change; (2) increases in human-caused fire starts (accidental, arson, back burns); and (3) conversion of native forests to flammable tree plantations[11].

Over half of recent increases in wildfire acres burning has been attributed to climate change[12] (see top figure below as generalization) with 84% of all fire ignitions nationwide in recent decades caused by people (bottom figure below)[13]. Human-caused wildfire ignitions vary regionally based on population densities and remoteness.

Areas of Disagreement

While most land managers and decision makers are preoccupied with "fuels," two of the main drivers of fire behavior (climate change, human-caused ignitions) are largely ignored (except when used to justify logging for forest resilience). Additionally, roads (a principal source of human-caused fire ignitions) are almost never addressed in fire risk reduction measures. Uncertainty exists regarding whether large-scale thinning will work in a changing climate where fire behavior will be increasingly governed by extreme fire weather (high temperatures, low soil moisture, high winds, see below)[14]. Storing more carbon in ecosystems will help mitigate climate effects, although land managers often prioritize generating revenue from commercial sales over carbon storage[15].

Issue 5: Does "Active Management" Reduce Wildfire Intensity and Lower Fire Risks?

Background

Active management encompasses a wide spectrum of actions and opinions mostly focused on pre- (thinning) and post-fire ("salvage" logging) logging widely debated by scientists, conservation groups, and decision makers. This is arguably the number one area of fire-related conflicts on public lands with the underlying assumption that forests are overstocked, they need active management to reduce fire risks, and environmental safeguards are preventing management of forests that otherwise will burn out of control.

Areas of Agreement

Post-fire logging is unequivocally damaging to the pyrodiverse landscapes and complex early seral forests. In general, the larger the fire, the bigger the logging project[16]. Post-fire logging involves clearcutting both live and mostly dead trees, kills naturally regenerating conifers, and often is followed by herbicides to reduce competing yet beneficial vegetation and allow for subsequent planting of artificially grown trees (from nursery stock) in dense rows. As artificial plantations increasingly replace native forests, plantations act as kindling for intense fires (i.e.,

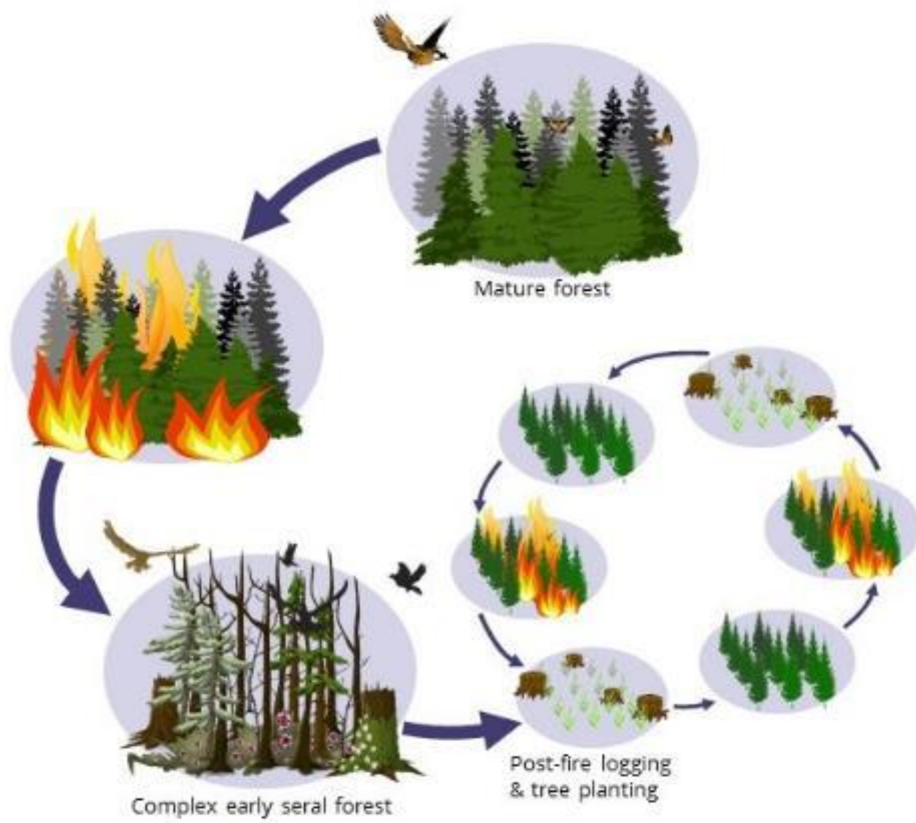
[15] Moritz, M.A. et al. 2014 (ibid). Law, B.E et al. 2018. Land use strategies to mitigate climate change in carbon dense temperate forests. PNAS http://www.pnas.org/cgi/doi/10.1073/pnas.1720064115

[16] DellaSala, D.A., et al. 2015. In the aftermath of fire: logging and related actions degrade mixed- and high-severity burn areas. Pp. 313-347, *In* DellaSala, D.A., and C.T. Hanson (eds), The ecological importance of mixed-severity fires: nature's phoenix. Elsevier, United Kingdom

"fire's gasoline")[17]. Post-fire logging creates a catastrophic feedback loop where fires in older forests create ecologically beneficial snag forests, those forests are then clearcut and replanted with small trees in dense rows lacking structural complexity, only to burn in higher intensities and so on (see figure below)[17,18]. Legacy trees removed by logging operations anchor soils, provide shade for developing seedlings, "nurse logs" for new growth and soil moisture retention for amphibians and invertebrates, habitat for aquatic species when snags fall into streams, and they store vast amounts of carbon as they slowly (decades to centuries) decompose. The scientific community is generally at consensus with regard to post-fire logging as damaging to ecosystems[19], particularly to spotted owl habitat[20].



Fire in a mature forest produces complex early seral (snag) forest that connects the stages of forest development through time. This cycle is interrupted by post-fire logging and tree planting leading to type conversions (native forest to flammable plantation) and unnatural fire severity.

[17] Odion, D.C., et al. 2004. Ibid. Thompson, J.R., et al. 2007. Reburn severity in managed and unmanaged vegetation in a large wildfire. PNAS 104:10743-10748.
[18] Bradley, C.M., et al. 2016. Does increased forest protection correspond to higher fire severity in frequent-fire forests of the western United States? Ecosphere 7:1-13.
[19] Lindenmayer, D.B., P.J. Burton, and J.F. Franklin. 2008. Salvage logging and its ecological consequences. Island Press: Washington, D.C.
[20] C.T. Hanson, M.L. Bond, and D.E. Lee. 2018. Effects of post-fire logging on California spotted owl occupancy. Nature Conservation 24:93-105.

Areas of Disagreement

In contrast to post-fire logging, thinning involves partial logging of trees for various purposes, including reducing competition among nearby trees, increasing tree vigor, and accelerating tree growth (e.g., in wet forests it is commonly used to accelerate development of older forest conditions as specified under the Northwest Forest Plan). Thinning also is commonly used to reduce "fuels" in dry forests and has support in the scientific community and with NGOs. When done properly, thinning of small trees followed by prescribed burning[14], or prescribed burning alone in some cases[21], can reduce fire intensity. However, it remains controversial, has significant ecological consequences (short and long-term), and substantial limitations given high costs and the massive scale believed needed to influence fire behavior especially in a changing climate (Box 1).

Large trees (dbh inches marked on trees) marked for removal on a BLM "fuels" project, southwest Oregon (L. Ruediger).

[21] Zachmann, L.J., D.W.H. Shaw, and B.G. Dickson. 2018. Prescribed fire and natural recovery produce similar long-term patterns of change in forest structure in the Lake Tahoe basin, California. Forest Ecol. & Manage. 409:276-287

Box 1. General limitations of thinning (and collateral ecosystem damages)

(1) Thinning reduces habitat for canopy dependent species, including spotted owls[22], requires an expansive road network damaging to aquatics, can spread invasive and flammable weeds, and, when implemented over large landscapes, releases more carbon emissions than fires, even severe ones[23].

(2) There is a very low probability (3-8%) that a thinned forest will encounter a fire during the narrow period (10-20 years depending on site factors) of reduced "fuels" [24], resulting in large-scale thinning proposals that alter forest conditions over large areas[6].

(3) Excessive thinning (e.g., reducing bulk crown density below 60%) can increase wind speeds and solar radiation to the ground causing increased flammable vegetation growth and fire spread.

(4) Thinning needs to be followed by prescribed fire to reduce flammable slash but this can cause soil damage especially if burning is concentrated in piles (intensifies heat effects.

(5) Thinning is seldom cost effective without public subsidies or removing large fire-resistant trees.

(6) In some regions (Sierra, Klamath-Siskiyou), time since fire is not associated with increasing fire risks (i.e., as forests mature, they become less flammable[25]).

(7) Thinning efficacy is limited under extreme fire weather (principal factor governing large fires).

(8) At regional scales, active management (unspecified forms of logging) have been associated with uncharacteristic levels of high severity fires (see figure below)[26].

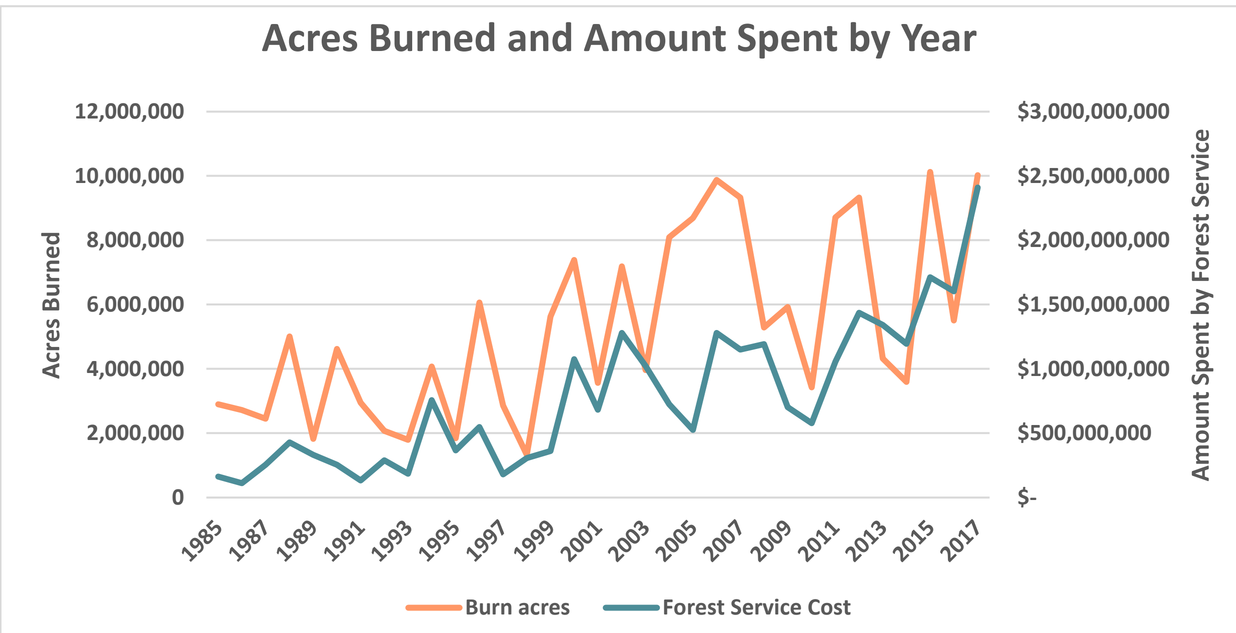
Issue 6: Will More Suppression Spending Make Us Safer?

Background

On March 21, 2018, Congress passed an omnibus spending package that established a dedicated wildfire "disaster" fund of > $2 billion per year that would increase steadily over a 10-year period. Spending measures include expanding the use of controversial categorical exclusions for logging projects up to 3,000 acres each that can conceivably be located adjacent to one another with no regard for cumulative impacts.

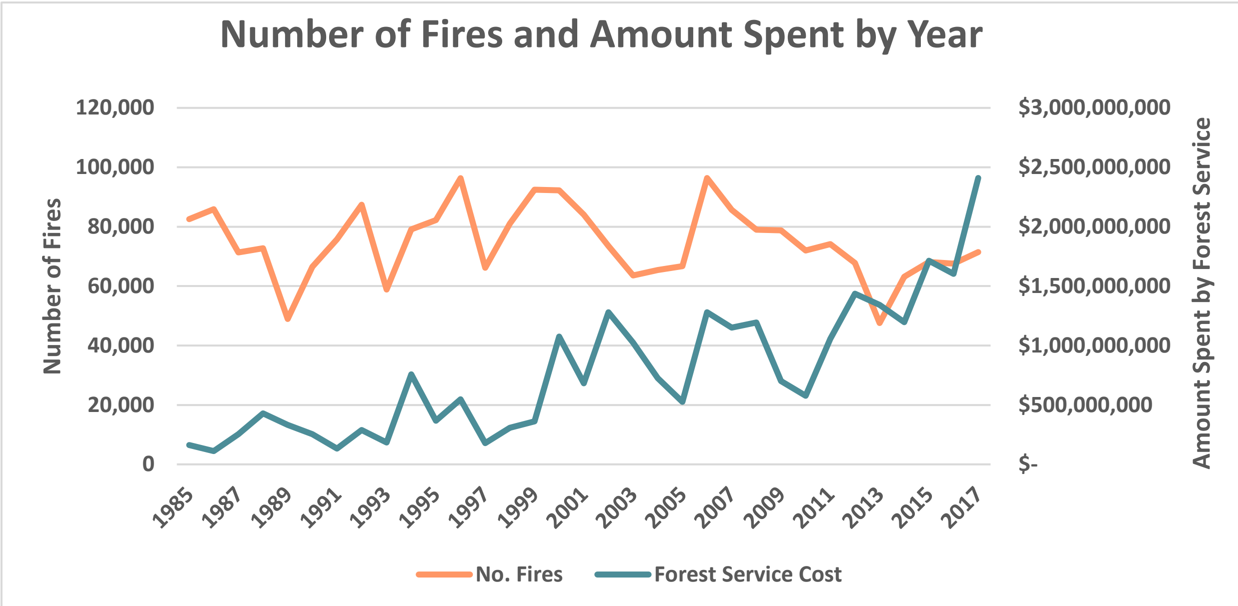
Areas of Agreement and Disagreement (combined)

While conservation groups pushed for a rider-free wildfire spending fix, throwing more money at fire suppression while expecting fewer fires is highly uncertain. In many ways, the two figures below illustrate the common definition of crazy – doing the same thing over and over again but expecting a different outcome. In sum, both acres burning and wildfire suppression costs of the Forest Service have risen dramatically over the past three decades (top figure) calling into question whether more money will achieve fewer fires or less acres burning. Interestingly, in some years (e.g., 2006-2012, bottom figure) total wildfire ignitions steadily dropped while costs generally rose presumably from fighting more fires in remote areas and few controls on spending[27] (figures prepared by J. Leonard, Geos Institute using fire data from National Interagency Fire Center[28]).



[27]Ingalsbee, T., and U. Raja. 2015. The rising cost of wildfire suppression and the case for ecological fire use. Pp. 348-317 In: D.A. DellaSala, C.T. Hanson (eds.). The ecological importance of mixed-severity fires: nature's phoenix. Elsevier: Boston.

[28] https://www.nifc.gov/fireInfo/fireInfo_statistics.html



As an example of unmitigated suppression spending, the 132,127-acre Soberanes fire in California (started by an illegal campfire) cost ~$236 million (nearly $1800 per acre) and deployed thousands of fire fighters and numerous air-tankers, making it the most expensive wildfire to fight in US history. Although the fire destroyed 57 homes (and took the life of a bulldozer operator), suppression forces were used on the fire as it burned safely in the back country far removed from homes. The fire was eventually extinguished by fall rains.

Conclusion: Moving Forward in the New Climate Wildfire Era

When it comes to fire, we each see what we want: land managers view the world as ready-to-burn ecosystems just lacking an ignition source and needing "fuels" reduction; ecologists see habitat restored by wildfires as part of the circle of life and death in a forest; the public fears fire and understandably has concerns about smoke emissions; the media portrays death and destruction during fires; conservation groups are either for or against large-scale thinning; and politicians race to sensationalize fire to justify increased commercial logging on public lands. This is no doubt the most difficult public lands issue we have ever faced as its wrapped in emotion, human health, self-interests, avarice, hyperbole, point-counter point arguments, and nearly everyone wants to do something – even if doing something is worse than the perceived problem. Moving beyond this will require communicating about fire with empathy and clear intent especially while recognizing genuine fear and health issues. It will involve a combination of science publications, public support for managing wildfires for ecosystem benefits (once safety has been addressed), tolerance for temporary smoke levels, and our own limitations in being able to influence ecological processes increasingly governed by top-down drivers (climate) rather than bottom up forest management. Based on climate change models, extreme fire conditions are predicted to be more common this century and thus the extensive thinning involved to theoretically reduce fire intensity (e.g., wide spacing among trees, open-park like conditions) would create novel or greatly engineered forest systems that impact biodiversity and ecosystem services (carbon stores, clean water) in undesirable ways.

Importantly, we need to solve for human safety with the most significant challenges coming from ex-urban sprawl (enabled by scant land-use zoning and building in the wrong places), a rapidly changing climate, an expanding logging footprint focused increasingly on extracting the "new coal" ("feed stock") for biomass burning. Rational fire approaches and communication strategies that do not sacrifice native forests for perceived fire safety are an area of much needed research and financial resources.

We know a lot more about wildfire today than in the last decade; however, much of the science is still in debate, it almost always lags behind or is ignored by decision makers, land managers, and even some scientists and conservation groups with entrenched views about fire (Box 2).

Box 2. What we know and do not know about wildfires.

- Complex early seral forests are as biodiverse as old growth, containing comparable levels of species richness (although species composition varies across seral stages).
- Wildfire effects on vegetation are highly variable (mixed)[29], calling into question fuel reduction projects (especially those that use a shifting baseline) based on restoring forests to an "historical" open park-like condition when there was a lot more variability and the climate is changing.
- It will be impossible to mechanically treat the substantial acres alleged to need fuel reduction to reduce fire intensity[7] (58 million acres according to the Forest Service), and, even if possible, this would have severe consequences to ecosystems, especially aquatics, and come with substantial taxpayer funded costs.
- Thinning under extreme fire weather ("the new norm") is highly uncertain in a changing climate.
- Additional increases in homes built within the Wildland Urban Interface (WUI) (now totaling 43.4 million)[30] will result in more human-caused fire ignitions and out of control suppression spending regardless of where the money comes from. Wildfire problems will not abate if this growth along with climate change accelerates.

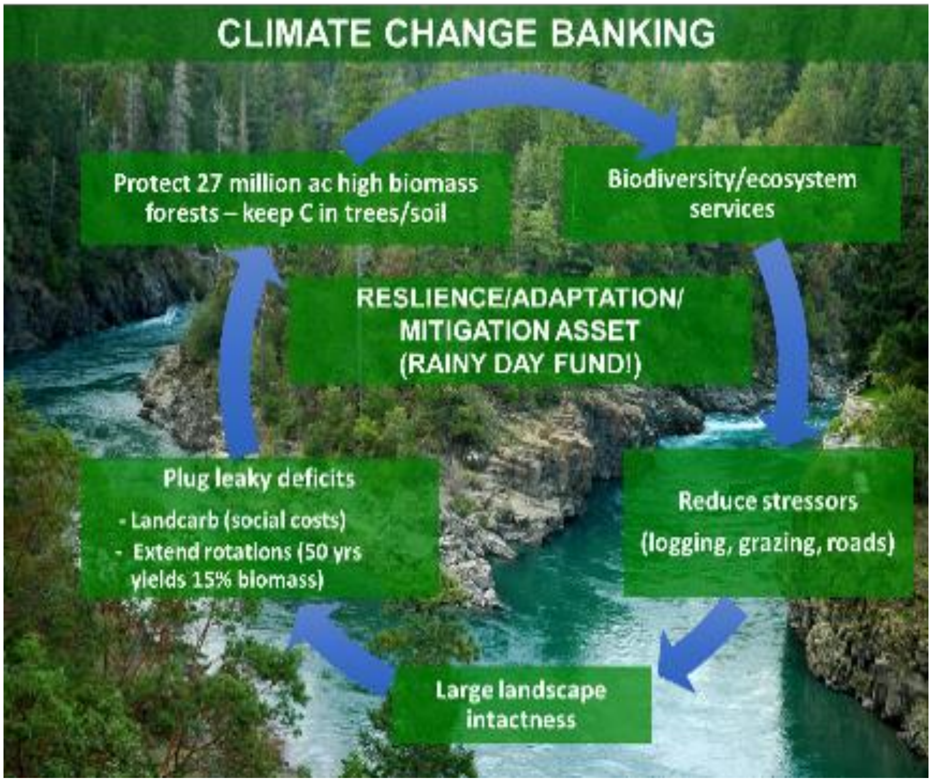
[30]Radeloff, V., et al. 2018. Rapid growth of the US wildland -urban interface raises wildfire risk. PNAS http://www.pnas.org/cgi/doi/10.1073/pnas.1718850115

There is no “right” or “wrong” or “good” or “bad” fire. Fire is a predatory force of Nature resulting in ecological winners and losers (at least temporarily). We in the environmental community do not speak of “good” wolves or “bad” mega-wolves (that eat sheep) yet the fire debate embraces this terminology. In sum, we do not have a fire problem per se but rather a people management problem – homes built in the wrong places and with the wrong materials, fire-fighters dropped into unsafe areas, hyped-up thinning projects that may or may not work, and a rapidly changing climate that will produce surprises.

There are plenty of management options that are compatible with western forest resilience and fire-mediated biodiversity in a changing climate, including:

- Removing land-use stressors (e.g., mining, livestock, Off Highway Vehicle impacts that accumulate in space and time) so that ecosystems can adapt to climate change;
- Maintaining viable populations of imperiled species and habitats, including climate sanctuaries such as older forests, forests on north-facing slopes, and riparian areas[31];
- Curtailing the spread of invasive species;
- Managing wildfires for ecosystem benefits and prescribed fire in appropriate types;
- Thinning and girdling (killing) small trees in young plantations (along with prescribed fire) to increase structural complexity and reduce fire intensity (but see limitations discussion);
- Replacing ineffective culverts (especially important in areas where climate change will trigger more floods); restoring floodplains so they can naturally store more water (e.g., reintroducing beavers) and attenuate floods; and removing damaging roads by re-contouring the road prism to natural features (e.g., to reduce sediments to streams and improve hydrological functions);
- Managing for connectivity (up-down elevation, latitudinal-longitudinal gradients); and
- Storing more carbon in forest ecosystems (see climate robust strategies).

[31]Olson, D.M., et al. 2012. Climate change refugia for biodiversity in the Klamath-Siskiyou ecoregion. Natural Areas Journal 32:65-74.



Climate robust conservation means protecting carbon dense forests nationwide as a foundation for biodiversity and ecosystem services, reducing land-use stressors, connecting landscapes for wildlife migrations and reducing carbon emissions from logging. Fire safety measures discussed herein are compatible with this overall strategy and represent a comprehensive path forward.

Importantly, managing wildfire for ecosystem benefits is not the same as “let burn.” Instead, this involves monitoring wildfire behavior initially, targeting suppression at fires likely to spread near towns, “loose-herding” and directing fire in the back-country under safe conditions, cutting fire lines nearest homes, and keeping fire fighters out of harm’s way. The same fire can be compartmentalized for different treatments. The Forest Service already has existing authorities that allow them to use such approaches in deciding when to attempt to use suppression vs. managing wildfire for ecosystem benefits[32]. Implementing this policy would help keep spiraling wildfire suppression costs in check[27].

In addition, local governments need to start embracing smart growth measures to limit sprawl within the WUI. Fire safety for existing homes is about reducing risks from the home-out (defensible space), rather than from the wildlands-in (logging)[33]. Defensible space has to become as routine as changing the batteries in a home’s smoke detectors and building with metal roofs the norm in home construction.

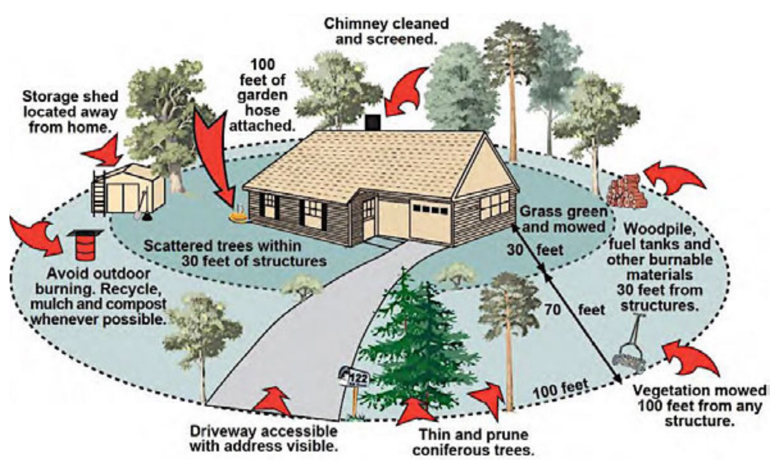
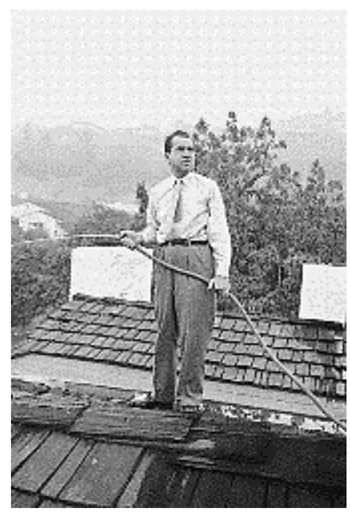
Fire prevention begins with land-use planning that limits growth in unsafe areas and includes defensible space management (figure prepared by A. Syphard, CBI; historical Nixon photo courtesy of San Francisco Chronicle[34]; lower figure – Homeowner fire safe guide for Montana).





Potential synergies and framing messages around forest issues cut across public lands campaigns that could benefit from working together, including the “keep it [carbon] in the ground,” “350.org,” and a much needed “keep it [carbon] in the forest” campaign. For instance, researchers at Oregon State University recently showed that the best way to increase carbon stores in Northwest forests is to reduce federal lands logging by at least 50%, increase the length of timber harvest rotations on private lands to 80 years, afforestation, and reforestation[35]. Notably, wildfires are currently not a significant contributor to greenhouse gas

[35]Law, B.E., et al. 2018. Land use strategies to mitigate climate change in carbon dense temperate forests. PNAS www.pnas.org/cgi/doi/10.1073/pnas.1720064115

emissions, contrary to many assertions[36]. Importantly, the Northwest Forest Plan resulted in ancillary climate benefits by shifting federal forest management from a substantial source of logging emissions in the 1980s to a current "sink" (warehouse) for carbon storage due to reduced (by 80%) timber harvest on federal lands[37]. As this forested warehouse continues to accumulate carbon, it is critical to protect carbon-dense older forests on public lands and incentivize forest carbon stewardship on non-federal lands. Making the link between climate mitigation and intact forest conservation currently lacks the recognition needed to offset fossil fuel emissions and keep the planet from heating above 2° C, which cannot be accomplished without forests in the mix[38].

The long-range prognosis for public lands forests is generally favorable. On the one hand, conservation groups with significant support of the donor community have held the line on decades of hard-fought victories centered on the Northwest Forest Plan and wilderness/ roadless protections. On the other hand, the pressure to develop forests is unprecedented globally and regionally with an urgent need to solve for increasingly complex social, economic, and engrained perceptions about forest management. Conservation science continues to be a leading voice for public lands by supporting effective communications, grass-roots organizing and campaigning, and responding to maladaptive climate policies by proposing climate robust conservation strategies. When it comes to fire science, however, we have as many questions as answers, more debate than consensus, but there have been important strides forward.

In closing, we have much work to do to change public attitudes about forest fires but optimism begins when we open our hearts and minds to the intricate dance between green and burned forest orchestrated by the natural disturbance processes that have been at play since the age of dinosaurs and will continue in largely unpredictable ways in the emerging novel climate. Preparing for these changes must be comprehensive, science-based, and solve for top-down drivers of change while we hold the line and then expand on a robust conservation vision.

Abstract

Understanding disturbance interactions and their ecological consequences remains a major challenge for research on the response of forests to a changing climate. When, where, and how one disturbance may alter the severity, extent, or occurrence probability of a subsequent disturbance is encapsulated by the concept of *linked disturbances*. Here, we evaluated 1) how climate and forest habitat variables, including disturbance history, interact to drive 2000s spruce beetle (*Dendroctonus rufipennis*) infestation of Engelmann spruce (*Picea engelmannii*) across the Southern Rocky Mountains; and 2) how previous spruce beetle infestation affects subsequent infestation across the Flat Tops Wilderness in northwestern Colorado, which experienced a severe landscape-scale spruce beetle infestation in the 1940s. We hypothesized that drought and warm temperatures would promote infestation, whereas small diameter and non-host trees, which may reflect past disturbance by spruce beetles, would inhibit infestation. Across the Southern Rocky Mountains, we found that climate and forest structure interacted to drive the 2000s infestation. Within the Flat Tops study area we found that stands infested in the 1940s were composed of higher proportions of small diameter and non-host trees ca. 60 years later. In this area, the 2000s infestation was constrained by a paucity of large diameter host trees (> 23 cm at diameter breast height), not climate. This suggests that there has not been sufficient time for trees to grow large enough to become susceptible to infestation. Concordantly, we found no overlap between areas affected by the 1940s infestation and the current infestation. These results show a severe spruce beetle infestation, which results in the depletion of susceptible hosts, can create a landscape template reducing the potential for future infestations.

Introduction

In the context of a changing climate and increases in forest disturbances such as bark beetle infestations and wildfires, disturbance interactions are receiving increased attention in ecological research [1,2]. In particular, there is a need to better understand when, where and how one disturbance event may alter the severity, extent, or probability of occurrence of a subsequent disturbance, a concept known as *linked disturbances* [3]. A prior disturbance may amplify the second by increasing its likelihood or severity through positive feedbacks (e.g. blowdowns may increase the amount breeding material thereby increasing insect populations and likelihood of outbreak [4]). Or, alternatively the first disturbance may dampen the probability of occurrence or severity of the second (e.g. stand-replacing fire may decrease the probability of subsequent fire [5]).

During the late 20th and early 21st century, warm and dry conditions and suitable hosts have promoted landscape-scale (sensu [6]) and severe bark beetle outbreaks, resulting in tree mortality across 8.4 ± 2.5 Mha in the western North America (1997–2010; [7]). Given this extensive tree mortality, there is an increased need for understanding how bark beetle infestations alter subsequent disturbance dynamics. Considerable research has emphasized the potential effects of bark beetle outbreak on the fire behavior [3,8–14], occurrence [15–19], and severity [15,20–22]. Recent research has also emphasized the compound effects of bark beetle outbreak and fire on ecosystem recovery [20–23]. Far less is understood about how one bark beetle outbreak affects a subsequent outbreak.

Bark beetles of the *Dendroctonus* genus inhabit the inner bark and feed on the tree's phloem tissues. Heavy colonization and reproduction within the inner bark interrupts the flow of water and nutrients throughout the tree and usually causes tree death. When and where bark beetle outbreaks occur is constrained by both weather and forest structure conditions [6,24,25]. Warm temperatures promote the rapid growth of beetle populations by increasing the proportion of beetles that develop within one year and decreasing overwintering mortality [26–28]. Drought may stress host trees, increasing the susceptibility of trees to infestation [29–32]. Forest structure also affects the occurrence of bark beetle infestations. Bark beetles prefer large diameter trees, growing in dense stands composed predominantly of the host tree species [6,33].

In the Southern Rocky Mountains, outbreaks of spruce beetles (*Dendroctonus rufipennis*) are among the most important broad-scale disturbances in subalpine forests. Spruce beetles are found in Engelmann spruce (*Picea engelmannii*) and subalpine fir (*Abies lasiocarpa*) forests, where they most frequently colonize large diameter (> 23 cm diameter at breast height; DBH) spruce trees. However when beetle population levels are high and host trees are severely-drought stressed, spruce beetles may attack trees less than 10 cm DBH [34]. Like other bark beetles, heavy colonization and reproduction within the inner bark usually kills the host tree. In northwestern Colorado, severe spruce beetle infestations tend to occur at median intervals of c. 70 years for the same stand [30,35]. The return interval of spruce beetle infestations to the same stand or relatively homogeneous landscape is hypothesized to be in part a function of a negative linkage between infestations. Thus, for forest stands (100s of hectares) and forest landscapes (1000s to tens of 1000s) that are characterized by similar forest compositions and tree population age structures, forest attributes are likely to affect the probability of occurrence and severity of an outbreak [32]. For example, a severe spruce beetle outbreak, which may result in the mortality of 90% of the mature host trees (Engelmann spruce), has been hypothesized to decrease the likelihood of subsequent infestation [33]. This decrease in susceptibility to infestation is hypothesized to persist until host trees reach a suitable size for infestation. While there are studies documenting the collapse of an outbreak evidently due to host depletion [29], there is no published empirical evidence for a bark beetle infestation negatively influencing the occurrence of a subsequent bark beetle infestation.

A widespread spruce beetle outbreak affected a large part of the spruce-fir forests of western Colorado in the 1940s. This outbreak was most severe in the Flat Tops Wilderness area of White River National Forest in northwestern Colorado where 99% of the overstory spruce were killed over an area of 2,700 km^2 [33,36]. The second most severely affected area in the 1940s outbreak was Grand Mesa National Forest to the southwest of White River National Forest where mortality was estimated at over 50% [32]. There are no other known 20th century spruce beetle outbreaks in Colorado of a comparable magnitude to the 1940s outbreak that was centered on the Flat Tops area of White River National Forest. Thus, in the context of the recent spruce beetle outbreak of 1997–2012, the concentration of high tree mortality during the 1940s outbreak in one large contiguous area created the opportunity to quantitatively evaluate the potential for a landscape-scale bark beetle infestation to negatively affect the probability of a subsequent infestation ca. 60 years later. Mapping of the recent spruce beetle outbreak from Aerial Detection Surveys [37] indicate a low spruce beetle infestation in the Flat Tops area in comparison with spruce-fir forests throughout Colorado (Fig 1). Thus, the primary aim of this study is to determine if the relative lack of recent spruce beetle infestation in the Flat Tops area is due to a negative feedback from host depletion attributable to the 1940s outbreak. Because spruce beetle infestation depends on both climate and forest conditions [6], we first assess the suitability of climate and forest attributes for spruce beetle infestation during 1997–2012 in the Flat Tops study area in comparison with the entire Southern Rocky Mountain Ecoregion of the U.S. Second, we examine forest attributes across the Flat Tops study area in relation to the mapped extent of the 1940s spruce beetle infestation and compare current forest structure in field sampled stands infested and not infested in the 1940s. Thus, by documenting the climatic suitability of the Flat Tops study area for the recent infestation, we are able to associate the relative absence of infestation with host depletion from the 1940s outbreak.

Materials and Methods

Study area

The study region (Fig 1) is the spruce-fir forest type of the Southern Rocky Mountain Ecoregion. The study region is characterized by high elevations (3215 ± 205 m), cold, wet winters (mean minimum January temperature -14°C and mean total January-March precipitation 241 mm; 1981–2010) and warm, dry summers (mean maximum July temperature 20.6°C and mean total June-August precipitation 169 mm; 1981–2010) [38]. Engelmann spruce and subalpine fir co-dominate the spruce-fir forest type.

We examine the potential for spruce beetle infestation to affect the area of forest structure suitable for subsequent spruce beetle infestation within a subset of the study region comprised of the Flat Tops Wilderness and adjacent areas of White River National Forest of northwestern Colorado, USA (Fig 1). The Flat Tops study area was chosen because of the unique availability of maps of both the 1940s spruce beetle infestation derived from air photo interpretation [5] and the current (1997–2012) spruce beetle infestation produced from Aerial Detection Surveys (ADS; [37]). Historical reports document widespread spruce beetle infestation in the 1940s, when about 25% of the merchantable volume of Colorado's spruce was killed. The Flat Tops study area experienced particularly abundant mortality, characterized by more than 90% canopy mortality [33].

(B) Map of the Flat Tops study area comprised of the Flat Tops Wilderness (black line) and adjacent areas of White River National Forest and areas infested by spruce beetles during the 1940s and 1997–2012 periods. Sources are given in Table 1.

doi:10.1371/journal.pone.0127975.g001

Data processing

We first obtained data on the occurrence of spruce-fir forest across the Southern Rocky Mountain study region (Table 1). Most vegetation cover-type datasets express only moderate (40–60%) overall agreement between field plot data and forest cover-type at 30 x 30 m spatial scale [39,40], thus we combined three datasets depicting the occurrence of spruce-fir forest [41]. For each vegetation dataset, we listed the presence of a spruce beetle host within a 990 x 990 m pixel, which approximates a stand scale [41]. We adopted a conservative criterion for mapping spruce-fir forest based on requiring its presence in all three datasets.

Next we obtained spatially explicit data on the presence of spruce beetle infestation over the time period from 1998–2013 from the United States Forest Service Region 2 ADS database [37]. Aerial Detection Surveys have been conducted annually in the Southern Rocky Mountains since 1994. To our knowledge robust accuracy assessments of ADS maps of spruce beetle infestation do not exist. However, accuracy assessments between ADS and ground reference data listing the presence/absence of bark beetle infestation in lodgepole pine show moderate-high agreement at coarse (500 m) spatial grains [39,40]. Thus we assumed ADS maps of spruce beetle infestation are most appropriate for assessing coarse-grain trends in presence/absence of infestation. To account for the ca. 1-year lag between initial infestation and ADS detection, we shifted the year of detection back one year to obtain year of attack [7]. Annual spatial polygon data listing the year of spruce beetle attack (1997–2012) were then converted to a 990 x 990 m grid listing the presence of spruce beetle infestation. Annual grids were then summed to obtain the cumulative area infested (1997–2012) and multiplied by a raster of spruce-fir presence to obtain a cross-validated grid of spruce beetle infestation [24].

Table 1. The GIS data layers and attributes used to examine linked spruce beetle disturbance.

Variable	Description	Data	Type	Resolution	Year
Damage casual agent	Name of forest pest or pathogen causing damage	Aerial Detection Survey Database [37]	Polygon	Compiled at 1:100,000 scale	1998–2013
1940s infestation	Presence /absence of 1940s spruce beetle infestation	Bebi et al. 2003 [5]	Polygon	Interpreted at 1:10,000 scale	Based on 1971 color & 1984 IR aerial imagery

doi:10.1371/journal.pone.0127975.t001

We also obtained a map of the presence of the 1940s infestation within the Flat Tops study area [5]. To our knowledge no other maps of the 1940s outbreak exist for the Southern Rocky Mountains. Maps of the 1940s infestation were developed from visual stereoscopic examination of 1971 color and 1984 IR aerial imagery (minimum mapping unit 5 ha). Stands mapped as infested by spruce beetles during the 1940s were defined as stands in which >30% of canopy trees were dead [5]. Spatial polygon data on the occurrence of the 1940s infestation was then converted to a 990 x 990 m grid listing the presence of spruce beetle infestation and multiplied by the raster of spruce-fir presence to obtain a cross-validated grid of spruce beetle infestation [24].

Finally we obtained spatial data on climate and forest structure variables, which were hypothesized to be important in predicting the occurrence of spruce beetle infestation. We obtained gridded monthly precipitation and temperature data from the Parameter-elevation Regressions on Independent Slopes Model (PRISM; [38]) (Table 1). To determine if warm and dry weather was associated with infestation, we calculated the 1997–2012 means of maximum August temperature and total annual precipitation, which previous research has shown to predict occurrence of spruce beetle infestations [25,29,45]. To determine if anomalously cold weather during the late autumn to early spring was associated with the presence/absence of infestation we calculated the 1997–2012 means of minimum October and March temperature, which are understood to inhibit infestation [25,45]. Next, we obtained vegetation layers depicting the mean diameter at breast height (DBH) size classes for the dominant canopy species, which were created from manual aerial photo interpretation of 1-m resolution color aerial photographs in 2002 (Table 1).

Determining the biophysical drivers of spruce beetle infestation

We used two methods to assess the biophysical variables driving the spatial variability in the occurrence of 1997–2012 spruce beetle infestation in the Southern Rocky Mountain study region. First, we used a spatial overlay approach [46,47], where spatial data on spruce beetle infestation were compared with spatially explicit climate and forest structure data (Table 1). We used spatial overlays to calculate the conditional probability of the presence/absence of spruce beetle infestation given each value of the independent variable. Conditional probability is a measure of the probability of the dependent variable (presence or absence of spruce beetle infestation) occurring given each value of the independent variable (biophysical variables). Continuous climate variables were first binned into four equal-interval classes [48]. Then we tabulated the number of 990 x 990 m pixels of all values of each independent variable that occurred in uninfested and infested areas and calculated the conditional probability of infestation. The null hypothesis is that spruce beetle infestation is independent of all values of each independent variable and thus observed conditional probabilities of infestation should equal conditional probabilities of uninfested stands. Our spatial overlays assessed entire populations and not samples. Thus all deviations between conditional probabilities are viewed as real differences between the datasets and statistical tests are not necessary. However, given that our spatial datasets exhibit classification error, we conservatively assumed that only differences greater than 10% are meaningful (e.g. [46]).

Second, to complement our conditional probability analysis of univariate relationships between biophysical predictors and the presence/absence of spruce beetle infestation, we used a Conditional Inference Framework (CIF; [49]) to assess multivariate relationships. CIF is similar to Random Forests [50] in that many classification trees are constructed by dividing the data into increasingly homogenous groups based on splits in the independent variables [49,51,52]. Classification trees are useful for detecting nonlinear relationships and interactions between variables [51]. In contrast to Random Forests where variable selection is based on the maximization of an information criterion (e.g. Gini coefficient), CIF uses conditional permutation-based significance tests to select variables [49]. This decreases selection bias in cases where independent variables have substantially different numbers of potential splits (e.g. categorical vs. continuous independent variables) [53], or where independent variables are correlated [54]. To evaluate the variables most important for predicting the presence/absence of spruce beetle infestation, we calculated conditional variable importance scores, a measure of each independent variable's contribution to overall model fit [54]. Because the calculation of conditional variable importance is computationally intensive, we randomly selected 2000 cases, stratified by spruce beetle infestation (1000 infested; 1000 uninfested). Model accuracy was asssed using overall accuracy and model sensitivity and specificity.

Effects of the 1940s spruce beetle infestation on the 1997–2012 infestation

To determine if the effects of the 1940s spruce beetle infestation on forest structure may affect the susceptibility of a stand to subsequent infestation in 1997–2012, we first used our model of the presence/absence of spruce beetle infestation to determine the relative importance of forest structure versus climate variables in constraining infestation within the Flat Tops study area. We tabulated the number of pixels within each model node and evaluated the relative importance of splits in climate vs. forest structure variables in predisposing the Flat Tops study area to infestation in 1997–2012. To this end, we calculated the percent of pixels in each model node for the entire Southern Rocky Mountain Study region and just the Flat Tops study area (Southern Rocky Mountain Study Region % | Flat Tops study area %). If the percent of pixels that met the condition were greatly different (>10%) for the Flat Tops study area than for entire Southern Rocky Mountain Study region, then that condition was interpret to be disproportionately important in constraining/promoting infestation within the Flat Tops study area.

Next, we coupled fine-scale field data with stand-level spatial data to determine if forest structure was altered by previous spruce beetle infestation. First, to test if large trees were depleted in areas of the 1940s infestation, we tabulated the number of 990 x 990 m pixels of all values of tree size that occurred in areas with and without 1940s infestation [55]. Then we calculated the conditional probability of the dominant tree size class (2.5–12.4, 12.5–22.9, 23–40.4, or $\geq$40.5 cm DBH) given the presence/absence of 1940s infestation.

Because the available GIS dataset depicting tree size is not species specific, we collected stand-scale (0.01 ha) field data to determine the delayed effects of a severe spruce beetle infestation on species composition. Field data were collected in the summer of 2013 at 7 sites (4 sites without evidence of 1940s infestation and 3 sites with evidence of severe spruce beetle infestation in the 1940s) across the Flat Tops study area. Plots were located using maps of the presence/absence of the 1940s infestation [5]. We field verified that our sites were located in areas affected by the 1940s infestation by locating large, dead, standing snags with spruce beetle galleries. At each site we collected data from a cluster of 10 randomly-located 100 m^2 plots. For each tree in the plot, we recorded the species, the diameter at breast height (DBH), and tree status (live, dead, or fallen). We then aggregated data for stands that experienced and did not experience severe spruce beetle infestation in the 1940s and calculated the 2000s density of live spruce and fir. We then compared 2000s stand structure and composition in stands uninfested and infested during the 1940s.

Finally, we used spatial data to assess if these structural differences between stands uninfested and infested during the 1940s affected the distribution of 1997–2012 infestation within the Flat Tops. We overlaid a 990 x 990 m grid of 1997–2012 spruce beetle infestation presence/absence with a 990 x 990 m grid of 1940s infestation presence/absence and calculated the area of overlap.

Results

Biophysical drivers of the 1997–2012 spruce beetle infestation

Across the Southern Rocky Mountain study region, spruce beetles infested approximately 15% of the spruce-fir zone over the period from 1997–2012 (areas mapped as infested in ADS surveys 1998–2013; Fig 1A). Over this time period, the Flat Tops study area has experienced very little infestation (2% of the spruce fir-zone recorded presence of infestation; Fig 1). While the annual area infested by spruce beetles across the Southern Rocky Mountain study region has been growing since 1998 [55], ADS data indicate that most spruce beetle activity in the Flat Tops study area occurred prior to 2005 (S1 Fig).

Across the Southern Rocky Mountain study region, spatial overlay analysis revealed meaningful differences between the conditional probabilities of uninfested and infested spruce-fir forest given climate and forest structure variables (Fig 2). Contrary to expectations, spruce beetle infestation was less likely in areas with high maximum August temperatures ($\geq$19.5°C; Fig 2B). However this difference was only meaningful in areas where the average maximum temperature was greater than $\geq$20.5°C. Areas with cooler maximum August temperatures ($<$18.5°C) were more likely to be infested. Also contrary to expectation, areas with high annual precipitation ($\geq$ 1050 mm/year) were more likely to experience spruce beetle infestation, while areas with moderately low annual precipitation (650–849 mm/year) were less likely to experience infestation (Fig 2A). There were no meaningful differences between the probabilities of uninfested and infested forest given any of the four classes of minimum March temperature or minimum October temperature (Fig 2C and 2D).

We also found that forest structure differed between forests uninfested and infested by spruce beetles in 1997–2012 (Fig 2E). Spruce beetle infestation was more likely to occur in areas with

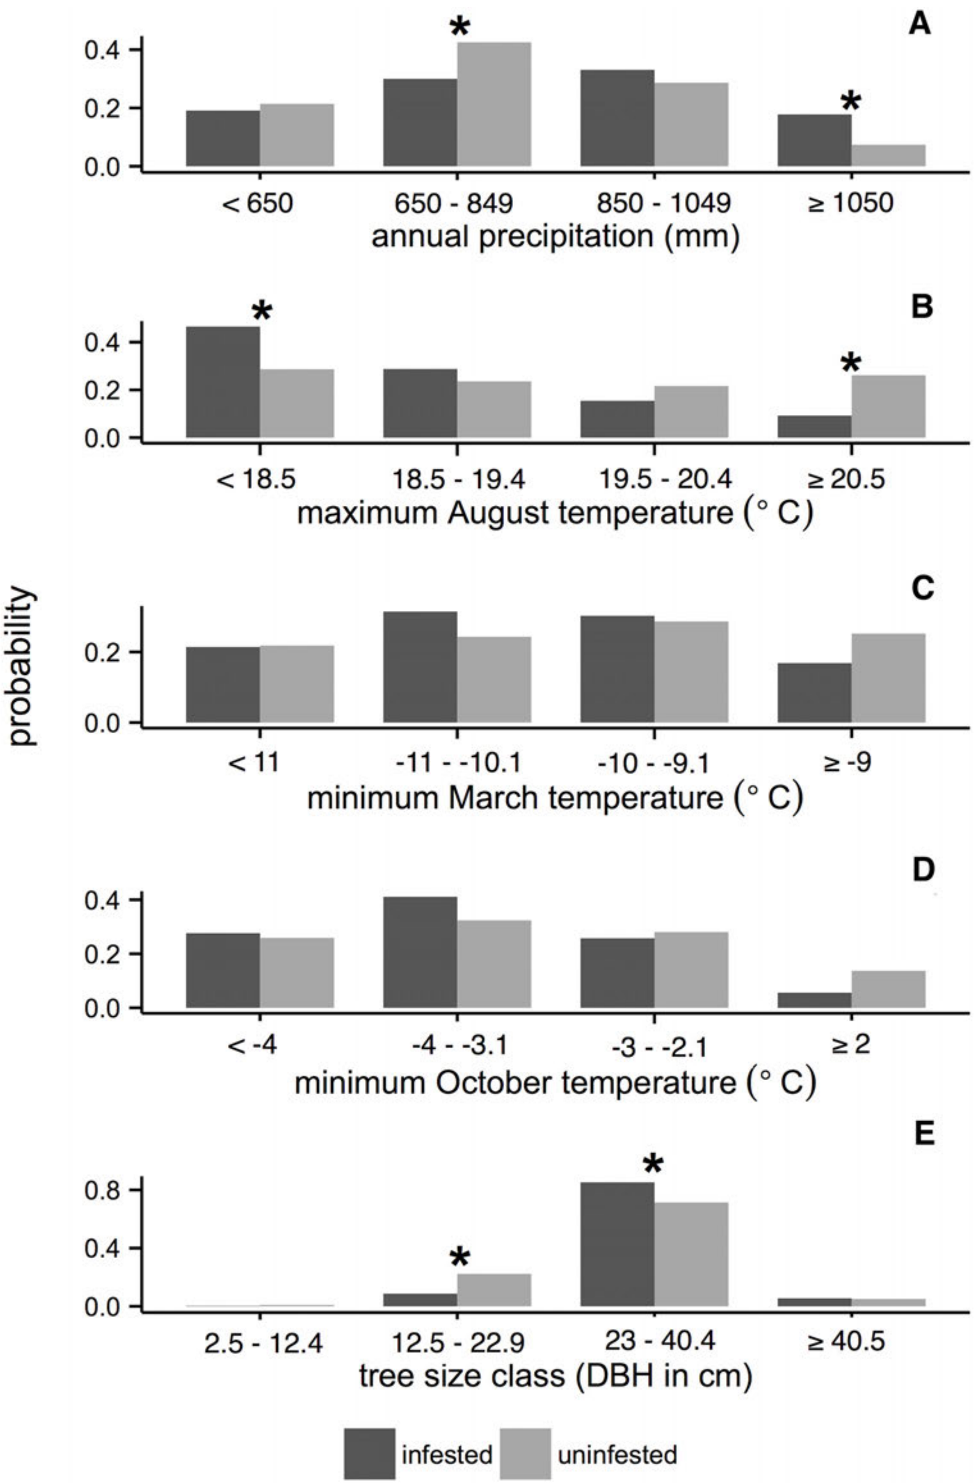

Fig 2. Conditional probabilities of the presence/absence of spruce beetle infestation (1997–2012) given selected bioclimatic variables in the Southern Rocky Mountains study region. (A) annual precipitation, (B) maximum August temperature, (C) minimum March temperature, (D) minimum October temperature, and (E) tree size class for uninfested and infested stands. Dark gray bars indicate conditional probability of spruce beetle infestation given that value of a bioclimate variable across the Southern Rocky Mountain study region. Light gray bars indicate the conditional probability of uninfested forest. The asterisk symbol (*) above a pair of bars indicates a meaningful difference between conditional probability of uninfested and infested forest (i.e. difference > 10%, see *Methods* for more description). Note y-axes extend over different ranges.

doi:10.1371/journal.pone.0127975.g002

large diameter trees (≥ 23 cm DBH; Fig 2E). For stands with smaller diameter trees (< 23 cm DBH), the probability of infestation was < 0.22 (Fig 2E).

The multivariate model of 2000s spruce beetle uninfested and infested forest performed reasonably well. The CIF model correctly predicted 809 of the 1000 pixels with spruce beetle infestation (i.e. sensitivity = 0.81), and correctly predicted 819 of the 1000 pixels without spruce beetle infestation (i.e., specificity = 0.82). Variables important in predicting 2000s spruce beetle infestation included maximum August temperature, annual precipitation, and tree size class (Fig 3A). Spruce beetle infestation was unlikely to occur in areas with maximum August temperatures above 20.3°C (probability of infestation = 0.276). Infestation was particularly unlikely when temperatures exceed 21.6°C (probability of infestation = 0.164; Fig 3B). However, more than 75% of the study area was characterized by 1997–2012 mean maximum August temperatures cooler than 20.3°C (S2 Fig). In these areas, spruce beetle infestation was particularly like to occur in areas with large trees (≥ 23 cm DBH; Fig 3A) and high precipitation (>1063 mm/year) (Fig 3B and S2 Fig).

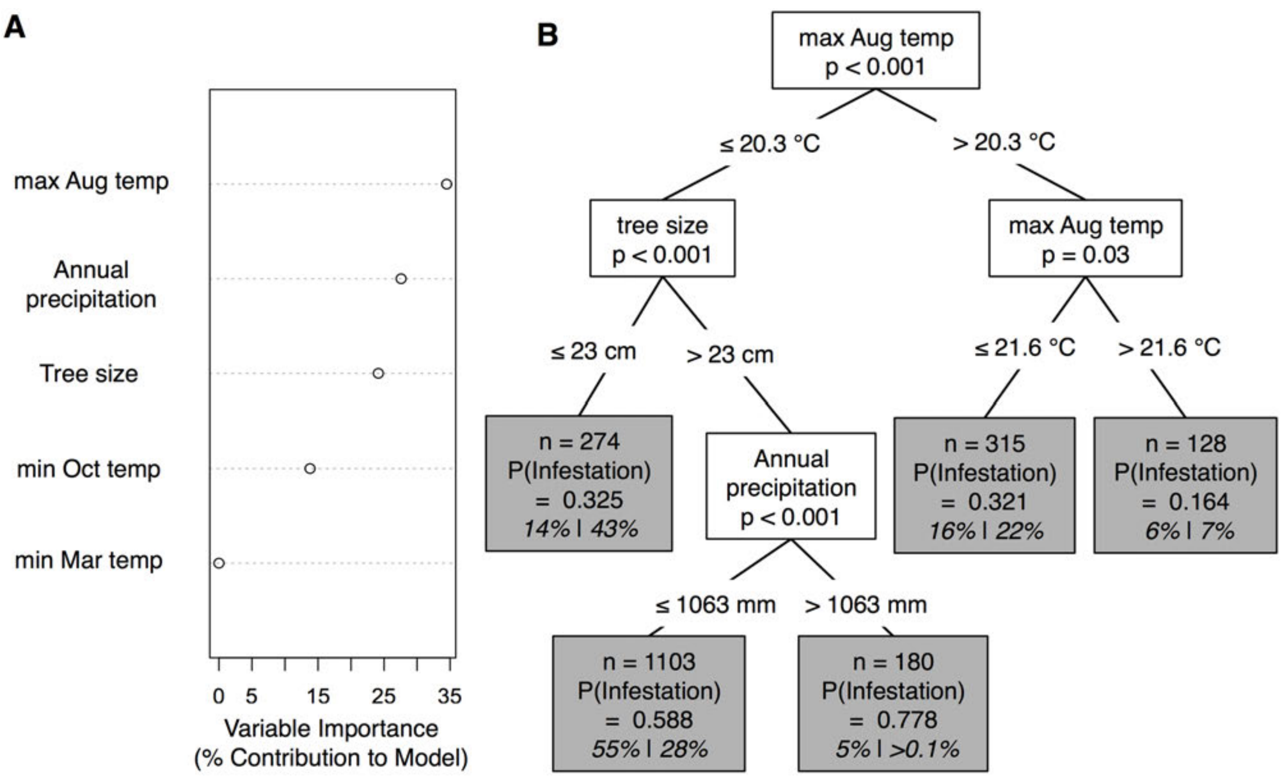

Fig 3. Results from conditional inference forest analysis of the presence/absence of spruce beetle infestation with climate and forest structure data in the Southern Rocky Mountain study region. (A) Conditional variable importance for the five biophysical variables used to model the occurrence of spruce beetle infestation across the Southern Rocky Mountain study region. Conditional variable importance scores were calculated following the Random Forest principle of mean decrease in accuracy and then transformed to express the contribution of each variable to the overall model. Higher values indicate variables are more important to the classification. Conditional variable importance scores represent 1000 model runs. All trees were built using a random sample of 2000 cases, stratified by the presence/absence of spruce beetle infestation (1000 infested and 1000 uninfested). Overall prediction accuracy is 81%. (B) A classification tree for determining the presence of spruce beetle infestation from uninfested spruce-fir stands across the Southern Rocky Mountains study region. On the tree, if condition is satisfied, proceed to the left of the tree. Tree nodes (gray boxes) describe the number of pixels across the entire Southern Rocky Mountain study region that meet the condition and the probability of spruce beetle infestation. The gray boxes also list the percent of pixels that meet the conditions for the entire Southern Rocky Mountain Study region and just the Flat Tops study area (Southern Rocky Mountain Study Region % | Flat Tops study area %). If the percent of pixels that meet the condition are greatly different (>10%) for the Flat Tops study area than for entire Southern Rocky Mountain Study region, then that condition is disproportionately important in constraining/promoting infestation within the Flat Tops study area.

Effects of the 1940s spruce beetle infestation on the 1997–2012 infestation

Applying the decision tree to the pixels within the Flat Tops study area provided insight into the biophysical predictors important in constraining infestation in the Flat Tops study area. Across the Flat Top study area about 29% of pixels were characterized by 1997–2012 mean maximum August temperatures unsuitable for infestation (<20.3°C; Fig 3B and S2 Fig). An additional 43% of the pixels within the Flat Tops study area were characterized by small diameter trees (<23 cm DBH), which inhibit infestation (Fig 3B and S2 Fig). In comparison to the entire Southern Rocky Mountain study region, the percent of pixels with small diameter trees (<23 cm DBH) in the Flat Tops study area was three times greater (43% vs. 14%, for the Flat Tops study area and entire Southern Rocky Mountain study region, respectively; Fig 3B and S2 Fig). As a result, the percentage of pixels that were split based on annual precipitation was far lower for the Flat Tops study than the Southern Rocky Mountain study region.

Within the Flat Tops study area, comparison of forest structure of 990 x 990 m in areas uninfested and infested by the 1940s infestation indicates that infested stands are characterized by smaller tree sizes (12.5–22.9 cm DBH) 60 years following infestation (Fig 4). This coarse-scale finding based on mapping from aerial photographs (Table 1) is supported by stand-level field measurements. During the 1997–2012 period of spruce beetle infestation, field data revealed that in comparison with stands infested during the 1940s, stands not infested in the 1940s had consistently higher densities of spruce in all size classes including the largest class (i.e. $\geq$ 40.5 cm DBH; Fig 5). In contrast, 60 years following the 1940s spruce beetle outbreak

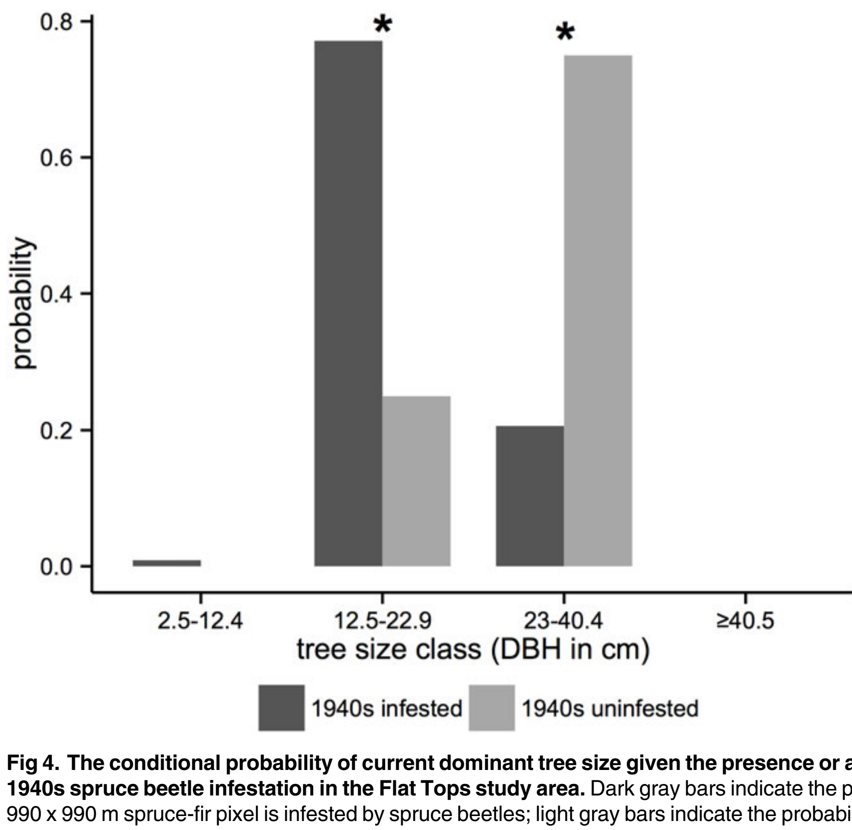

Fig 4. The conditional probability of current dominant tree size given the presence or absence of the 1940s spruce beetle infestation in the Flat Tops study area. Dark gray bars indicate the probability that a 990 x 990 m spruce-fir pixel is infested by spruce beetles; light gray bars indicate the probability a pixel is uninfested. The asterisk symbol (*) above a pair of bars indicates a meaningful difference between conditional probability of uninfested and infested forest.

doi:10.1371/journal.pone.0127975.g004

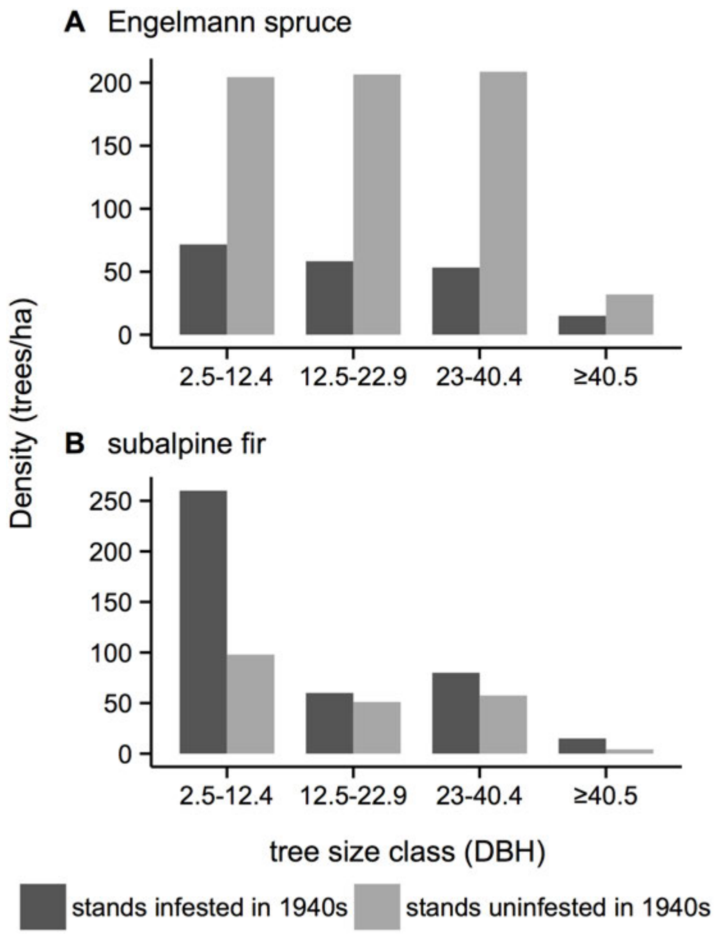

Fig 5. Current (2000s) tree size class distributions in stands uninfested and infested during the 1940s infestation within the Flat Tops and adjacent areas of White River National Forest. Data represent the aggregate of all plots (stands uninfested during the 1940s outbreak, n = 4 sites each with 10 ca. 100 m^2 plots; stands infested during 1940s outbreak, n = 3 sites each with 10 ca. 100 m^2 plots).

doi:10.1371/journal.pone.0127975.g005

subalpine fir was more abundant in all size classes in stands infested during the 1940s outbreak compared to uninfested stands. Concordantly, we found no overlap between areas infested during the 1940s and the 2000s infestation (Fig 1A). Within the Flat Tops region only three 990 x 990 m pixels were infested in 1997–2012, but none of those overlapped with the 254 pixels infested in the 1940s. Instead, all pixels infested in 1997–2012 were located in areas with large diameter trees ($\geq$ 23 cm DBH).

Discussion

Across the Southern Rocky Mountain study area, spruce beetle infestation was more likely to occur in areas with cool to moderately warm mean maximum August temperatures and higher amounts of annual precipitation. Although these results at first glance seem counter-intuitive given the importance of drought in triggering spruce beetle outbreaks [28–30,56], our results are spatial associations of infestation with mean conditions rather than temporal associations with drought events measured as departures from longer-term average conditions. While bark beetles preferentially attack drought-stressed trees [28, 29], our results describe habitat suitability for spruce beetle, which clearly is greater at the cooler and wetter sites where spruce is more common. In contrast, warmer sites are likely to be characterized by greater proportions of non-host species (e.g. lodgepole pine) and provide less potential for spruce beetle outbreak. Overall, we interpret the association of spruce beetle infestation with cooler and wetter sites as being explained primarily by the greater presence of host species at those sites.

Across the Southern Rocky Mountain study area, spruce beetle infestations have occurred overwhelmingly in spruce-fir stands dominated by large trees ($\geq$ 23 cm DBH). This corresponds with empirical results from Grand Mesa National Forest in western Colorado, which showed early 2000s spruce beetle infestation was significantly more likely in spruce larger than 24 cm DBH [57]. Spruce beetles prefer large trees, which provide both higher amounts of phloem for beetles to feed upon and thicker bark that increases overwinter survival rates [32].

While both climate and forest structure interacted to drive the occurrence of spruce beetle infestation across the Southern Rocky Mountains, our data suggest that the current infestation in the Flat Tops was severely constrained by a low proportion of large trees ($\geq$ 23 cm DBH). Our model suggests that climate variables were conducive to bark beetle infestation across most of the Flat Tops study area. Relative to the entire Southern Rocky Mountains (inclusive of the Flat Tops), infestation in the Flat Tops was severely constrained by forest structure. The paucity of large diameter trees within the Flat Tops study area was a result of a severe spruce beetle outbreak that occurred 60 years ago. Stands infested during the 1940s in Flat Tops were notably depleted of large spruce relative to uninfested stands. Given the preference of spruce beetles for large diameter spruce and relative absence of large diameter spruce in areas affected by the 1940s infestation, it is not surprising that we found no overlap between areas of current infestation and areas affected by the 1940s infestation. These results support the hypothesis that stands affected by severe spruce beetle infestation are less susceptible to infestation c. 60 years later due to a decrease in large diameter spruce.

The 1940s spruce beetle infestation in northwestern Colorado was most severe in the Flat Tops area, where three-quarters of the 1940s spruce beetle-induced tree mortality occurred [32]. Nearby spruce-fir forests in Grand Mesa National Forest also experienced 1940s spruce beetle infestation, however it was significantly less severe [32,58]. For instance, the basal area of beetle-killed spruce was ca. 4—7.5x greater in the Flat Tops than in Grand Mesa [58]. In contrast, the 1997–2012 spruce beetle infestation has affected 2% of the spruce-fir forest in Flat Tops and 19% of Grand Mesa's spruce-fir forest [34]. This suggests that the 1940s infestation in Grand Mesa was not severe enough to cause significant host depletion and thus Grand Mesa forests were much more susceptible to the 1997–2012 infestation.

Our study is notably limited by the availability of spatial datasets of both the 2000 and 1940s spruce beetle infestation. In particular we note that comparisons between these two datasets may be limited by the different methods used to map spruce beetle infestation (interpretation of aerial photography vs. aerial sketch mapping). However, our ability to accurately model the 1997–2012 infestation from a few ecologically meaningful biophysical predictors and the agreement between field data and maps of the 1940s outbreak suggest these datasets were appropriate for coarse assessment of the linkage between spruce beetle outbreaks. Subsequent analyses with datasets depicting severity of infestation at a fine spatial resolution would serve to advance our understanding of this linkage, however to our knowledge no such datasets exist for the Southern Rocky Mountains.

The findings of the current study indicate that at a broad spatial scale, severe spruce beetle outbreaks are linked disturbances (sensu [3]) at least over the 60-year period considered in our study. We suggest that the host depletion feedback not only may cause infestation collapse (sensu [32]), but may enhance ecological resistance (sensu [59]) of beetle-affected systems to spruce beetle infestation through long lasting effects of host depletion. Given that predictions of future beetle disturbance from climate-driven beetle population models do not incorporate process dynamics of disturbance-caused tree mortality and forest recovery [60], our results underscore the need for additional research on forecasting future forest dynamics, which may affect host availability for bark beetle infestations. In particular, the dampening effect of the 1940s spruce beetle infestation on the spread of the early 2000s infestation in the Southern Rocky Mountains implies that future infestations in the 21st century may be similarly restricted by disturbance-caused depletion of susceptible hosts.

Most previous studies of linked disturbances in the coniferous forests of the Rocky Mountain region have addressed how previous fire affects subsequent bark beetle outbreaks [61,62] or how previous bark beetle outbreaks alters the probability, extent or severity of subsequent fire [5,15,20,36]. To our knowledge this is the first broad-scale analysis of how prior bark beetle outbreak affects susceptibility to subsequent bark beetle outbreak. Our findings of a dampening effect of the 1940s spruce beetle outbreak on susceptibility to spruce beetle infestation 60 years later highlights the need for incorporating the process dynamics of tree growth and mortality in predictive modeling of the likelihood of bark beetle outbreaks under future climate scenarios. Simulation modeling of the probability of future insect outbreaks based on climate suitability for the growth of the insect populations has been important in identifying likely trends over relatively short time periods. However, our results show that even at a time scale of 60 years, failure to incorporate negative feedbacks into prediction of future bark beetle outbreaks is likely to over-predict the extent or severity of future outbreaks and by implication under-estimate forest resistance to altered disturbance regimes under climate change.

Supporting Information

S1 Fig. Time series displaying the percentage of spruce-fir forest infested by spruce beetles. Data is shown for the Southern Rocky Mountain Ecoregion (inclusive of the Flat Tops) and only in the Flat Tops. For each region, the percent area was calculated by the determining the number of 990 x 990 m pixels within the spruce-fir zone identified as infested by the United States Forest Service in annual Aerial Detection Surveys (ADS) and dividing it by the total number of spruce-fir pixels.
(TIFF)

S2 Fig. The importance of biophysical predictors in promoting spruce beetle infestation the Southern Rocky Mountain study region. Maps of (A) mean maximum August temperature (1997–2012), (B) mean annual precipitation (1997–2012), and (C) tree size class. The probability of infestation (derived from the classification tree in Fig 3B) is indicated by pixel color. Dark green indicates a probability of infestation <0.3, light green indicates a probability of infestation of 0.3–0.49, dark yellow indicates a probability of infestation 0.5–0.69, and dark brown indicates a probability of infestation >0.7. Sources are given in Table 1.

Conservation Planning for US National Forests: Conducting Comprehensive Biodiversity Assessments

BARRY R. NOON, DENNIS D. MURPHY, STEVEN R. BEISSINGER, MARK L. SHAFFER, AND DOMINICK DELLASALA

The US Forest Service has proposed new regulations under the National Forest Management Act that would replace a long-standing requirement that the agency manage its lands "to maintain viable populations of existing native and desired non-native vertebrate species." In its place, the Forest Service would be obligated merely to assess ecosystem and species diversity. A landscape assessment process would rely on ecosystem-level surrogate measures, such as maps of vegetation communities and soils, to estimate species diversity. Reliance on such "coarse-filter" assessment techniques is problematic because there tends to be poor concordance between species distributions predicted by vegetation models and observations from species surveys. The proposed changes would increase the likelihood of continued declines in biodiversity and fail to address the original intent of the act. We contend that responsible stewardship requires a comprehensive strategy that includes not only coarse-filter, ecosystem-level assessment but also fine-filter, species-level assessments and viability assessments for at-risk species.

Keywords: forestry, forests, management, policy, conservation

The US National Forest Management Act (NFMA) is an essential statute for maintaining biotic diversity on 192 million acres of national forests and national grasslands. It was enacted in 1976 as reform legislation in response to environmental impacts from timber harvest, grazing, and mining on national forest lands, which the public and Congress found increasingly unacceptable (Wilkinson and Anderson 1987). Among many provisions for resource protection, a primary emphasis was the protection of individual species. The statutory language of NFMA requires management of the national forests and grasslands to "provide for diversity of plant and animal communities based on the suitability and capability of the specific land area in order to meet overall multiple-use objectives" (16 US Code 1604[g][3][B]). Since 1982, the regulations governing implementation of NFMA have addressed this diversity provision by requiring that "fish and wildlife habitat shall be managed to maintain viable populations of existing native and desired non-native vertebrate species in the planning area" (36 Code of Federal Regulations, sec. 219.19, app. 13). Revisions to NFMA regulations adopted in 2000 retained the requirement for viable populations and expanded it to include all plant and animal species (Federal Register 65 [218]: 67514–67581).

Although NFMA has remained essentially unchanged since its enactment, the US Forest Service has now proposed regulations that eliminate an explicit population viability requirement and that restrict management responsibility to vertebrates and vascular plants (Federal Register 67 [235]: 72770–72816). The proposed regulations require only a "hierarchical, sequential approach to consider and assess both ecosystem diversity and species diversity" and that the Forest Service "identify species for which substantive evidence exists that continued persistence in the planning or assessment area is at risk, specific risks or threats to these species, and measures required for their conservation or restoration" (Federal Register 67 [235]: 72801). No specific language to compel species-level analyses of viability has been proposed. Moreover, the proposed regulations would subsume the existing species conservation requirement into a landscape assessment process that would use a variety of unproven

ecosystem-level surrogates to estimate species diversity without necessarily examining the condition or status of individual species. Although not explicitly stated, the substance of these proposed regulations hinges on two underlying assumptions: (1) Land-use planning that relies solely on such "coarse-filter" (Hunter et al. 1988) approaches to assess the distributions and status of ecological communities is adequate to assess how well the needs of all their constituent species will be met, and (2) the uncertainty that accompanies indirect assessments of species status provided by coarse-filter tools is acceptable because species-level assessments are too difficult or too expensive to implement. These assumptions are not only counter to current understanding of the role and dynamics of specific species in sustaining ecosystem processes (e.g., Kinzig et al. 2002), they also negate the nature and appropriate role of population viability analyses in land-use planning.

Inadequacies of assessments employing only a coarse-filter approach

To understand the functioning of any complex system, it is necessary to identify and attempt to elucidate the parts that it comprises. For ecological systems, the most fundamental "parts" are species. Sir Arthur Tansley originally defined ecosystems as biotic communities or assemblages of species and their physical environment in specific places (Tansley 1935). Directly contradicting this view of ecosystems as collections of interacting species, the proposed regulations focus resource assessments almost entirely on vegetation types and successional stages, geology, landforms, and soils. The logic behind this coarse-filter approach is that the majority of species can be protected by conserving examples of natural vegetation communities, obviating the need to evaluate the status of each species individually (Noss 1987, Noss and Cooperrider 1994).

The original intent of coarse-filter approaches to landscape planning was to provide distribution maps of land cover that could be used to inform the conservation of entire species assemblages, including communities of interacting or potentially interacting species (Jennings 2000, Groves et al. 2002). Broadscale applications of coarse-filter methods have relied on ecoregional classifications determined by a variety of measures of climate, substrate, and plant composition. However, they commonly and often exclusively default to dominant vegetation, because vegetation types can be assessed by remote-sensing technologies and have been linked, using general habitat models, to the distributions of many vertebrate species (Scott et al. 1993). For example, recent planning efforts by the Forest Service for 4.4 million hectares of public forests and grasslands in the Sierra Nevada of California assessed the effects of various management alternatives on vertebrate species using wildlife–habitat relationship models (Mayer and Laudenslayer 1988) to classify habitats based on three attributes—dominant vegetation type, successional stage, and canopy closure. When these models were coupled with a vegetation growth and yield model (Davis and Johnson 1987), they allowed a comparison of how competing forest management scenarios would be likely to affect future wildlife populations (Forest Service 2001).

Coarse-filter approaches to assess the viability of species for land-use planning purposes can provide cost-efficient, indirect methods of assessing species distributions, but to assess the viability of species, at least three assumptions must hold true: (1) Attributes that define the coarse filter (i.e., dominant vegetation types) are sufficient and reliable surrogates for habitat and can effectively predict the occurrence of a given species; (2) managing coarse-filter attributes will address the factor(s) currently limiting abundance, density, and persistence of each species; and (3) the spatial resolution of the coarse filter matches the scale at which given species respond to environmental heterogeneity. Although these assumptions may be valid for some species in many circumstances, especially species that are small-bodied, abundant, and tightly linked to a particular vegetation community, the likelihood that the assumptions are met for all, or even most, species in an assemblage is low. For that reason, landscape planning employs "fine-filter" assessments, which are based on direct measures of the status and trends of individual species or on models of population viability to evaluate the needs of species at risk of decline.

The utility of the coarse-filter approach has been tested for many individual species with equivocal success (see Scott et al. [2002]). In general, there has been poor concordance between predicted and observed distributions. Commission errors (false positives, or predictions that a species is present when it is absent) have been shown to be more common than omission errors (false negatives, or predictions that a species is absent when it is present) at spatial scales appropriate to regional conservation planning—for example, vertebrates in the state of Maine and in national parks in Utah and breeding birds in California (Edwards et al. 1996, Boone and Krohn 1999, 2000, Garrison et al. 2000, Garrison and Lupo 2002, Robertson et al. 2002). Thus, coarse-filter assessments often overestimate the presence and, presumably, the viability of species on the planning landscape.

Only by increasing the resolution of the coarse filter (which reduces the area predicted to be suitable habitat for the species), as well as the number of land-cover types (usually by stratifying the vegetation communities more finely), can commission and omission errors be simultaneously reduced (Karl et al. 2000). Prediction errors are also related to ecological attributes of a species: Species that are rare, colonial, or habitat specialists, or that have small home ranges, are most likely to be misclassified (Karl et al. 2000, Scott et al. 2002). The misclassified groups of species usually include those most likely to be at risk of population declines or extirpation—that is, those that should be targets of conservation planning efforts (McKinney 1997). In sum, these prediction errors suggest that employing a coarse-filter approach alone is inadequate to meet NFMA requirements to provide for the diversity and viability of plant and animal communities.

Integrating the fine filter with population viability analysis

Coarse- and fine-filter approaches to conservation planning differ in both the extent and resolution of measurement employed and the targeted level of biological organization. In general, mapped coarse-filter attributes reflect higher-level processes and patterns that arise, for example, from disturbance processes that operate across entire landscapes. For pragmatic reasons, coarse-filter attributes considered during the planning process are often those that can be measured inexpensively using remote imagery. Coarse filters rarely will accurately reflect the complex and dynamic habitat requirements of any individual species. In contrast, a fine filter makes measurements directly at the species level for the subset of species whose habitat requirements were not captured by the attributes that define the coarse filter.

Neither coarse- nor fine-filter assessments alone can prescribe the extent or area of habitat necessary to maintain viable populations of plant and animal species on the landscape. Many rare and declining species are limited primarily by the availability of suitable habitat (Wilcove et al. 1998), and the viability of such species depends to a great extent on how much of their habitat is conserved. Population viability analysis (PVA) is an in-depth method of fine-filter assessment used to evaluate habitat loss or similar risk factors for specific species (Boyce 2002, Shaffer et al. 2002).

An assessment approach that includes both coarse and fine filters and PVA was recommended by the Committee of Scientists to the US Forest Service and incorporated into the 2000 NFMA regulations (COS 1999). In addition to rare and at-risk species, the committee recommended that two groups of species be evaluated using fine filters—those that provide comprehensive information on the state of a given ecosystem (indicator species) and those that play significant functional roles in ecosystems (focal species). The latter category includes species that contribute disproportionately to the transfer of matter and energy (e.g., keystone species), structure the environment and create opportunities for additional species (e.g., ecological engineers), or exercise control over competitive dominants, thereby promoting increased biotic diversity (e.g., strong interactors). Thus, fine-filter assessments might be needed for 10 to 50 of the 200 to 1100 species typically evaluated in regional planning efforts carried out by the Forest Service and may need to include select invertebrates as well as vertebrates and plants.

Formal PVAs are needed only for species in decline or at high risk or for species with such functional significance that their loss might have unacceptable ecological effects. Many methods of viability assessment exist to accommodate diverse sources and amounts of data (Beissinger and Westphal 1998, Andelman et al. 2001). All methods explicitly or implicitly require some sort of model that relates population dynamics to environmental variables, including variables affected by management. The range of available methods offers a tradeoff between complexity of analysis and generality of results.

Population viability analysis is neither inherently difficult nor expensive, but it does require thoughtful model choice and construction and good judgment in the implementation of analyses. Perhaps the most demanding aspect of building realistic PVA models for assessment of alternative management scenarios is acquisition of sufficient data to yield accurate and precise parameter estimates (Beissinger and Westphal 1998). These models then permit reliable assessments of alternative management scenarios (Noon and McKelvey 1996). The choice of models and data collection methods depends in part on the life history characteristics of the species to be assessed, the quality and quantity of existing data, the time and money available for additional data acquisition, and the resolution and extent of analysis (Beissinger and Westphal 1998, Andelman et al. 2001). A method that uses a formal mathematical model of analysis is often preferable to less quantitative methods for analyzing viability when there is sufficient knowledge of demography, dispersal, habitat use, and threats.

Currently, population viability analyses are required to address the viability requirements of NFMA. In the context of the act, viable populations consist of "self-sustaining and interacting populations that are well distributed through the species' range. Self-sustaining populations are those that are sufficiently abundant and have sufficient diversity to display the array of life history strategies and forms to provide for their long-term persistence and adaptability over time" (Federal Register 65 [218]: 67580–67581). Many population attributes included in this definition can be evaluated using population viability analyses, but they cannot be addressed solely through the application of coarse-filter analyses.

A scientifically credible approach to national forest planning

An expert panel convened by the National Center for Ecological Analysis and Synthesis, at the request of the Forest Service, concluded that "viability assessment is an essential component of ongoing forest management and forest planning processes. A variety of methods can and should be incorporated into viability assessments" (Andelman et al. 2001, p. 136). A scientifically credible approach to management of a diversity of plant and animal communities in US national forests and national grasslands combines coarse-filter and fine-filter approaches to identify conservation targets, including the judicious use of PVA for focal species and species at risk. Scientifically valid and pragmatic management does not require that the status of all species be directly assessed. But failure to detect declining species and to address the putative threats to their persistence leaves only the prohibitive provisions of the Endangered Species Act to serve as a safety net.

Although coarse-filter, fine-filter, and PVA assessment tools are imperfect, their weaknesses are sufficiently understood that the information they provide is, on balance, useful, and the Forest Service's failure to require their use is irresponsible. Insights provided by the use of these tools will inform managers about the condition of the ecosystems they are charged with protecting and the likely consequences of the management decisions they are empowered to make. Acting on these insights to change management practices when needed will aid biodiversity conservation and enable the Forest Service to meet its stewardship responsibilities.

ECOSYSTEMS

Fire Severity in Conifer Forests of the Sierra Nevada, California

Dennis C. Odion[1,2]* and Chad T. Hanson[3]

[1]Institute for Computational Earth Systems Science, University of California, Santa Barbara, California 93106, USA; [2]Department of Biology, Southern Oregon University, 1250 Siskiyou Blvd, Ashland, OR 97520-5011, USA; [3]Graduate Group in Ecology, Department of Plant Sciences, University of California, Davis, California 95616, USA

Abstract

Natural disturbances are an important source of environmental heterogeneity that have been linked to species diversity in ecosystems. However, spatial and temporal patterns of disturbances are often evaluated separately. Consequently, rates and scales of existing disturbance processes and their effects on biodiversity are often uncertain. We have studied both spatial and temporal patterns of contemporary fires in the Sierra Nevada Mountains, California, USA. Patterns of fire severity were analyzed for conifer forests in the three largest fires since 1999. These fires account for most cumulative area that has burned in recent years. They burned relatively remote areas where there was little timber management. To better characterize high-severity fire, we analyzed its effect on the survival of pines. We evaluated temporal patterns of fire since 1950 in the larger landscapes in which the three fires occurred. Finally, we evaluated the utility of a metric for the effects of fire suppression. Known as Condition Class it is now being used throughout the United States to predict where fire will be uncharacteristically severe. Contrary to the assumptions of fire management, we found that high-severity fire was uncommon. Moreover, pines were remarkably tolerant of it. The wildfires helped to restore landscape structure and heterogeneity, as well as producing fire effects associated with natural diversity. However, even with large recent fires, rates of burning are relatively low due to modern fire management. Condition Class was not able to predict patterns of high-severity fire. Our findings underscore the need to conduct more comprehensive assessments of existing disturbance regimes and to determine whether natural disturbances are occurring at rates and scales compatible with the maintenance of biodiversity.

Key words: Condition Class; ecological restoration; Jeffrey and ponderosa pine; fire rotation interval; fire severity; fire spread; mixed conifer forests; spatial heterogeneity.

Introduction

The diversity of species in ecosystems is linked to natural disturbances and the environmental heterogeneity they create (Connell 1978; Huston 1979). However, managing the rates and scales of disturbance processes to allow for natural levels of environmental heterogeneity has its inherent risks and difficulties. This is particularly true for large disturbances that have profound influences on ecosystem structure, function, and composition (Turner and Dale 1998). Thus, although natural disturbances are vital to ecosystem integrity, maintaining their full range of variability is often at odds with management (Holling and Meffe 1996). How can disturbance-mediated environmental heterogeneity be most effectively maintained or restored where it has been suppressed over large areas? How can we recognize the levels and types of disturbance and heterogeneity that are appropriate for maintaining biodiversity? Here we explore these questions by focusing on the management of fire. Enormous resources are expended

Received 23 September 2005; accepted 24 January 2006; published online 17 November 2006.

worldwide in efforts to manage this important disturbance or restore its effects.

To date there has been little direct assessment of how fire-mediated spatial heterogeneity might be restored or managed for in many fire-prone systems, such as the conifer forests of western North America (Rocca 2004). In many of these areas management policy is focused on the use of mechanical treatments to modify forest structure as a means of counteracting the effects of fire suppression. These efforts are controversial and are often not based on a sound understanding of the ecological role of fire as a disturbance process and the methods needed to restore its effects (Johnson 2003; DellaSala and others 2004). Perhaps nowhere in western North America has the appropriateness of structure-versus process-based forest management approaches been more controversial than in the conifer forests of the Sierra Nevada Mountains of California, USA (Stephenson 1999; Miller and Urban 2000).

Since the 1850s, grazing and fire suppression have reduced fire frequencies in the forests of the Sierra Nevada (Stephenson 1999; Miller and Urban 2000). The prevailing management view is that, because of fire exclusion, forest fires in the Sierra, which once varied considerably in severity, are now almost exclusively large, high-severity, stand-replacing events (Skinner and Chang 1996). As a consequence, an extensive program for the management of national forest lands was initiated in 2004. Its goal is to modify the structure of 283,000 ha of vegetation per decade, mainly in the dominant mixed conifer forests (USDA 2004). However, the actual severity of contemporary fire on these lands has yet to be analyzed to determine how well the prevailing view of dramatically increased fire severity and decreased heterogeneity is supported by empirical evidence.

Under the provisions of the National Forest Management Act of 1976, the national forests in the Sierra Nevada and throughout the United States are directed to ''provide for diversity of plant and animal communities.'' Natural variation and the maintenance of biodiversity in ecosystems can be assessed based on the concept of ecological integrity. ''Ecological integrity'' refers to ecosystem wholeness, including the occurrence of ecological processes such as natural disturbances at appropriate rates and scales to maintain natural levels of biodiversity (Karr 1991; Angermeier and Karr 1994). To determine the appropriateness of process-based versus structure-based management approaches for the maintenance biodiversity, we need to understand how ecological integrity is affected by contemporary fires. Thus, one of our primary objectives is to evaluate the rates and scales of contemporary fire as a disturbance process and assess their appropriateness in the context of ecological integrity.

To pursue this objective, we analyzed fire-severity data from the three largest fires that have occurred in the Sierra Nevada since 1999, accounting for most of the area burned over this time. These fires occurred in landscapes where timber harvest and silvicultural activities have been uncommon. After these burns, fire severity was classified by multi–US agency Burned Area Emergency Rehabilitation (BAER) teams. The BAER fire-severity data are derived from pre- and post-burn satellite and photo images and are used to map the effects of the fire on overstory vegetation canopy. We supplement these data with measures of ponderosa and Jeffrey pine mortality taken on the ground in areas of high-severity as defined by BAER. These pines have been harvested in many areas, and there is considerable interest in restoring their natural abundance (SNEP 1996). To gain further insight into the rates and scales of disturbance by fire under current management, we also evaluated temporal patterns of burning since 1950 in the broader landscapes in which the three fires occurred. Fire suppression has been mechanized in its current form since about 1950.

Another of our objectives was to evaluate the effectiveness of a national approach for the assessment of fire regimes and to discover how they have changed. The current basis for this approach, now used throughout the United States, is Fire Regime Condition Class (hereafter Condition Class), (Hann and Bunnell 2001); see also http://www.frcc.gov). It is an index that Estimates departure from reference conditions in vegetation, fuels, and disturbance regimes. In the national forests of the Sierra Nevada, Condition Class has been based on the number of fires estimated to have been exclude in the landscape due to fire suppression. Considerable research has revealed that historically Sierran forests were burned mostly by surface fire, but that this regime has decreased dramatically due to fire suppression (Caprio and Swetnam 1995; Skinner and Chang 1996). Condition Class predicts that these circumstances will lead to a dramatic increase in fire severity and place forest ecosystems at high risk losing key components due to fire (Hann and Strohm 2003).

A new approach to mapping departure from reference conditions, LANDFIRE, is currently under development (http: www.landfire.gov). In addition to Condition Class, it relies on the rapid assessment and mapping of wildland fuels to identify potential conditions that promote fire. The use of approaches that map departure from historic reference conditions in management is advancing rapidly. In the United States, 25 million ha have been identified for fuel treatments based on Condition Class (Brown and others 2004). Thus, it is especially timely now to evaluate the efficacy of approaches that map departure from historic reference conditions as a means of predicting fire severity.

Methods

Study Areas

The Sierra Nevada Mountains of California are a high-elevation (3000–4000 + m tall), 8-million-ha, north/south-trending mountain range (Figure 1, inset). They are forested primarily by conifer vegetation. We evaluated fire severity in the three largest burns in the Sierra since 1999—the McNally, Manter, and Storrie fires. Older fires lacked comparable fire-severity data in digital form. Smaller burns since 1999 in the main part of the Sierra occurred in areas that have been altered by past or recent timber harvesting and silvicultural activities. These effects were rare in the three burns we studied. The 2002 McNally and 2000 Manter fires occurred in close proximity in the southern Sierra (Figure 1), whereas the 2000 Storrie fire occurred in the northern Sierra near the southern Cascades (Figure 2). Together, these fires encompassed most of the area of Sierran conifer forest that has burned in the last 5 years, for a total of 49,917 ha. The McNally fire burned within the Sequoia National Forest from 22 July until 27 August 2002. The Manter and Storrie fires burned in 2000, the former from 7 July until 10 August and the latter from 17 August until 17 September. Weather initially conducive to fire spread, combined with rugged topography, enabled these fires to escape control and subsequently burn for 4–5 weeks under variable weather conditions. All three of the burns occurred in landscapes where most forests were not located within known, historic fire perimeters. In the McNally fire area, shrub ages indicate that fires had occurred there 125–150 years earlier in locations where there was no mapped record of fire (Keeley and others 2005).

Conifer forests typical of midelevations of the western Sierra (for a more detailed description of Sierran forests, see Rundel and others 1977) were abundant in the landscape that burned in the fires, particularly mixed or individually dominated for-

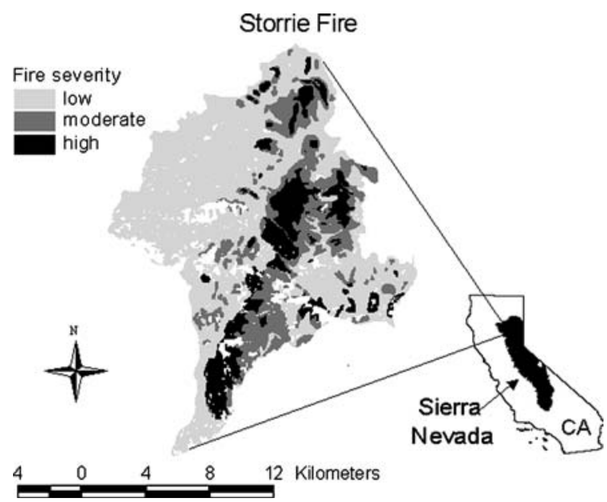

Figure 2. Patterns of burn severity in conifer-forested portions of the 2000 Storrie fire in the northern Sierra Nevada, California.

ests of red and white fir (*Abies magnifica, A. concolor*); Jeffrey, ponderosa, and sugar pine (*Pinus jeffreyi, P. ponderosa, P. lambertiana*); and incense cedar (*Calocedrus decurrens*). These species are often mixed with a deciduous and an evergreen oak (*Quercus kellogii, Q. chrysolepis*). Trees in these forests are generally tall, with many overstory trees exceeding 40–50 m. Canopies are usually closed but can be open as a result of rocky substrata and other edaphic factors, particularly on granitic ridges. Open forests are mostly dominated by Jeffrey pine, often with shrubs in the understory. These forests are common in the Manter fire area and a portion of the McNally fire area. Closed mixed conifer forests predominated in the Storrie and McNally burn areas. One conifer, Douglas-fir (*Pseudotsuga menzesii*), is common in the Storrie fire area but absent from the southern Sierra.

Spatial Patterns of Fire Severity

BAER severity Mapping is designed to identify areas with high potential for soil erosion, which is generally based on the extent to which the fire affects the vegetation overstory canopy. The ability of remotely sensed data to identify patterns of fire severity based on the spectral response of tree canopies has been demonstrated in the Sierra (van Wagtendonk and others 2004). BAER severity in the McNally fire was mapped with Landsat 7 and SPOT multispectral satellite imagery (30-m pixel resolution) obtained immediately before and after the fire (Parsons 2002). A band ratio of mid-infrared and near-infrared reflectance was calculated from pre- and postburn image data. The band ratio data were classified and interpreted by staff at the USDA Forest Service Remote Sensing Applications Center in Salt Lake City Utah. BAER severity for the Manter and Storrie fires was mapped using aerial reconnaissance, infrared aerial photographs, and ground surveys (USDA 2000, 2002). General guidelines for severity classes are from the Forest Service Handbook (USDA 1995).

The BAER mapping identified three to four classes of fire severity based on the level of canopy effects detected. *Unburned* included areas where 0–10% canopy change was detected; this classification was distinguished only in the McNally fire. *Low severity* included areas where fire-caused crown scorch (heat-induced mortality of canopy foliage) affected less than 40% of overstory canopy foliage. The unburned and low-severity classes killed primarily conifer seedlings and saplings. *Moderate severity* included areas where fire scorched 40–89% of the forest canopy in the McNally fire and 40–80% in the other two fires. This level of severity was lethal to most conifer seedlings, saplings, and many small trees, but most overstory trees survived. *High severity* included areas where 90% or more of the canopy was scorched or affected by varying levels of incineration (direct consumption of crown foliage) in the McNally fire, whereas an excess of 80% of canopy showing these effects was considered high-severity in the Manter and Storrie fires. High-severity fire generally resulted in complete understory mortality. Overstory mortality ranged from complete to mixed depending on degree of canopy scorch and consumption (incineration), forest composition, and whether the threshold was 80% or 90% canopy mortality. Depending on imagery and other factors, different thresholds may be used for these severity levels in BAER mapping.

To characterize the spatial scales of the effects of high-severity fire in conifer forests, we describe the size of high-severity patches in each fire. To better characterize the effects, we evaluated the mortality of ponderosa and Jeffrey pine in areas of high-severity burn. Mortality assessments were restricted to a section of roadway in the McNally fire along which initial crown scorch had been assessed before there was any flushing of foliage. We identified five patches along this roadway that were dominated by trees that had no green foliage after the fire. These patches had fire effects ranging from 100% crown scorch (needles killed but not consumed) to needles consumed by crown fire. Within the patches, we chose to monitor all pines showing this range of high-severity effects that had a diameter at breast height (dbh) of more than 25 cm. These trees were generally within 50 m of the road. Our survival data are from 2 years postfire, following Stephens and Finney (2002). We did not observe any further indirect mortality caused by bark beetles over this period. Some trees were considered dead and were harvested over the course of the monitoring. We classified them as having been fire-killed, thus providing a maximum estimate of direct fire-induced mortality in the five sites.

Spatial and Temporal Patterns of Fire

To help assess the landscape-level influence of fire over time under modern fire suppression management, we calculated fire rotation intervals (amount of time needed for an area the size of the area of interest to burn one time) using fire perimeter data obtained from the US Forest Service and the California Department of Forest and Fire Protection. We used the total area of fire that has occurred from 1950 to 2005. Fire perimeters are complete and accurate over this period, and modern fire suppression was a consistent factor. Only conifer-forested areas were analyzed. The landscape we used to calculate fire rotation intervals in the McNally and Manter fire region was the southern portion of the Sequoia National Forest (210,932 ha of conifer forest), along with a smaller amount of the adjacent Inyo National Forest (10,000 ha of conifer forest), including and just beyond the northern boundary of the McNally fire (Figure 1). The landscape used to calculate fire rotation intervals in the Storrie fire region was the largest area within the Lassen and Plumas National Forests; that had the same forest vegetation types found within the Storrie fire region, which was in the center of this landscape. This landscape was more strongly dominated by conifer vegetation, which totaled 488,337 ha, than the landscape where the other two burns had occured. An estimate of rotation intervals for different severity classes in the two landscapes was calculated by assuming that all the conifer forest landscape that burned from 1950 to 2005 had the same severity proportions for the respective landscapes as either the McNally and Manter fires combined or the Storrie fire. This estimate integrates frequency and severity to help illustrate the influence of fire in the two landscapes under current management.

Fire Patterns and Condition Class

We evaluated fire patterns as a function of Condition Class in detail for the McNally fire, where preburn Condition Class data were available. These Condition Class data were mapped to the same vegetation units used in the Cal-Veg map (see Data Analysis). The Condition Class data were based on preburn Fire Return Interval Departure (FRID) and have been applied in planning efforts across the Sierra (USDA 2003, 2004). In other regions of the United States, the Condition Class approach is not necessarily based only on the estimation of FRID (http://www.frcc.gov). We obtained FRID data from the Southern Sierra Geographic Information System Cooperative, which helped to prepare them and still had a version that had not been updated after the McNally fire.

The Fire Return Interval Departure is the number of fires that, on average, may have been excluded. It is based on the time when fire last occurred in an area and the estimated historical fire frequency for the type of vegetation in that area. FRID was thus calculated as:

$$\text{FRID} = (Tsf - Fri)/Fri \qquad (1)$$

where Tsf equals time since the last fire in the landscape and Fri is the estimated fire interval for a vegetation type in the landscape. Estimated historical fire intervals for forests were developed from fire scar studies undertaken in the Sierra Nevada, southern Cascades, and the mountains of northwest and southern California, as reported by Skinner and Chang (1996). Table 1 shows estimated historic fire intervals for each forest type that burned in the McNally fire.

The FRID data we obtained identify the following categories of the number of fires that, on average, may have been excluded: *Extreme* denotes more than five (Condition Class 3 in the national three-level system), *High* is between two and five (Condition Class 3), *Moderate* is between one and two (Condition Class 2), and *Low* is less than one, or not outside the estimated historic fire return interval for a forest type (Condition Class 1) (USDA 2003). We kept the high and extreme FRID categories separate in our calculations and refer to extreme FRID as ''Condition Class 3+''.

Although preburn Condition Class data used in forest planning were not available for the same assessment in the Manter and Storrie fires, we make some inferences based on previous fire history, the Cal-Veg vegetation type within the burn perimeters, and the Condition Classes that would have been assigned based on the Condition Class criteria used in the Sequoia National Forest.

To determine how Condition Class might relate to fire spread rate—a likely predictor of fire severity that integrates weather, fuel, and topographic influences—we chose to assess BAER fire severity in relation to Condition Class in the McNally fire on days when the spread rate of fire was relatively rapid versus slow. To accomplish this, we plotted the ranked daily extent of total fire progression using data obtained from the Sequoia National Forest. This plot (Figure 3) shows that fire spread was particularly high on 2 days. Rather than analyze severity on just these 2 days, we selected additional days in which at least 2000 ha burned. On all the remaining days, an area equal to 1500 ha or less burned (Figure 3). The total areas on days where at least 2000 ha or 1500 ha or less burned were similar and constituted our relatively rapid- and slow-spread landscapes, respectively.

Data Analysis

We calculated fire-severity proportions in conifer forest vegetation types based on the primary vegetation type indicated in the vegetation map, Cal-Veg, that was used to develop Condition Class. It is a standard planning map used on national forest lands in California. Cal-Veg is a map representing current vegetation that is derived from satellite data. The map version used for the two fires in Sequoia had been updated just prior to the Manter fire, and the one for the Storrie fire had been updated the year before the fire. Updates were based

Table 1. Area of Different Conifer Forest Types Burned in the McNally Fire, Estimated Fire Interval used to Calculate Condition Class, and Percent BAER Severity for each Type

Type of Forest	Area (ha)	Fire Interval for Condition Class (y)	Percent Fire Severity			
			Unburned	Low	Moderate	High
Mixed conifer/fir	10,378	16	20.7	36.9	30.5	11.9
Red fir	10,323	50	38.6	35.1	16.3	10.0
Mixed conifer/pine	4154	16	5.5	33.5	52.1	9.0
Jeffrey pine	39,341	50	5.9	23.5	49.0	21.6
Ponderosa pine	2455	6	9.8	38.6	44.0	7.6
Lodgepole pine	1559	163	49.5	39.7	10.7	0.0
Subalpine conifers	692	163	28.9	60.8	9.9	0.4
White fir	117	16	14.9	47.0	34.4	3.6
Foxtail pine	92	163	70.5	29.5	0.0	0.0
Totals	33,704		23.4	35.1	30.5	10.9

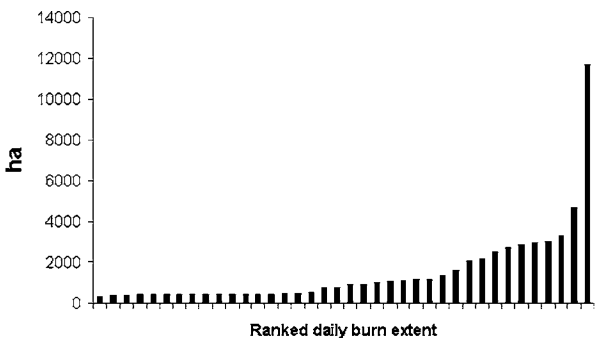

Figure 3. Ranked daily burn extent in the McNally fire as determined from the fire progression data of the Sequoia National Forest.

on accuracy assessments. A detailed description of the Cal-Veg map, and its development and accuracy for Forest Service lands, is at http://www.fs.fed.us/r5/rsl/projects/mapping. The minimum mapping unit is 1 ha. A description of the forest vegetation alliances mapped for the southern and northern Sierra and described in the results can be accessed at http://www.fs.fed.us/r5/rsl/projects/classification/zone-map.shtml.

We excluded pinyon/juniper woodlands and a small amount of open forest on the more arid east side of the Manter fire because it was not in national forest land and was subjected to different mapping protocols. Conversely, we included a small amount of area where the vegetation map indicated a hardwood conifer mix, but where the primary dominant was a conifer forest tree.

A formal statistical approach to testing for differences in severity proportions among Condition Classes by resampling independent, random point locations was not possible (for example, Odion and others 2004) because there was only enough area in some classes to locate a small number of independent points. Therefore, we present the proportions of fire severity by vegetation type and Condition Class and generally evaluate the weight of evidence provided by this information and other descriptors of the current fire regime in the context of the objectives described in the introduction.

Tree mortality was assessed for two diameter-size classes, 25–50 cm and larger than 50 cm. These two classes were compared for differences using a chi-square 2×2 independence test of the hypothesis that smaller trees would suffer greater mortality.

Results

Spatial Patterns of Fire Severity

Most of the conifer forests that burned in the McNally fire (Figure 1) showed characteristics of moderate- or lower-severity fire. High-severity fire accounted for 10.9% of all forest area (Table 1). The highest percentage of high-severity fire occurred in forests dominated by Jeffrey pine (22%), a species that is common on relatively dry and wind-exposed ridges. Most Jeffrey pine forest (83%) burned on the 3rd, 4th, and 5th most extreme-spread days of the McNally fire. Other forest types had much less high-severity fire—in particular, ponderosa pine, mixed conifer/pine, and the relatively small area of forest with long intervals of natural fire (mixed subalpine conifers, lodgepole pine, and foxtail pine). Although the McNally fire burned mostly fir and mixed conifer forests, most of the area that burned in the Manter fire was Jeffrey pine forest. The conifer forests in the Manter fire had more high-severity fire (29%) (Table 2). However, the Manter fire also had a lower

Table 2. Area of Different Conifer Forest Types Burned in the 2000 Manter and Storrie Fires, and the Percent BAER Severity for each Type

	Forest type	Area (ha)	Percent Fire Severity		
			Low	Moderate	High
Manter fire	Jeffrey pine	5,508	24.5	43.6	31.9
	Mixed conifer/fir	1,145	31.9	50.3	17.8
	Red fir	162	68.1	31.9	0.0
	Lodgepole pine	15	0.0	26.7	73.3
Totals		6,829	26.7	44.4	28.9
Storrie Fire	Mixed conifer/fir	7,583	85.8	10.0	4.2
	Mixed conifer/pine	6,577	45.6	26.3	28.1
	Douglas-fir/ponderosa pine	2,986	54.2	35.9	10.0
	White fir	1,511	72.6	5.9	21.6
	Red fir	591	95.8	2.4	1.8
	Jerey pine	128	41.7	52.8	5.6
	Lodgepole pine	7	100.0	0.0	0.0
	Ponderosa pine	2	100.0	0.0	0.0
Totals		19,384	66.3	19.2	14.5

threshold for high-severity fire than the McNally fire (80% versus 90% or more canopy foliage mortality).

For the Storrie fire, severity mapping also used the 80% threshold for high-severity fire. High-severity fire totaled 14.5% among all conifer forests, but the area incurred only about half as much moderate-severity fire as the area burned by the other two fires and consequently considerably more low-severity fire (Figure 2 and Table 2). Of the total area that did burn at high severity (2805 ha), most (1730 ha) of this fire occurred in mixed conifer/pine forests. However, forests dominated by ponderosa and Jeffrey pine had little high-severity fire. Conversely, white fir forests incurred much more high-severity fire than mixed conifer/fir, the most common forest type in the Storrie burn area. Thus, this fire had lower overall severity than the others, and even in different areas mapped with forest types that included many of the same species, the fire nonetheless burned with varying severity.

A few large high-severity patches accounted for much of the total area of high-severity fire in the conifer forests affected by the three burns (Figure 4A–C). However, all three fires produced mostly relatively small patches of high-severity fire. Patches totaling less than 5 ha accounted for 107 of the total of 157 high-severity patches in the McNally fire. They accounted for 28 of a total of 40 in the Manter fire, and 59 of 102 in the Storrie fire.

Many of the pines we monitored that incurred severe burn effects nonetheless produced new foliage from surviving terminal buds in the year after the fire. All surviving trees had either 100% crown scorch and no incineration of foliage or 100% scorch and incineration extending upward to at most 50% of total tree height. For Jeffrey pines incurring these fire effects, 22 of 44 trees survived and there was no difference between the 25–50 cm and greater than 50-cm diameter size classes in terms of the percentage of trees that survived. For the more abundant ponderosa pine, 42 of 83 and 57 of 83 trees in these two size classes survived, and diameter exerted a significant, positive effect (chi-square = 5.6, $P < 0.01$). None of the trees ($n = 90$) with higher levels of crown incineration, survived, indicating that there are significant differences between the effects of crown fire that incinerates foliage and the effects of severe surface fire, which primarily results in the death of foliage due to heat scorch.

Spatial and Temporal Patterns of Fire

For the larger landscape of the national forest in which the McNally and Manter fires occurred, the rotation interval from 1950 to the present for all fire was 185 years. The McNally and Manter fires were responsible for two-thirds of the area that was burned over this time. For both burns combined, the overall percentage proportions of high- and moderate-severity damage in conifer forests was 14% and 33%, respectively. Using these values, the rotation interval in conifer forests was estimated to be about 1330 years, for high-severity fire and about 565 years for moderate-severity fire. Fire has been less common in conifer forests of the Storrie

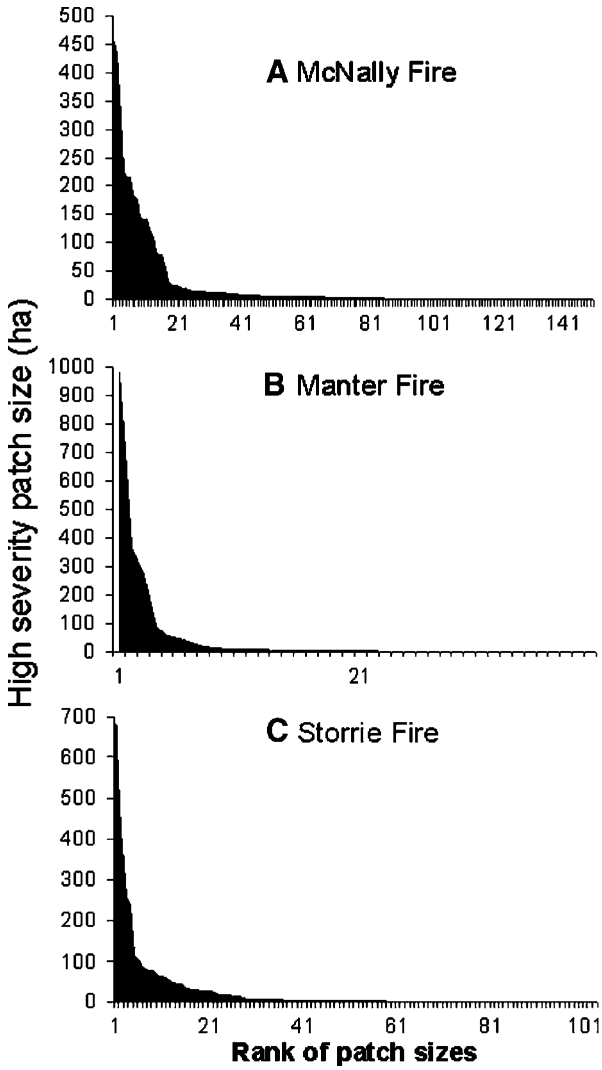

Figure 4. Ranked size of high-severity burn patches in conifer vegetation in the **A** McNally, **B** Manter, and **C** Storrie fires.

fire region. The rotation interval for all fire since 1950 was 507 years. The Storrie fire accounted for about half of all fire in conifer forests over this time period. The estimated rotation interval since 1950 was 3503 years, for high-severity fire and 2460 years for moderate-severity fire in the region in which the Storrie fire occurred.

Severity Patterns and Condition Class

Fire severity proportions by Condition Class under slow- and rapid-spread days in the Sequoia National Forest portion of the McNally fire are shown in Figure 5A–B. The 3939 ha comprising Condition Class 1 forests (2505 ha on slow-spread days plus 1424 ha on rapid-spread days) had almost no high-severity fire. These forests were predominantly comprised of subalpine and other high-elevation forests of red fir, lodgepole pine, and foxtail pine that grow on the relatively flat Kern Plateau.

For Condition Classes 2, 3, and 3+, there were distinctions in degree of severity between rapid- and slow-spread days. In particular, on rapid-spread days, moderate-severity fire was considerably more common, whereas low-severity was less common. The largest area of high-severity fire occurred on rapid-spread days in Condition Class 2 forests (Figure 5A). These forests were comprised mainly of red fir (62%) and Jeffrey pine (22%). Condition Class 3 forests consisted entirely of mixed conifer/fir or pine, whereas Condition Class 3+ forest were ponderosa pine. They had the same proportions of high-severity fire (13%) on rapid- and slow-spread days. This figure was very similar to that for conifer forests throughout the area covered by Condition Class data (Figure 1), which was 11.8%. Condition Class did not appear to have a strong effect in promoting rate of spread because a considerable area of Condition Class 3+ forest burned on slow-spread days (Figure 5).

Applying the McNally Condition Class criteria to the Manter burn area, we find that the 5400 ha of Jeffrey pine and 1145 ha of mixed conifer/fir forests that had no record of previous fire would be Condition Classes 2 and 3+, respectively. Jeffrey pine had 32% high-severity fire, and mixed conifer/fir forests had 17% high-severity. A small area of Jeffrey and lodgepole pine forest (94 ha) that would have been Condition Class 1 had 43% high-severity fire.

Applying the McNally Condition Class criteria to the Storrie fire area and presuming Douglas-fir/ponderosa pine to have an estimated past fire return interval of 16 years, like similar forests (Table 1), we find that there were 792 ha of Condition Class 2 mixed conifer forests. Most of this are burned previously in the 1970s and was primarily forested by Douglas-fir/ponderosa pine. In the Storrie fire, these forests burned with 20% high-severity and 53% moderate severity. Red fir and Jeffrey pine forests (719 ha) had no record of previous fire and would also have been Condition Class 2. They burned at much lower severity than most forests (Table 2). The rest of the forests affected by the Storrie fire had not burned for a long time and would have been condition Class 3+. Collectively they experienced the same severity proportions observed for the burn as a whole—lower than that seen in the Condition Class 2 mixed conifer forests.

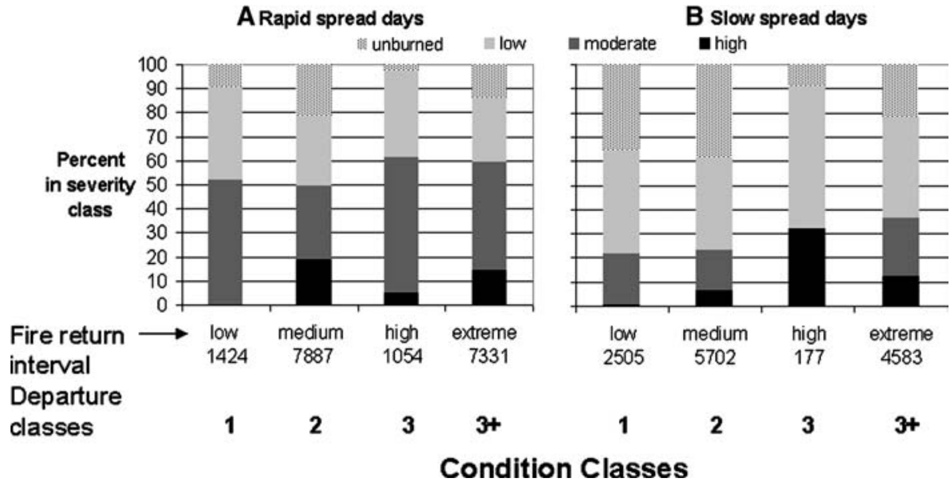

Figure 5. McNally fire severity proportions by Condition Class occurring during **A** days of relatively rapid fire spread (n = 10) and **B** days of relatively slow spread (n = 28). Numbers below columns are hectares burned.

Discussion

Contemporary fire is clearly not almost exclusively high-severity and stand-replacing in long-unburned areas of Sierran conifer forests. In the large area of burned forest that we evaluated, fire severity was highly variable and caused a relatively small amount of high-severity effects. Van Wagtendonk and others (2004) found similar levels of variation and severity proportions in another recent Sierra Nevada burn in the same forest types examined in our study. Our findings are also consistent with the result of recent modeling, which showed that long-unburned Sierran forests unaffected by silvicultural activities would not incur crown fire until temperature, relative humidity, and wind exceeded the 97.5th percentile of their summertime levels (Stephens and Moghaddas 2005).

The burn patterns we observed are also consistent with descriptions and evidence in Sierran forests not influenced by fire suppression and silviculture. There are a number of historical accounts of variability in fire ranging from light understory burning to patchy high-severity fire in Sierran mixed conifer forests, including one by the famed naturalist John Muir (reviewed by Stephenson and others 1991; Stephenson 1999), and another by a forest surveyor John Leiberg (1902). Recent studies using historic photos and field sampling have concluded that patches of high-severity fire have shaped mixed conifer forests in the Sierra Nevada and the adjacent southern Cascades (Russell and others 1998; Beaty and Taylor 2001; Taylor 2002). Show and Kotok (1924), Russell and others (1998), Beaty and Taylor (2001), and Taylor (2002) describe historic high-severity burn patches in the Sierra that are comparable in size to many of the larger patches produced by the three fires we studied. Smaller patches or gaps have also played an important role in determining forest and landscape structure and composition (Stephenson and others 1991; Keeley and Stephenson 2000) and were common in the three fires we studied. Leiberg (1902) and Beaty and Taylor (2001) have also describe the occurrence of large historic fires.

Because the fires we studied burned for 4–5 weeks, mainly in July and August, they were influenced by a range of weather conditions. This may help to explain why they were heterogeneous and qualitatively similar to descriptions of pre–suppression era fires. Most lightning ignitions occur in the Sierra during July and early August (Caprio and Swetnam 1995). Historic lightning ignitions that led to spreading fires would have been driven by the same seasonal patterns of warm, dry weather that typifies the Sierran summers. The large size of the fires we studied likely enhanced their variability by creating both fire-generated winds, which that can make combustion more active, and dense smoke, which can lower temperatures and mitigate fire behavior (Pyne 1984). Thus, it is important to stress that our results apply to fires in the Sierra that burn for long durations and spread over relatively large areas in mid- and late summer. These circumstances are representative of much of the areas burned by contemporary fire, and presumably fire in the past, given the effect of large fire on the cumulative amount of area burned. Much less heterogeneity may result from fires that burn for a shorter time and cover small areas. Our results also apply only to areas in the Sierra where timber harvesting and silvicultural activities have not been common. There are many areas of the Sierra that have been modified considerably by intensive silvicultural activities (SNEP 1996) and where severity is expected to be higher due to increases in available fuel and the loss of fire-resistant trees (Stephens and Moghaddas 2005).

After a long period of reduced fire influence, large, heterogeneous fires can hasten ecological restoration (Baker 1992; Miller and Urban 2000; Fulé and others 2004). They may affect biodiversity by thinning trees and decreasing competitive exclusion processes and by increasing structural and landscape diversity. Fire-created gaps provide opportunities for the natural regeneration of light-demanding conifers such as pines and giant Sequoia (*Sequoiadendron giganteum*) (Stephenson and others 1991; Keeley and Zedler 1998; Stephens and others 1999) whose natural abundance in the Sierra has been reduced (SNEP 1996). There are concerns about the lack of natural regeneration in these species due to the absence of fire severe enough to create openings, consume sufficient duff and litter to facilitate successful germination, and open cones in giant Sequoia (Stephenson and others 1991; Stephens and others 1999). Such fire effects may not only promote the natural reproduction of these conifers, but also favor the relative abundance of these species because they have a greater ability to survive. Large giant Sequoia may survive in areas of crown fire (Stephenson and others 1991), and we found that many medium and large ponderosa and Jeffrey pines can survive severe surface fire. There may be some additional mortality among these trees, but those that survive are likely to experience rapid growth and increased vigor, much like giant Sequoia after severe fire (Stephenson and others 1991). Mature white fir may also be more fire resistant in the Sierra than previously suspected, aided by their ability to produce epicormic branches (Hanson and North 2006). Surviving conifers may serve as sources of seed that help to ensure natural regeneration in high-severity burn patches.

Patches of habitat created by high-severity fire, with their rich array of snags, logs, and nonarborescent vegetation, are among the scarcest habitats in many forested landscapes (Lindenmayer and Franklin 2002). After 50–100 years this early successional habitat can succeed to forest (Russell and others 1998). Thus, based on estimates the area of high-severity fire predicted by our fire rotation analyses for the period since 1950 in the Sequoia and Storrie fire regions, about 4.2% and 1.5% of these landscapes, respectively, may have naturally developed early successional burned forest habitat under the current fire regimes. The maintenance of this habitat in the landscape by fire promotes biodiversity because it supports plant, insect, and wildlife assemblages not found in other Sierran habitats. In addition, there are numerous plant and animal species that have become rare due to their requirements for burned forest habitat. For example, there is some concern over the local extirpation of avian species with these habitat requirements (Kotliar and others 2002). Species such as the black-backed woodpecker (*Picoides arcticus*) may be indicators of whether sufficient, severely burned forest habitat is being maintained for biodiversity (Hutto 1995). These birds require young, severely burned patches of at least 12–25 ha (Saab and others 2002). The three fires we studied created 70 severe-burn patches larger than 12 ha where there had been none or very few due to the lack of fire.

Thus, the effects of the large fires we studied are consistent with the diversity goals of the National Forest Management Act. Elsewhere in the western United States, a number of large fires have also been found to perform the desired ecological functions of fire (for example, Turner and others 2003; Kotliar and others 2003; Fulé and others 2004; Odion and others 2004; Schoennagel and others 2004; Smucker and others 2005). These specific effects may ultimately be necessary for maintaining biodiversity that depends on fire. Prescribed burning can help, but it is limited in extent, severity, and heterogeneity (Baker 1994; Rocca 2004) and may not mimic natural fire (Moritz and Odion 2004). On National Forest Service lands, prescribed burning is often conducted outside the normal fire season, when flaming is subdued but wildlife such as herptofauna are highly vulnerable to smoldering combustion (Bury 2004). Neither these fires, nor the structural modification of forests through mechanical treatments, may provide fire-specific effects for species that require them (for example, flowering plants with fire-dependent seed germination that is sensitive to burn season, conifers with heat-opened cones, and cavity-nesting species that dependent on standing dead trees for nesting and foraging).

Fire Patterns and Condition Class

We found that the proxy for fire suppression effects, Condition Class, was not effective in identifying locations of high-severity fire. Condition

Classes 2, 3, and 3+ in the McNally fire all had similar fire severity proportions. When the same Condition Class criteria were applied to the other two fires, we found that fire severity generally decreased rather than increasing from Condition Class 2 to 3+. In short, Condition Class identified nearly all forests as being at high risk of burning with a dramatic increase in fire severity compared to past fires. Instead, we found that the forests under investigation were at low risk for burning at high-severity, especially when both spatial and temporal patterns of fire are considered.

The lack of an observed relationship between Condition Class and fire severity suggests that exogeneous forces such as weather, climate, topography, and neighboring vegetation (for example, pyrogenic shrubs) largely determine fire-severity patterns in forests. Because fire severity did not increase above Condition Class 2, the combustibility of Sierran forests may reach a maximum at the fire-free intervals indicated by this class (32–48 years for many forest types), (Table 1).

A number of interrelated factors may explain why these forests reach a maximum in combustibility. For example, the total leaf area of a forest reaches a maximum (Waring and Schlesinger 1985). Once forest overstories close in the Sierra, they may exclude pyrogenic shrubs with high light requirements (Show and Kotok 1924), greatly decreasing the potential intensity of understory combustion. The base height of the forest canopy sufficiently dense to propagate fire may also become relatively high in long-unburned forests (Stephens and Moghaddas 2005). In terms of surface fuel beds, those associated with Sierran conifers that increase in abundance with time since fire (for example, fir) are more dense than those found under pine and thus less combustible (van Wagtendonk and others 1998).

Conclusions

Our findings suggest that elevated risk of high-severity fire due to the effects of fire suppression is not the pervasive, predictable ecological problem that it has often been portrayed to be in the Sierran forests we studied. In addition, they provide evidence that fire alone can restore its past influence as a patchwise and stand-thinning disturbance agent as well as a facilitator of species diversity and fire-adapted conifers in these forests. Thus, it appears that management can shift toward process restoration by introducing more fire and increasing the use of wildland fire (Miller 2003). There may be no other effective strategy for restoring and maintaining ecological integrity and for fostering the natural diversity of species dependent on effects specific to fire. The structural modifications of forests cannot mimic the heterogeneous effects of fire. Instituting a policy that allows more fire to burn would require considerable planning and additional efforts to improve human safety, but such efforts are needed under any management scenario.

Both Condition Class and the new LANDFIRE approach are based on mapping any departure in fire regimes from reference conditions. Presuppression reference conditions for fire must be based on retrospective studies. These studies are too methodologically limited to provide a comprehensive description of the spatial extent and variation in the effects of past fires (reviewed by Veblen 2003). As a result, the importance of past surface fire may be overestimated and conversely, past heterogeneity in fire may be underestimated (for example, Minnich and others 2000). To add to the problem of uncertainty about past fire, there may be significant misconceptions about current fire severity that lead to further overestimation of the differences between past and present fire regimes.

By directly assessing existing fire regimes in the context of ecological integrity, we can avoid some of the problems that may arise when current methods for estimating departure in fire regimes are used. A general approach based on the assessment of existing rates and scales of processes in the context of ecological integrity has been recommended for the management of biodiversity as a means of overcoming problems in defining the ''natural'' range of variation in ecological systems (Parrish and others 2003). The direct assessment of fire regimes can be improved by applying more sophisticated mapping of fire severity and performing landscape analyses that provide a clearer link between pattern and process (Wagner and Fortin 2005). In the Sierra Nevada, it is important to distinguish high-severity surface fire from crown fire because the two types of behavior may have very different effects on tree mortality. There is also a need for analyses of fire behavior in areas affected by timber harvesting and silviculture. Finally, better integration of the spatial and temporal components of other forest disturbances in the Sierra Nevada in addition to fire, is needed to determine if their rates and scales are compatible with ecological integrity.

Abstract

There is widespread concern that fire exclusion has led to an unprecedented threat of uncharacteristically severe fires in ponderosa pine (*Pinus ponderosa* Dougl. ex. Laws) and mixed-conifer forests of western North America. These extensive montane forests are considered to be adapted to a low/moderate-severity fire regime that maintained stands of relatively old trees. However, there is increasing recognition from landscape-scale assessments that, prior to any significant effects of fire exclusion, fires and forest structure were more variable in these forests. Biota in these forests are also dependent on the resources made available by higher-severity fire. A better understanding of historical fire regimes in the ponderosa pine and mixed-conifer forests of western North America is therefore needed to define reference conditions and help maintain characteristic ecological diversity of these systems. We compiled landscape-scale evidence of historical fire severity patterns in the ponderosa pine and mixed-conifer forests from published literature sources and stand ages available from the Forest Inventory and Analysis program in the USA. The consensus from this evidence is that the traditional reference conditions of low-severity fire regimes are inaccurate for most forests of western North America. Instead, most forests appear to have been characterized by mixed-severity fire that included ecologically significant amounts of weather-driven, high-severity fire. Diverse forests in different stages of succession, with a high proportion in relatively young stages, occurred prior to fire exclusion. Over the past century, successional diversity created by fire decreased. Our findings suggest that ecological management goals that incorporate successional diversity created by fire may support characteristic biodiversity, whereas current attempts to "restore" forests to open, low-severity fire conditions may not align with historical reference conditions in most ponderosa pine and mixed-conifer forests of western North America.

Introduction

In just two days in 1910, 1.2 million ha of forestlands in Idaho and Montana in the western USA burned in a massive fire driven by exceptional winds [1]. In the aftermath, the United States instituted a policy of aggressive fire suppression [2]. Decades of fire suppression activities since 1910 have reduced the extent and number of wildfires in the USA, as well as parts of Canada. There is now widespread concern that fire exclusion has caused vegetation in western North America to be much more susceptible to uncharacteristically severe fire. This concern is greatest in the extensive, often drier forests of the North American Cordillera, especially those dominated by ponderosa pine (*Pinus ponderosa* Dougl. ex. Laws) and Jeffrey pine (*P. jeffreyi* Grev. & Balf.), or those mixed with ponderosa/Jeffrey-pine and other conifer species (hereafter ponderosa pine and mixed-conifer forests of western North America, defined in Table 1 and further described in Methods).

The ponderosa pine and mixed-conifer forests of western North America have traditionally been considered adapted to a low- or low/moderate-severity fire regime (see Tables 1 and 2 for definitions of fire terms) [3–8]. There have been many large mixed-severity fires in western North America in recent years [9] that have helped create widespread concern that fire exclusion has caused an unprecedented threat of uncharacteristically severe fires [6–15]. Concomitantly, however, there has been increasing recognition that fires in ponderosa pine and mixed-conifer forests of western North America were also mixed in severity prior to any significant effects of fire exclusion (Table 2) [16,17]. It has also been increasingly recognized that these forests support biota that are not adapted to low/moderate-severity fire, but rather are dependent on the high-severity fire component of mixed-severity regimes [18–22]. Thus, a better understanding of historical (i.e., generally prior to fire suppression and timber harvesting) fire regimes in these forests is needed to define reference conditions and maintain characteristic ecological diversity.

In recent decades, to address the widespread concerns about uncharacteristically severe fire in western North America, fuel reduction treatments have been implemented on millions of hectares of ponderosa pine and mixed-conifer forests at a cost of billions of dollars [23]. These treatments consist mainly of harvesting smaller trees to reduce forest density [8], but larger trees are typically harvested as well for economic reasons [24]. These treatments can negatively affect fire dependent species. For example, the Black-backed Woodpecker (*Picoides arcticus*), an imperiled fire-dependent species, largely avoids previously thinned forest areas burned at high-severity [18]. Thinning treatments also eliminate/degrade dense forest, which many species need, including the Northern Spotted Owl (*Strix occidentalis caurina*), a Threatened Species under the USA Endangered Species Act [25], and the Pacific fisher (*Pekania pennanti*), a Candidate Species under the USA Endangered Species Act [26]. In addition, forest thinning treatments often require the reopening or construction of access roads, which have many ecosystem impacts [27], and both the thinning treatments and roads promote the establishment of invasive species [27,28]. Thinning ultimately exacerbates fire suppression impacts if it facilitates fire control, or if it becomes a prerequisite for allowing wildfires to burn [13,29]. Thus, there is a need to ensure that actions are ecologically justified.

Most descriptions of the fire regimes that characterize the ponderosa pine and mixed-conifer forests of western North America (e.g., [5–7,11]) emphasize how low-severity fires maintain forests dominated by relatively old and large, fire-resistant trees, with few understory trees, dead or dying trees, or shrubs [3–7,11–13] (Table 2). Park-like conditions and low fuel loads are thought to result from effects of frequent surface fire, which kills young, fire-sensitive trees, while older, fire-resistant trees survive [4,6,7,11,12].

In contrast, mixed-severity fire regimes are characterized by more variable fire and forest structure across a wide range of spatial and temporal scales [17,21] (Tables 1 and 2). The creation of complex early seral vegetation by high-severity fire often occurs in irregular patches across the landscape and at irregular intervals [30]. Over time, the complex early successional vegetation created by fire, if not reburned, transitions to mid- and then late-successional forest, often containing pre-disturbance legacies, such as standing or fallen dead trees and often some fire resistant, large trees that survive fire crown fire (e.g., [31]). Thus, mixed-severity fire regimes create complex successional diversity high beta diversity, and diverse stand-structure across the landscape [17,21,30,32–35].

The concepts and nomenclature used to describe fire regimes in western North America can be ambiguous. Part of the problem with defining fire regimes for the drier forests of western North America is the classification of fire regimes into distinct categories of low-, mixed-, and high-severity [5], or low/moderate-severity

Table 1. Definitions of terms as used in this paper.

Term	Definition
Ponderosa pine and mixed-conifer forests of Western North America	Low- to mid-elevation, montane, non-coastal forests of western North America where a regime of low/moderate-severity fire (see Table 2 for explanation) that limit tree recruitment has traditionally been applied. These extensive forests are dominated by ponderosa pine (*Pinus ponderosa*), Douglas-fir (*Pseudotsuga menziesii*) and fir (*Abies concolor* and *A. grandis*) (see Methods). These forests are drier than coastal forests or most forests at higher elevations, though one region, the Klamath, is more mesic.
Fire dependent	Biota that occur most abundantly after high-severity fire, and which are largely or entirely absent where high-severity fire has not occurred for a long period.
Fire regime	The frequency, size, seasonality, impacts and other characteristics of naturally occurring fires that have occurred in a vegetation type over its lifespan, generally 1–3 millennia [133].
High-severity fire rotation (or moderate to high-severity fire rotation)	The length of time required for an area equal to the area of interest to burn [134]. For high-severity fire, this is calculated as the time period over which high-severity fire (or moderate- and high severity fire combined) is observed, divided by the proportion of the area of interest that burns in that time period at high- or moderate/high-severity.
High-severity fire	Fire that burns on the ground surface, and typically in the overstory canopy (crown fire) as well. Mortality of woody species as measured by basal area is generally >70%. However, sprouting canopy species, such as oaks (*Quercus* spp.) typically survive these fires. High-severity fire mainly occurs in relatively discrete patches under high winds that cause blow ups in fire behavior [108]. These patches range in size from the area occupied by a small group of trees to many thousands of ha in size, as in the case of the 1910 fires.
Low-severity fire	Fire that burns on the ground surface such that relatively little or no mortality of live, standing vegetation occurs. Mortality of woody species as measured by basal area is 0–20%, but is mostly 0–5%. See Table 2 for a detailed explanation of the effects of a regime of low-severity fire.
Moderate-severity fire	Fire that burns only on the ground surface and that has effects that are intermediate between low- and high-severity fire as defined here. Mortality of woody species as measured by basal area is generally 20–70% within a given area.
Mixed-severity fire	Fire that includes low-, moderate-, and high-severity effects. See Table 2 for a detailed explanation of the effects of a regime of mixed-severity fire.
Park-like forest	A forest of widely-spaced live, mature trees and very few, if any, dead trees (snags). The understory is open, often dominated by bunchgrasses, and is mostly lacking woody plants.
Stand age	The age within a stand of the dominant overstory canopy vegetation that recruited more or less as a cohort, typically after a previous disturbance.

These terms may have different meanings in the literature depending on the context in which they are used.
doi:10.1371/journal.pone.0087852.t001

Table 2. Characteristics of fire regimes in ponderosa pine and mixed-conifer forests of Western North America.

	Low/moderate-severity model	Mixed-severity model
Tree populations	1. Stable. Gap phase recruitment dynamics.	1. Unstable. Gap and stand-level mortality and recruitment. Stand-replacement fires at intervals often shorter than tree lifespans.
	2. Recruitment limited by frequent fire.	2. Recruitment abundant and stimulated by fire.
	3. Resistant to fire (though often described as "fire-resilient").	3. Resilient following fire.
Landscape patterns	1. Successional diversity low.	1. Successional diversity high.
	2. Gradual variation along environmental gradients.	2. Variation along environmental gradients interrupted by sharp boundaries and patchiness.
	3. Low contrast heterogeneity. Intensity/complexity of spatial pattern is low.	3. High contrast spatial heterogeneity. Intensity/complexity of spatial pattern is high.
	4. Low beta diversity.	4. High beta diversity.
Stand structure	1. Does not vary markedly over time.	1. Varies markedly as a function of time since fire disturbance.
	2. Open canopy of mature, medium and large trees; density low.	2. Variable canopy, tree size, and density variable; even-aged cohorts stimulated by fire.
	3. Understory with few trees or shrubs.	3. Understory varies.
Fire behavior	1. Typically low intensity surface fire with flame lengths <3 m; short residence time.	1. Variable intensity surface or crown fire, variable residence time.
	2. Fuel limited. Crown fire cannot initiate.	2. Not necessarily fuel limited. Crown fire can initiate under extreme conditions.
Individual fire canopy mortality	1. Mortality of canopy trees <20% by basal area.	1. Mix of low-, intermediate- and high-severity fire with (0–20%, 20–70%, >70%) mortality of canopy trees by basal area respectively.
Interactive effects of fire on fuels and forest flammability	1. Fires continuously limit fuels and fire sensitive trees.	1. Fires only temporarily lower fuels.
	2. Maintain low flammability and forest mortality over time.	2. Do not maintain low flammability and forest mortality, except initially after fires.
Evolutionary responses	1. Fire resistant trees.	1. Fire resistant and fire-dependent or specialized biota. The latter includes species with reproduction timed to coincide with fire via fire-cued germination, fire "embracer" plant species, and post-fire insect and bird specialists).
Fire exclusion leads to	1. High tree regeneration*.	1. Low tree regeneration.
	2. Greatly increased flammability.	2. Small changes in flammability (vegetation is continuously flammable except initially after fire).
	3. Increased forest susceptibility to mixed-severity fire.	3. Decreased susceptibility to mixed-severity fire.
Carbon storage[1]	1. Low-moderate; considerably lower than carrying capacity.	1. Moderate to high; Near carrying capacity.
Fuel treatments (forest thinning)	1. Restores forest tree structure and fuel loads where infill associated with fire exclusion is removed.	1. May create uncharacteristic structure and composition (reduction in small and intermediate and some overstory trees, shrubs, down wood).
	2. Increase open forest (woodland) biota.	2. Decrease in dense forest biota and post-fire habitat specialists.
	3. May create low contrast heterogeneity.	3. May reduce high-contrast heterogeneity.

[1][135–137].
doi:10.1371/journal.pone.0087852.t002

and high-severity [9], when nearly all fire regimes include a mix of all three severities. Greater clarity in terminology is needed to improve communication about fire regimes. Tables 1 and 2 document the terminology used herein.

In addition to unclear terminology, other factors create difficulties for identifying which historical (i.e. prior to fire exclusion) fire regime applies to a particular forest region. Where fire has been excluded from a mixed-severity landscape for 100 years, early- and mid-successional patches created by high-severity fire become late-successional patches, making it more likely that these patches, indicative of a mixed–severity regime, will be undetected. For example, high-severity fire patches may be detected in old but not recent aerial imagery [35]. A primary source of data on historical fires are scars in the growth rings of surviving trees damaged by fire, which can provide annually precise dates for past fires at the sampled locations [36–40]. However, these methods cannot effectively determine past occurrence of high-severity fire. Thus, additional evidence is needed to characterize historical fire regimes over more extensive areas.

The US Forest Service Inventory and Analysis (FIA) program provides an extensive dataset that is a probabilistic sample of forest structure in large landscapes. This dataset allows for landscape-scale inference and statistical analyses of forest age and structure parameters consistent with a low- or mixed-severity fire regime.

Using the FIA data, and published sources of landscape-scale (area of inference >25,000 ha) data, our objectives were to address two broad questions: (1) How prevalent were mixed-severity fire regimes historically in ponderosa pine and mixed-conifer forests of western North America; and (2) How have mixed-severity fire patterns in these forests changed with fire exclusion? Consistent with common perceptions and restoration models applied to these forests, we hypothesized that: (1) forest age-class diversity was low, reflecting long-term effects of low/moderate-severity fire regimes (Table 1); and (2) fire exclusion has led to vegetation changes that have increased the prevalence of high-severity fire.

Methods

Study Area

FIA and published sources of landscape-scale (area of inference >25,000 ha) data with inference to pre-settlement fire severity and forest structure were available from the following regions of western North America: Baja California, the Sierra Nevada, the Klamath Region, the eastern Cascades, the northern Rockies, the central Rockies, and the southwestern USA (Figure 1). We used ecoregional class III data from the US Environmental Protection Agency (http://www.epa.gov/wed/pages/ecoregions/level_iii_iv.htm) to define the Sierra Nevada, Klamath, and eastern Cascades regions. The Sierra Nevada was split along the distinct crest of the range into the east and west slopes. The portions of the northern Cascades east of the crest and the main Cascades within California were combined into the eastern Cascades. The Modoc Plateau and eastern Sierra Nevada was also combined with the eastern Cascades. The northern Rockies were in Idaho and Montana, and the central Rockies were in Colorado, Wyoming and South Dakota. The southwestern USA included Arizona and New Mexico.

The dominant conifer over most of the low- to mid-elevation, montane forests in these regions is ponderosa pine, often with lesser amounts of Douglas-fir, white fir (*Abies concolor* (Gord. and Glend.) Lindl.), and/or grand fir (*A. grandis* (Douglas ex D. Don) Lindl.). In the Sierra Nevada and Klamath regions, ponderosa pine is common and may be dominant, especially in low-elevation forests, and mixed-conifer forests generally include components of ponderosa pine, white fir, Douglas-fir, incense-cedar (*Calocedrus decurrens* (Torr.) Florin), sugar pine (*P. lambertiana* Dougl.), California black oak (*Quercus kelloggii* Newb.) and evergreen canyon live oak (*Q. chysolepsis* Liebm.). Mid-elevation forests of the Sierra Nevada and Cascades are often dominated by Jeffrey pine, ponderosa pine, white fir and sugar pine. Low- to mid-montane forests of the eastern Cascades are dominated by ponderosa pine and Douglas-fir, and can include components of white fir, grand fir (*Abies grandis* Dougl. ex D. Don.) Lindl.), and western hemlock (*Tsuga heterophylla* (Raf.) Sarg). Low- and mid-elevation forests of the Rocky Mountains are dominated by ponderosa pine and Douglas-fir. In the northern Rockies, these two dominants may co-occur with white fir and grand fir, and with western hemlock, western redcedar (*Thuja plicata* Donn. Ex D. Don.) and quaking aspen (*Populus tremuloides*). Forests of the southwestern U.S. are heavily dominated by ponderosa pine, with some white fir and Douglas-fir at middle elevations. Precipitation and temperature data for each region in this study are provided in Table 3.

Evidence for Historical Mixed-severity Fire Regimes in Ponderosa Pine and Mixed-conifer Forests

Rotations of high- and moderate-to high-severity fire. We summarized rotations for high-severity fire from published studies with inference to large landscapes (>25,000 ha) in ponderosa pine and mixed-conifer forest landscapes of western NA over a period of 70 or more years. The high-severity fire rotation is equal to the average interval between high-severity fire across the affected landscape (Table 1). Additionally, we summarized other evidence regarding the occurrence of high-severity fire where rotations could not be calculated, but where landscape-scale inference regarding the relative importance of high-severity fire was presented, or where rotations could be calculated but landscapes were <25,000 ha or the time period was <70 years.

Dominant overstory tree age distributions. To assess successional patterns indicative of mixed- vs. low/moderate-severity fire regimes, we analyzed US Forest Service Inventory and Analysis (FIA) stand ages (data available at http://www.fia.fs.fed.us/tools-data/) by region. These data capture the average age of the trees dominating the canopy layer in forest stands (stand age, Table 1) that have been sampled probabilistically, with inference to more extensive landscapes. Because the dominant trees in ponderosa pine and mixed-conifer forests may be several centuries old in the absence of disturbance [e.g., 41,42], we reasoned that the age of relatively young and intermediate-aged stands (e.g. <200 years) reflects the time since a disturbance that shifted dominance from older to younger trees. The FIA database indicated that young stands (generally 0–30 years) were initiated by fire. To determine whether disturbances in other plots were caused by fire, we evaluated the effects of fire exclusion on rates of disturbance, as described below. It is not possible to specify the level of mortality that fire or other disturbances may have caused, but it is possible to determine the extent to which forests were dominated by older age classes, which would be consistent with low−/moderate severity fire, versus stands of more diverse age classes, consistent with mixed-severity fire.

FIA is a monitoring system based on one permanent, random 1-ha plot per ~2400 ha across forested lands in the USA. For tree measurements, the plot area is sub-sampled with four circular plots of 0.1 ha for large trees and 0.017 ha for smaller trees nested within the larger tree plots. Diameter at breast height (dbh) and crown position of each tree and the ring count from cores of the dominant and co-dominant trees (i.e., the main overstory canopy layer) of each tree species are measured in each subplot [43]. The stand-age variable for a "stocked" FIA plot (i.e., one containing trees of any age) is determined from the average of all ring counts from subplot samples of dominant and codominant trees in the size class characteristic of the overstory canopy structure, weighted by cover of sampled trees, and 8 years are added for estimated time to grow to breast height (1.4 m) at which cores are sampled.

We selected FIA data from low- to mid-elevation forest types in Wilderness, Inventoried Roadless Areas, and National Parks to ensure as best we could that stand initiation was not caused by commercial harvesting of trees or other land use (Fig. 1). We had no independent way to confirm that trees were never cut at each plot location, so we interpret the results assuming only that such management was of minor importance, given that Wilderness, Roadless, and National Park designations reflect a lack of past timber harvesting. We selected lands classified as "timberlands" in Pacific states' data sets. In the Rockies and southwestern USA, where there was no such designation, we selected all areas where the potential vegetation was considered capable of >10 percent tree cover.

A small number of plots had different stand ages for different subplots due to disturbances that affected some, but not all, subplots. In FIA split-age plots where both plot ages were ≤100 years, plots were split into two stand ages by FIA if they differed by as little as 1 year. In split-age plots in which both ages were 100–199 years old, plots were split into two stand ages if they differed by as little as 2 years. In split-age plots where both ages were ≥200

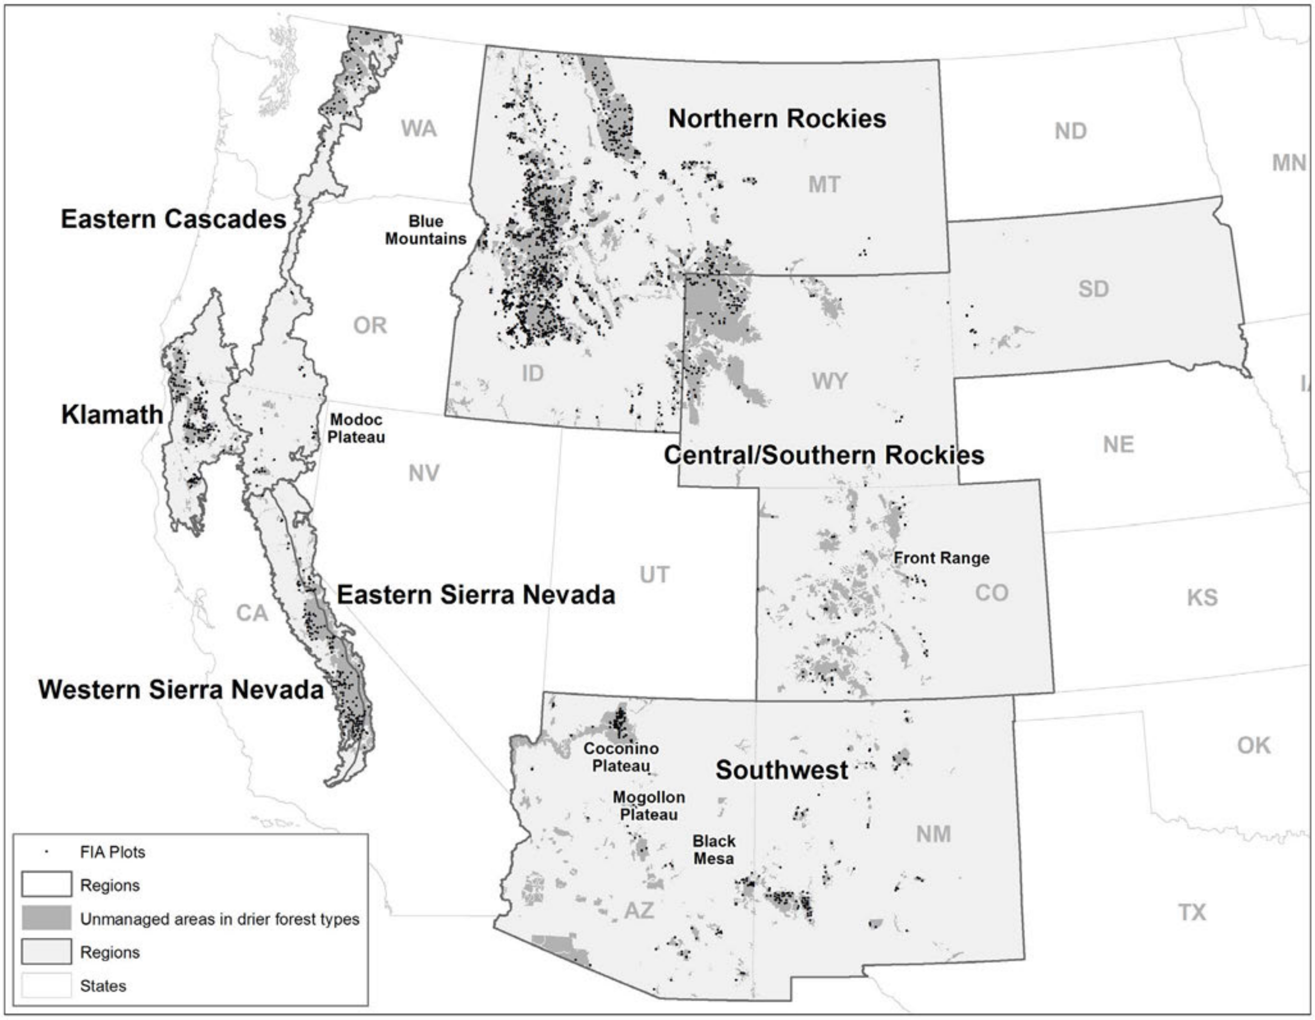

Figure 1. Study area. Dots indicate the general locations of Forest Inventory and Analysis (FIA) plots.
doi:10.1371/journal.pone.0087852.g001

years, plots were split into two stand ages if they differed by as little as 15 years. To assess the within plot variability in tree ages, we calculated the standard deviation of the trees used to age each plot. We standardized this across the range of stand ages by calculating the standard deviation of the proportional difference between stand age, and the individual trees used to determine stand age in each plot, over the range of stand ages.

We reasoned that, prior to fire suppression, under a low/moderate-severity fire regime, successional, or age-class diversity, would be low, while it would be high under a mixed-severity fire regime. With fire exclusion and greater amounts of uncharacter-

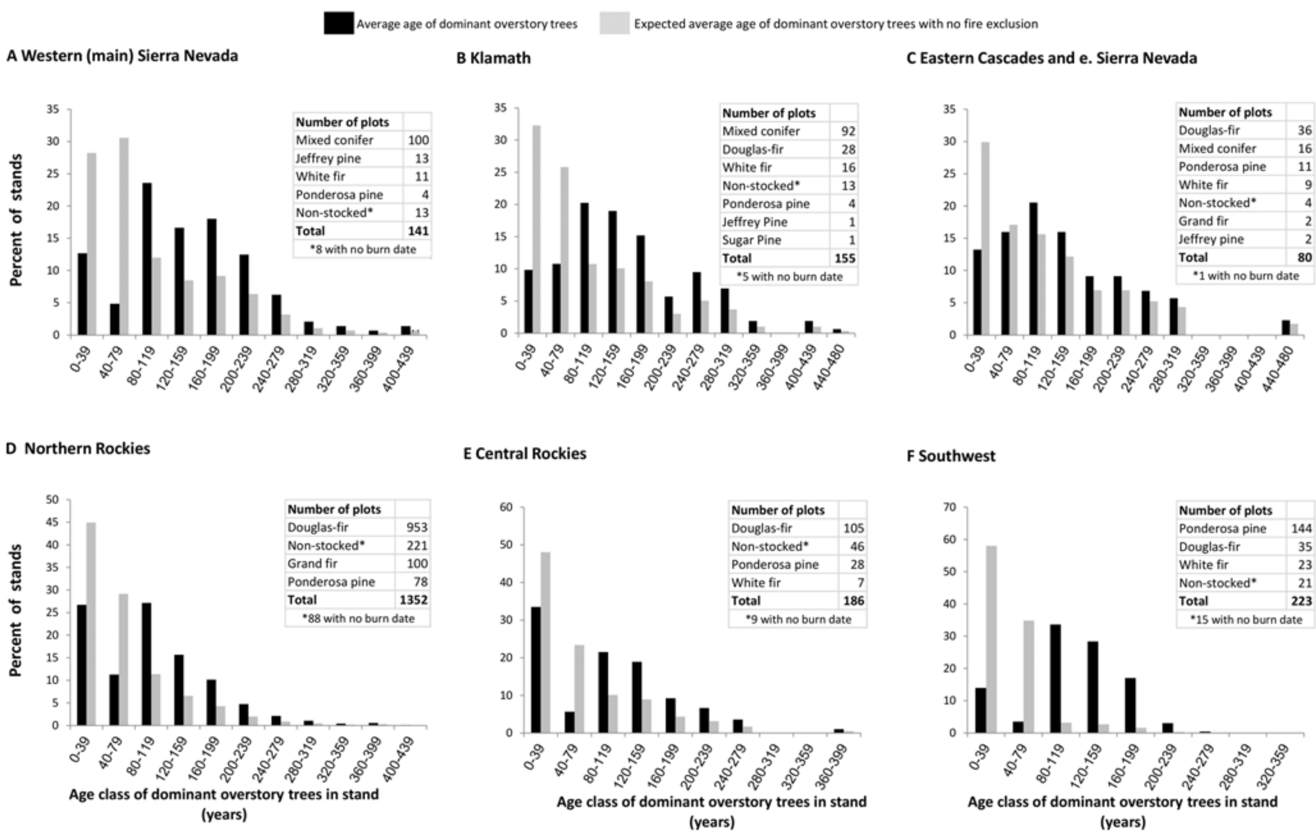
doi:10.1371/journal.pone.0087852.t003

istically severe fire the pattern should reverse in both cases (i.e. increased age-class diversity in low-severity systems and decreased diversity in mixed-severity systems). We used a Chi-square test of proportions [44] to test the null hypothesis that there would be no difference between the actual distribution of stand ages and the distribution based on a hypothetical scenario of no fire exclusion. No effect of fire exclusion would indicate that fire was not a dominant influence on age class diversity. To create a distribution of average dominant stand ages by region that would exist in today's stands had fire exclusion never occurred, we used the distribution of plots with stand ages dating from 1889 or before. This time period was immediately prior to the onset of fire suppression activities by settlers and government agencies [35,45–56]. Because the average tree ages are somewhat imprecise, we binned the data into 40-year age classes for hypothesis testing. In each region, the present age structure for 80 years during effective fire suppression (1930–2009) was compared with the age structure prior to fire suppression (1810–1889). For visual analysis, we shifted the pre-fire suppression (pre-1890) tree age distributions to present (i.e., shifting 1810–1849 to 1930–1969, and shifting 1850–1889 to 1970–2009) to compare with the current age distributions (see Figure 2). This allows a clear, visual comparison of stand ages that currently exist with those that would exist had the same fire regime from 1810–1889 occurred from 1930–2009.

We included only plots where there was one stand age for the full plot because we wanted to evaluate high-severity fire occurrence in patches at least 1 ha in size, rather than include smaller torching of groups of trees. Excluding the split-age plots (27% of plots in the Sierra Nevada, 40% in eastern-Cascades/eastern-Sierra, 26% in Klamath, 14% in northern Rockies, 36% in central/southern Rockies and 14% in southwestern USA) omits some additional evidence for local high-severity fire effects; thus our results may be conservative.

We used FIA data drawn from 2001–2009, comprising 90% of available plots, in our classification of low/mid-elevation forests in the Sierra Nevada, Klamath, and eastern Cascades. In the other regions, FIA plots represented 100% of the data from low- to mid-elevation, montane forests. The number of plots in the 0–39 year age bins may be slight underestimates of the amount of high-severity fire in the last 40 years because severe fire could have occurred subsequent to the sample date (plots were sampled between 1995–2009 in the northern, central and southern Rockies, and southwestern USA and 2001–2009 in the Sierra Nevada, Klamath and eastern Cascades). To estimate the number of plots that burned severely after the sample date, we increased the 0–39 year old bin by a factor of 40/36 in the Sierra Nevada, Klamath and eastern Cascades, 40/34 in the northern Rockies and 40/32.5 in the central/southern Rockies and southwestern USA region. The denominator in these weightings is based on 40



Figures 2. Age class distributions of dominant overstory trees. Data are from US Forest Service Forest Inventory and Monitoring plots from forested areas protected from logging in A. the western (main) Sierra Nevada, B. the Klamath Region, C. the eastern Cascades and Sierra Nevada, D. the northern Rockies, E. the central/southern Rockies, and F. the southwestern USA. Shown in black bars is the current distributions of stand ages. Grey bars show an expected distribution (average age of dominant overstory trees with no fire exclusion), based on projecting the occurrence of the same age distributions that occurred from 1810–1889 into the most recent 80 year time period and rescaling these data. The number of plots by forest type are shown in the imbedded tables. Non-stocked stands are those lacking trees that grew after the fire that could be aged non-destructively.

doi:10.1371/journal.pone.0087852.g002

minus the mean amount of time in which plots in each region could have burned after being sampled.

We used year of the recent fire disturbance, captured in the disturbance data field, to define the age of very young FIA plots not containing trees that could be aged in a non-destructive way (FIA surveys do not allow trees to be killed). These "non-stocked" plots were relatively rare, as reported in the results, and ages, based on fire dates, all fell within the 0–39 age category. Some non-stocked stands had no disturbance coded. In California, Oregon, and Washington (Pacific states), disturbances were only coded if they were <6 years old. We placed all non-stocked plots where no disturbance was coded in the database into the 0–39 stand age bin.

Next, we considered whether the age distributions as shaped by fire were consistent with mixed- or low/moderate-severity fire regimes. We reasoned that a wide range in the plot stand ages in a landscape would be consistent with age-class diversity created by mixed-severity fire, while stand ages that were evenly distributed in predominantly older age classes would be consistent with a low/moderate-severity fire regime. To test whether stand age distributions were consistent with mixed- or low/moderate-severity fire regimes, we again used a Chi-square comparison of proportions [44]. Specifically, we tested the probability that the actual age distributions differed from an expected stand-age distribution for a low/moderate-severity fire regime. The low/moderate-severity (expected) distribution was based on 12.5% of stands falling into each 40-year age class between 80–399 years (0–319) years at the onset of fire exclusion. Our null hypothesis was that there would be no significant difference between the actual and expected (low/moderate-severity) distributions.

Third, we tested, again using a Chi-square comparison of proportions [44], the hypothesis that there would be less evidence for historical mixed-severity fire in the generally drier ponderosa and Jeffrey pine stands than in the mixed-conifer forests (i.e., the pine forests would be more frequently dominated by older stands).

Results

Evidence for Historical Mixed-severity Fire Regimes in Ponderosa Pine and Mixed-conifer Forests

Rotations of high- and moderate- to high-severity fire. The studies that allow calculation of rotations of high-severity fire over large, ponderosa pine and mixed-conifer forest landscapes of western North America over time periods of at least 70 years include areas ranging from 40,700 to 1,193,200 ha (Table 4). These large landscapes totaled 2.2 million ha in Baja California, the Sierra Nevada, eastern Cascades, northern Rockies (Blue Mountains of Oregon), the Colorado Front Range and Arizona (Black Mesa and the Mogollon Plateau). Most of the evidence presented in these studies was from ponderosa pine forests.

The high-severity fire rotations in Table 4 do not support the hypothesis that low/moderate-severity fire regimes were predominant in the majority of ponderosa pine and mixed-conifer forests of western North America. In all the large, forest landscapes for which data covering at least 70 years exist, high-severity fire rotations ranged from about 217 to 849 years [57], and were mostly ~200–500 years. This is generally less than potential tree lifespans. For combined moderate- and high-severity fires in the eastern Cascades, rotations were 115–128 years (Table 4: [35]), while they were 249 years in the Colorado Front Range (Table 4: [58]). In the Blue Mountains (northern Rockies) and on the Mogollon Plateau in Arizona, high-severity fire rotations of 849 and 828 years, and moderate/high-severity fire rotations of 235 and 319 years, respectively [57], occurred. Where high-severity rotations are relatively long, as they are in these regions, forest structure in portions of the landscape will lack evidence for high-severity fire even though it occurs often enough to create age-class diversity. Thus, while about 40% of the Blue Mountains forests and about 62% of those on the Mogollon Plateau had evidence from GLO surveys of forests shaped by low/moderate-severity fire only [57], similar to the nearby Coconino Plateau [59], structural diversity created by high-severity fire was evident on the remainder of the landscape [57,59].

Numerous other studies that describe historical patterns of fire behavior also have documented or described evidence for mixed-severity fire effects in the ponderosa pine and mixed-conifer forests of western North American, including the occurrence of large high-severity fire patches (Table S1), and high-severity fire occurring over substantial areas of smaller landscapes over a time period of only a few decades prior to fire exclusion (e.g., Klamath region and a transitional area between the Sierra Nevada and eastern Cascades [60–63]).

Previous studies (Table 4) have used evidence of past fire severity from a variety of sources: GLO and other survey data, historical aerial photos; and mapping of vegetation and burns done prior to fire exclusion. The GLO analyses have been formally assessed for accuracy [64]. The methods performed well for addressing general hypotheses about the presence or absence of vegetation shaped by low- or high-severity fire. This was tested using existing vegetation plot data with an error of 14.4–23% [64].

Plot age distributions. A total of 2119 FIA plots representing a sample population of about 5.1 million ha of unmanaged low- to mid-elevation, montane forests in six regions (Figure 1, Table 5) were included in our analysis. Stand ages from ponderosa pine and mixed-conifer forests across the western USA never managed for timber cover areas ranging from 192,200 ha in eastern Cascades-eastern Sierra Nevada to 3,244,800 ha in the northern Rockies. Average stand ages ranged from 0 to 814 years, with the oldest stand in ponderosa pine in the eastern Cascades. The within plot standard deviation of the proportional difference among individual tree ages and stand age across all plots was 0.14 (e.g., for stands 100 years old, one standard deviation would include individual trees ~86–114 years old, and two standard deviations would include trees ~72–128 years old).

The comparison of actual stand ages from 1930–2009 and the rescaled (expected) stand ages from 1810–1889 assuming no effect of fire exclusion are shown in Figs. 2A–F. In all regions, there were highly significant differences between the actual and expected stand age distributions (average ages of dominant trees with no fire exclusion) ($P<0.001$, Fig. 2A–F), indicating that fire was the predominant disturbance prior to effective fire exclusion. The FIA database also indicates that, since the onset of fire suppression, the great majority of stands were initiated by fire. As illustrated by the abundance of plots with stand ages that date to the decades prior to fire exclusion (e.g. 80–160 years old presently), much of the landscapes had young forests, but the rate of establishment decreased dramatically after 1930 (stand ages <80 years are rare). The rate of young forest establishment decreased by a factor of 4 in the Sierra Nevada and southwestern USA, by 3x in the Klamath, and 2x in the eastern Cascades and central and northern Rockies.

Chi-square comparisons between actual stand-age distributions at the onset of fire exclusion versus the expected stand-age distributions for a low/moderate-severity fire had exceptionally low probabilities in all regions ($P \ll .00001$, $n = 61–877$). This was because plots were mostly dominated by young and intermediate aged trees prior to fire exclusion (Figs. 2A–F). The mean stand

Data from General Land Office or mapped data over large areas (>25,000 ha) over >70 or more years prior to fire exclusion.

[1]Study area was dominated by mixed conifer and Jeffrey pine and minimally logged. Fire exclusion only began in the 1970s and has had only a modest impact [138]. Thus, historical and current rates are assumed to be comparable.

[2]Analysis of Leiberg's mapping of high-severity fire areas within unlogged mixed-conifer Sierran stands is found in [139]. According to Leiberg [51], most such fire occurred prior to 1850. In addition, he stated ''If the many small lots [<32 ha] scattered throughout still growing stands were taken into account, the figure [amount of area burned severely] would be considerably increased.''

[3]The numerator was estimated at 100 years based on ponderosa pine in this region [140], whose growth would surpass 30 cm dbh, rendering mixed and high-severity effects indistinguishable (see [35: Table 1]). This calculation is conservative because tree growth to 30 cm dbh in moister forests is faster than 100 years.

[4]High- and mixed-severity fire consistent with a definition of >70% and 20–70% basal area mortality, respectively, was identified from overstory canopy percentage, the overstory size class, the understory size class, and the fire tolerance of the cover type (see [35: Table 1]). Large patch sizes of historical high severity fire (100s to >5000 ha) from this work are reported in [17].

[5]The estimate is from the span of years over which fire effects were distinguishable, using forest structure evident in the Government Land Office historical survey data, divided by the fraction of the forested landscape in which those fires occurred [56]. Rotations for high-severity fire are determined by dividing the observation period (the period of time over which fire effects are distinguishable by stand structure) by the percentage of the landscape experiencing high-severity fire. The methods were found to have 14.4–23% accuracy compared to plot sampling.

[6]High- and mixed-severity fire, consistent with a definition of >70% and 20–70%, respectively, were identified from overstory canopy percentage, the overstory size class, the understory size class, and the fire tolerance of the cover type (see [35: Table 1]).

[7]High-severity consistent with a definition of >70% basal area mortality [35] was identified having a percentage of small trees >50% and a percentage of large trees <20% [56,57,73],

[8]Estimated from the length of General Land Office section lines intercepted by moderate- and high-severity fire. Accuracy tests using the length of section lines intercepted by modern moderate- and high-severity fire yielded a relative error of 15.6%.

doi:10.1371/journal.pone.0087852.t005

ages at the time of onset of fire exclusion were 59–114 years, depending on the region, considerably shorter than current mean ages (105–148 years: Table 5). Therefore, the FIA data were inconsistent with the hypothesis that the ponderosa pine and mixed-conifer forests of western North America, in unmanaged landscapes, were predominantly park-like with low age-class diversity due to the dominant influence of low/moderate-severity fire.

The hypothesis that mixed-severity fire prior to fire exclusion would be lower in the driest (ponderosa and Jeffrey pine) forests than other forests also was not supported. Based on stand-ages (not shown), there was as much as or more mixed-severity fire in the pine forests. In the Pacific states, we found almost identical stand-age distributions from 1800–1900 in ponderosa/Jeffrey pine stands (n = 20 plots) versus all non-ponderosa stands (n = 204 plots). Plots from the time period 1800–1900 accounted for 70% and 73%, respectively, of all plots with dominant trees that established in or before 1900. In the northern and central Rockies, 86% of ponderosa pine stands (n = 66 plots) and 81% of the non-ponderosa pine stands (n = 615 plots) that established in or before 1900 had stand-ages between 1800 and 1900 ($\chi^2 = 0.85$, n = 676, $P > 0.6$). Likewise, in the southwestern USA, 98% of ponderosa pine stands (n = 96 plots) and 92% of the non-ponderosa stands (n = 37 plots) that established in or before 1900 had stand-ages between 1800 and 1900 ($\chi^2 = 1.27$, n = 133, $P > 0.25$). However, when all plots were considered, significantly more stands established from 1800–1900 in ponderosa pine than non-ponderosa forests ($\chi^2 = 11.96$, n = 1038, $P < 0.001$), indicating higher fire disturbance in pine forests.

Comparing the Weight of Landscape-scale Evidence by Region

The consistency of multiple lines of evidence for mixed-severity fire in the ponderosa pine and mixed-conifer forests is an important finding. In all regions, there were tree-age data supporting considerable age-class diversity created by mixed-severity fire, and a paucity of undisturbed park-like forests. The full weight of landscape-scale evidence is greatest in the regions with area-specific rotations of severe fire from GLO data: the eastern Cascades, nearby Blue Mountains in the northern Rockies, central Rockies, and southwestern USA (Table 4). In the Cascades, these data are further supported by analyses of early aerial photography at a regional scale [35], and in small landscapes [61–63] and numerous historical descriptions (see [56]: Table S1). In the northern Rockies, historical documentation (e.g., [45–48,50,53,54]) of mixed-severity regimes has been summarized in regional reviews [16,65,66], and stand-age reconstructions of historical fire regimes indicate mixed-severity fire in ponderosa-pine/Douglas-fir forests [67–69]. In the Colorado Front Range, the findings based on GLO data [57,58] are remarkably consistent with earlier studies based on tree-ring stand reconstructions from broadly distributed samples [70–72]. In the

Table 6. Current high-severity fire rotations.

Region	Source	Forest Types	Time period	Rotation (yrs)

Data cited are from low/mid-elevation conifer forests in western North America.
[1]Higher-severity fire: includes moderate- and high-severity.
doi:10.1371/journal.pone.0087852.t006

southwestern USA, GLO data are supportive of mixed-severity fire on most of Black Mesa and much of the Mogollon and Coconino Plateaus [57,59], while a number of other studies also describe evidence for mixed-severity fire [9,14,55,73–77].

The remaining forest regions that we assessed lack GLO analyses. However, in the Sierra Nevada and Klamath regions historical surveys and early air photo data describe mixed-severity fire regimes [20,30,49,51,60,78–87] (see Table S1 for descriptions). In all regions except the Klamath, there are multiple lines of evidence from landscape-scale studies, each supporting mixed-severity fire. In contrast, evidence supporting low/moderate-severity fire is confined to relatively small areas (e.g., [88–91]).

Historic vs. Contemporary Fire Regimes

We did not find evidence to support the hypothesis that fire exclusion has greatly increased the prevalence of severe fire in ponderosa pine and mixed-conifer forests (Tables 4–6, and Figs. 2A–F). Comparing current versus historical high-severity fire rotations, we found that current rotations were generally longer (less high-severity fire) in the Sierra Nevada and central Rockies (Tables 4 and 6, Table S1). No direct historical comparison could be made between current and historical high-severity rotations in the Klamath and northern Rockies at the spatial scale required in Table 4, but evidence presented in Table S1 suggests that current rotations of 599 years and 500 years, respectively, may be longer. The estimated rotation of 625 years for recent high-severity fire in the southwestern USA [92] was shorter than the historical estimate of 828 years for the Mogollon Plateau in Arizona. Combining the Mogollon Plateau and Black Mesa to provide a better comparison with fire across the southwestern USA produces a historical high-severity rotation of 522 years [57]. In the eastern Cascades, high-severity fire rotations since 1984 (889 years) were longer than historical rotations (Table 6 vs. Table 4).

Discussion

Historical Fire Regimes

The primary objective of this paper was to address how prevalent mixed-severity fire regimes were historically in ponderosa pine, mixed conifer, and other low- to mid- elevation, montane forests of western North America. We hypothesized that age-class diversity was low, consistent with long-term effects of low/moderate-severity fire regimes (Table 1). We reviewed evidence with inference across both large and smaller landscapes across many forest regions. The majority of the evidence did not support the low/moderate-severity fire hypothesis, but, instead, supported the alternate hypothesis that mixed-severity fire shaped these forest landscapes. This finding applies to Pacific states ponderosa pine, Jeffrey pine, and California mixed-conifer forests, as well as ponderosa pine and mixed-conifer forests in the eastern Cascades, Rockies and southwestern USA, where low/moderate-severity regimes have often been applied. In some areas (Blue Mountains, Mogollon and Coconino Plateaus) high-severity fire occurred at less frequent intervals (rotations of 828–849 years) [57,59]. Even at these rotations, high-severity fire creates considerable age-class diversity in a landscape, and moderate/high-severity fire rotations were 235–319 years, which further enhances diversity (with small groupings of high-severity fire interspersed within moderate-severity fire areas).

FIA stand ages in the unmanaged forests in all regions reflect a pattern of high age-class diversity occurring prior to federal fire suppression policies and reductions in Native American burning (by the early 20th century) with the arrival of settlers [20,46,49,51] Natural disturbances occurred at rates that led to stands numerically dominated mainly by young and intermediate-aged trees. Disturbance processes dramatically declined following the onset of fire exclusion, suggesting fire was the primary disturbance agent [35]. However, in considering the age patterns of dominant trees in the FIA plots, it is essential to also address alternative explanations for the dominance of young- and intermediate-aged stands prior to fire exclusion, such as climate variability and disturbance by insect outbreaks.

While we recognize that climate variability influences rates of tree regeneration generally [93], and may determine success or failure of tree regeneration specifically following disturbance, we believe that the broad patterns of dominant overstory tree ages in the FIA plots mainly reflect the effects of past fire for several reasons. The dominant stand ages of young and intermediate aged trees prior to fire exclusion are consistent with periodic disturbances with significant tree mortality that shifted dominance to a new generation of trees, rather than solely episodic tree establishment due to climatic variation at a multi-decadal scale. This is supported by research in the central Rockies where, at a multi-decadal time scales, large datasets of tree recruitment dates over the past c. 250 years do not correlate with moister climate at the same time scale, but instead correlate with drier climate that was conducive to high-severity fires [70–72,91]. Likewise, studies in the same area show that outbreaks of bark beetles and defoliators result in growth releases of non-host trees rather than even-aged, multi-species tree cohorts [94,95], thus facilitating discrimination from post-fire stand structures [91]. Fire exclusion was likely effective in some areas between 1900 and 1930, which could have led to understory tree recruitment in this time frame. However, research suggests that in some areas the favorable influences of timber harvesting and/or cattle grazing on tree establishment may confound the attribution of tree recruitment to fire exclusion [96]. In addition, the plot age data demonstrate that recruitment was just as common or more common in decades before 1900 as between 1890 and 1930. Lastly, while it is possible that greater mortality in older trees, from competition or insects and pathogens, might explain high levels of recruitment prior to fire exclusion, we do not see this pattern during the suppression era. Thus, higher levels of mortality in older trees seems likely to have been caused by fire.

Our findings illustrate the need for studies with a spatial scale of inference suited to describing patterns across large, heterogeneous landscapes. This is illustrated by three recent studies from old forest stands (one in the Black Hills (500 ha), one in the Sierra Nevada (3,000 ha), and one in the southwestern USA (307 ha)) that reported very little or no historical high-severity fire, and hence low-severity regimes (Table S1: [88–90]). In contrast, broader-scale analyses of historical data for the Sierra Nevada (Table S1: [78]:), Black Hills [65], and southwestern USA [57] suggest fire regimes in the broader landscape within which these three studies occurred were mixed-severity.

A fourth study [97] analyzed 1914–1922 Bureau of Indian Affairs (BIA) timber cruise plot data from within a larger area (38,651 ha), and found relatively low tree densities in ponderosa pine and mixed-conifer forests of the eastern Klamath region in Oregon, and suggested that forests were too open to support any significant crown fire. However, only a subset of the townships surveyed by BIA in these forest types were included in the analysis (Table S1), and the surveys did not include trees 10–15 cm dbh, which comprise ~20% of all trees [97], and most surveys did not include lodgepole pine, which comprise ~10% or more of these forest types in that region within unlogged areas [49]. In addition, historical data indicate that extensive timber harvesting had occurred in the areas analyzed by 1914–1922 (Table S1), and evidence of previous timber harvesting was not among the factors that BIA surveyors were required to note (Table S1). Tree densities in unlogged reference ponderosa pine and mixed-conifer forests in this landscape from the late 19th century and early 20th century indicate much denser and more variable forest conditions (Table S1). Also, USGS surveys conducted in the 1890s within unlogged ponderosa pine and mixed-conifer forests across a larger expanse (310,267 ha) map substantial high-severity fire from 1855–1900 (high-severity rotation of 352 years), suggesting a mixed-severity regime (Table S1).

The absence of evidence for mixed-severity fire in some older forests selected for study may be due to fire exclusion. If the effect of fire exclusion in reducing mixed-severity fire is not accounted for in describing reference conditions, it may lead to shifting baseline syndrome (i.e., a system is not measured against the true baseline, but against one that already has departed from the true baseline [98]). This effect may be caused or compounded by diminishing evidence of age-class diversity. For example, high-severity fire can be mapped at landscape scales from early air photos [9,17,61–63,99], but the same historic fire effects may not be visible from current imagery that can be used for assessing landscape-scale patterns.

Data with greater temporal depth than analyzed here can better capture past variability in the frequency of large fire events. Thus, it is noteworthy that paleoecological studies also support mixed-severity fire regimes for the ponderosa pine and mixed-conifer forests. These studies have found charcoal depositions from major fire episodes in ponderosa pine and interior Douglas-fir forests occurring for millennia in the northern Rockies (central Idaho: [100,101]), Klamath [102], Sierra Nevada [103], eastern Oregon Cascades [104], and southwestern USA [105–107]. These major episodes are generally interpreted as large, severe fire events [101–107].

The occurrence of mixed-severity fire prior to fire exclusion is also well supported by another line of evidence: the potential behavior of wildfire as affected by weather and climate. Based on direct observations of fire behavior, high winds (generally 10 m open wind speeds >32–35 kilometers/hr) may subject virtually any conifer forest, regardless of fuel density, to crown fire [108]. Thus, empirical data call into question a major premise of the low/moderate-severity fire regime: that ponderosa pine and mixed-conifer forests may be completely resistant to crown fire. Fire intensity increases with winds, and at winds of >30 km/hr spot fires may be ignited over 1 km ahead of the fire front [109]. The coalescing of separate spot fires with the fire front can further energize wind-driven fire [110,111]. Severe droughts also intensify fires by reducing fuel moisture to extremely low levels, allowing crown fire under less windy conditions [108,112]. Severe drought years throughout much of western North America occurred from 1856 to 1865, 1870 to 1877 and 1890 to 1896 [113]. The extensive high-severity fires of 1910 (the Big Burn in Idaho and Montana), when large areas of drier forests burned at high severity prior to fire exclusion–much of it in ponderosa pine–illustrate how fire behavior that is rare temporally due to extreme climate and weather can dominate in space [1]. Many fire episodes in the charcoal records that exceed modern fires undoubtedly involve combinations of extreme wind, drought, and mass fire.

The largest patch sizes of high-severity fire likely occurred during the most extreme conditions for fire behavior. While patch sizes of high-severity fire are difficult to document, it follows from commonly observed heavy-tailed distributions of patch sizes created by fire [114,115] that very large patches of high-severity fire (thousands of ha, e.g., [17: Fig. 1, 58]) were a primary reason why considerable area exhibited forest structure consistent with high-severity fire historically in all regions. Large patches, though numerically subordinate, are dominant in terms of total area burned, while the opposite applies to small patches [58].

There is abundant evidence that past forests may not have required extreme weather and climate for mixed-severity fire to have occurred. Younger, more flammable forests [32] appear to have been widespread in dry-forest regions based on dominant stand ages prior to fire exclusion (Fig. 2). In addition, the ranges in fire-free intervals in many low- to mid-elevation forested areas were sufficient to allow for substantial vegetation growth and recovery of fuels between fires (e.g., 20–50+ year rotations [61–63,116–118]). For example, in the Sierra Nevada, fuels may recover to pre-burn levels in nine years [119,120], so fire-free interludes (or fire rotations), more often than not, may have been sufficient to allow growth of significant amounts of high-energy shrub fuels. In describing low/mid-elevation forests throughout the northern Sierra Nevada, Leiberg [51: page 32) states: "There is a great amount of undergrowth in the forest which has attained its present proportions chiefly through the agency of fire. Most of it [undergrowth] consists of species of *Ceanothus*." For mid-elevation forests, he reports (page 37): "Nearly all the type situated at altitudes below 7,000' [2134 m] carries a vast amount of undergrowth. It consists mainly of manzanita [*Arctostaphylos* spp.], ceanothus, and scrub oak [*Quercus chrysolepis, Q.vaccinifolia*]." Similarly abundant shrub fuels were also documented historically in the westside of the central/southern Sierra Nevada [51], in the eastern Oregon Cascades [56: Appendix A] and in Oregon's Blue Mountains [57]. Flame lengths in actively burning manzanita and ceanothus are typically 4–5 times the ~1–2 m height of the shrubs, sufficient to cause ignition of forest canopy tree crowns under favorable burning conditions. Many of these shrub species recruit primarily, if not exclusively, after severe fire, and their occurrence is a further indication of the historical presence of such fire [121].

Changes in Fire Regimes and Stand Age Distributions with Fire Exclusion

We also hypothesized, consistent with existing concerns about unprecedented fire severity in western North America (e.g., [6–9,11,13,15,17,28]), that fire exclusion has greatly increased the prevalence of severe fire in ponderosa pine and mixed-conifer forests. We found little support for this hypothesis. Over the full period of effective fire exclusion in unmanaged forests, average ages of dominant overstory trees in FIA plots suggest there has been about a threefold to fourfold decrease in stand initiation due to fire in the Sierra Nevada, Klamath, and southwestern USA, and about a twofold decrease in the eastern Cascades, central and northern Rockies (Figs. 2A–F). In addition, patch sizes of high-severity fire in the central Rockies have not increased [58]. Our assessment of high-severity rotations based upon existing literature also revealed a generally lower incidence of high-severity fire in these forests in recent decades (Tables 4 and 6, and S1).

Conclusion

The importance of multiple lines of evidence has been stressed in determining whether mixed-severity fire regimes applied historically [122]. Our results illustrate broad evidence of mixed-severity fire regimes in ponderosa pine and mixed-conifer forests of western North America. Prior to settlement and fire exclusion, these forests historically exhibited much greater structural and successional diversity than implied by the low/moderate-severity model (Table 2). Lack of recognition of past variability in fire may be due, in part, to common misclassifications of fire regimes. To improve clarity in communication, we propose that "low/moderate-severity" be applied to those regimes where, as the term implies, high-severity fire is absent. These circumstances appear to be quite rare in the ponderosa pine and mixed-conifer forests of western North America. Therefore, a fire regime with a high-severity component of any amount should not be classified as low/moderate-severity [e.g., 9,17,28].

Our findings suggest a need to recognize mixed-severity fire regimes (Table 2) as the predominant fire regime for most of the ponderosa pine and mixed-conifer forests of western North America. Given societal aversion to wildfires, the threat to human assets from wildfires, and anticipated effects of climate change on future wildfires, many will question the wisdom of incorporating historical mixed-severity fire into management goals. However, focusing fire risk reduction activities adjacent to homes is needed to protect communities [123], and this may expand opportunities for managed wildland fire–away from towns–for ecological benefits of fire-dependent biota. However, a major challenge lies with the transfer of information needed to move the public and decision-makers from the current perspective–that the effects of contemporary mixed-severity fire events are unnatural, harmful, inappropriate and more extensive due to fire exclusion–to embrace a different paradigm [124]. This paradigm would not emphasize a single, appropriate condition, but would explicitly recognize the vital role of variation in fire in maintaining successional diversity and fire-dependent biota [125], and allow natural rates of ecological succession [18,19,126–128]. It would also recognize that these effects have generally diminished, and that more fire, including high-severity fire, where it is in deficit, is an ecologically desirable goal. Of course, while most current research indicates that fire severity is not increasing in ponderosa pine and mixed-conifer forests of western North America [129–132], it will be critical to continually assess fire regimes in a changing climate.

For management, perhaps the most profound implication of this study is that the need for forest "restoration" designed to reduce variation in fire behavior may be much less extensive than implied by many current forest management plans or promoted by recent legislation. Incorporating mixed-severity fire into management goals, and adapting human communities to fire by focusing fire risk reduction activities adjacent to homes [123], may help maintain characteristic biodiversity, expand opportunities to manage fire for ecological benefits, reduce management costs, and protect human communities.

Supporting Information

Table S1 Evidence of historic fire severity in ponderosa pine and mixed-conifer forests of western North America. A summary of published studies and historical documents that provide evidence regarding mixed-severity fire in the ponderosa pine and mixed-conifer forests of western North America, but do not provide sufficient information to estimate high-severity fire rotations, or were conducted in smaller landscapes. Many fire scar studies have also been done in these forests, but fire scars alone are not sufficient to distinguish low-from mixed-severity regimes.

Abstract

In a recent PLOS ONE paper, we conducted an evidence-based analysis of current versus historical fire regimes and concluded that traditionally defined reference conditions of low-severity fire regimes for ponderosa pine (*Pinus ponderosa*) and mixed-conifer forests were incomplete, missing considerable variability in forest structure and fire regimes. Stevens et al. (this issue) agree that high-severity fire was a component of these forests, but disagree that one of the several sources of evidence, stand age from a large number of forest inventory and analysis (FIA) plots across the western USA, support our findings that severe fire played more than a minor role ecologically in these forests. Here we highlight areas of agreement and disagreement about past fire, and analyze the methods Stevens et al. used to assess the FIA stand-age data. We found a major problem with a calculation they used to conclude that the FIA data were not useful for evaluating fire regimes. Their calculation, as well as a narrowing of the definition of high-severity fire from the one we used, leads to a large underestimate of conditions consistent with historical high-severity fire. The FIA stand age data do have limitations but they are consistent with other landscape-inference data sources in supporting a broader paradigm about historical variability of fire in ponderosa and mixed-conifer forests than had been traditionally recognized, as described in our previous PLOS paper.

Introduction

The accompanying paper by Stevens et al. [1] is critical of one of the several lines of evidence in Odion et al. (2014) [2] that indicate the traditional reference conditions of low-severity fire regimes are incomplete for most ponderosa pine and mixed-conifer forests of western North America. Specifically, Stevens et al. [1] believe that the stand age attribute in Forest Inventory and Analysis (FIA) data is not a useful descriptor of historical fire regimes in ponderosa pine and mixed-conifer forests.

Here, we first briefly summarize points of agreement between Stevens et al. [1] and us, and then discuss in more detail areas where we disagree, including the analysis and interpretation of FIA stand age data. Authorship of this reply is comprised by those who conducted the FIA portion of Odion et al. (2014) [2], as well as authors of Odion et al. whose contributions and backgrounds were needed to respond to FIA-critique elements by Stevens et al. [1] that went beyond the scope of the FIA analysis in Odion et al. (2014) [2].

Areas of Agreement

High-severity fire is a natural component of ponderosa pine and mixed-conifer fire regimes

In Odion et al. (2014) [2], we presented several lines of converging evidence that high-severity fire was an important part of historical fire regimes in ponderosa pine and mixed-conifer forests. Over three-quarters of our results pertained to lines of evidence other than FIA stand age data. Stevens et al. [1] reviewed this evidence, some of which was based upon studies published by co-authors of Stevens et al., and concluded the following: "High-severity fire was undoubtedly a component of fire regimes in ponderosa pine and drier mixed-conifer forests." This represents a significant shift from perspectives in much of the literature in recent decades, which often mentions only low- or low-moderate severity fire in describing historical fire regimes in ponderosa pine and mixed-conifer forests.

Significant tree recruitment occurs in the absence of fire

We did not intend to suggest that tree recruitment occurred only with fire. Stevens et al. hypothesize that pulsed recruitment in the absence of fire has shaped the age distributions in many FIA plots. We agree that this process occurred historically. There is also agreement that a dominant cohort of trees will establish after high-severity fire, but that later in stand development understory recruitment can happen with favorable climate or following insect outbreaks. This, along with the presence of some trees that pre-date the fire, will create an uneven-aged stand, but there may still be a dominant overstory size class established after fire.

FIA Stand Age Data May Provide Evidence Consistent with Past High-Severity Fire

Stevens et al. [1] report that 42% of the FIA plots used in Odion et al. (2014) [2] had demographic characteristics consistent with a mortality and recruitment event corresponding generally with the FIA stand age. These plots had an estimated 0–10% of the stand basal area in trees that were older than the stand age. The rest of the basal area (all of it in many cases) was from trees that established after (more recently than) the stand age date, even though most of the plots had stand ages < 200 years old. Despite some qualifications, Stevens et al. [1] conclude that it is plausible that these 42% of plots were visited by historical high-severity fire. However, although Stevens et al. recognize high-severity fire as a component of ponderosa pine and mixed-conifer forests, the definition (threshold of mortality) and patch size of high-severity fire remain a matter of considerable debate.

Areas of Disagreement

Appropriate threshold of mortality for high severity fire

Stevens et al. replaced the traditional 70–100% mortality definition for high-severity fire (see, e.g., [3]) that we used with a new 90–100% definition, which means their analysis does not replicate ours and does not refute our findings. Even though this replacement invalidates their analysis of our study, 42% of the FIA plots still have demographic characteristics consistent with high-severity fire with their narrowed definition. Using our original 70–100% mortality definition, there is agreement on 68% of FIA plots regarding demographic characteristics consistent with high-severity fire (and the level of agreement is even higher than this, due to a calculation error in Stevens et al., as discussed below).

Stevens et al. [1] suggest, based on findings of Miller and Quayle (2015) [4], that the high-severity fire definition used by Odion et al. (2014) [2] should be narrowed from 70–100% basal area mortality to 90–100% basal area mortality because Miller and Quayle found that high-severity fire field plots with less than 100% tree mortality were rare. However, 34% of all of their plots with $\geq$75% basal area mortality had live, surviving trees [4]. Thus, surviving trees in high-severity fire plots were not rare based on data that they cite. Further, Miller and Quayle [4] used plots ranging in size from 0.07 ha to 0.63 ha, while FIA plots consist of four subplots spread over an area of 1.0 ha. Thus, the plots of interest here are more likely to contain surviving trees than those of Miller and Quayle [4]. Further, Miller and Quayle (2015) [4] indicate a user and producer accuracy of 11.1 and 19.2 percent for classifying areas with 75–89% percent basal area mortality. Therefore areas with 75–89% mortality were often not identified correctly in their study.

There is also a logical problem: if high-severity fire predominantly caused 90–100% mortality historically, and 70–89% mortality was rare, then there would be very little difference between the number of FIA plots with 90–100% mortality and the number with 70–100% mortality. But, Stevens et al. found a large difference when using these basal area thresholds. Therefore, plots with 70–89% mortality were not rare, and narrowing the fire-severity definition is not supported.

Stevens et al. [1] state that the "minimum threshold of 70% mortality used by Odion et al. [2] to describe a high-severity patch (and the 75% threshold employed by Landfire) was not developed to describe mortality within a stand, but rather mortality across an entire fire." However, the two studies cited by Stevens et al. [1] to support this, Agee (1993) [3] and Barrett et al. (2010) [5], say the opposite (see page 23 of Agee 1993 [3], and page 30 of Barrett et al. (2010) [5].

Plot sizes needed to define high-severity fire

Stevens et al. [1] point out that FIA plot footprints are only 0.4 ha in size in California, Oregon, and Washington, and are only 0.067 ha in size in the other western U.S. states, and use this to suggest that the FIA plots analyzed by Odion et al. [2] were too small to capture true high-severity fire effects. However, Stevens et al. [1] recognize high-severity fire patches as small as 0.4 ha as representing high-severity fire effects. Further, although the total footprint of subplots in FIA plots may be only 0.067 or 0.4 ha, these subplots are representative of a 1.0 ha area. The FIA plots do not capture the size and shape of patches of historical fire, and do not encompass many high-severity patches, which we recognize. But, because they are probabilistic samples, the amount of high-severity fire captured by FIA is a statistical estimate of total amount of high-severity fire. It would be a problem if high-severity fire were rare, or if only a small number of FIA plots were analyzed, but evidence for high-severity fire was abundant, and we analyzed thousands of plots.

Use of diameter-age relationships for reconstructing past basal area of trees

To understand historical forest structure and fire, it is common to reconstruct the size of trees in the 1800s by subtracting tree growth since that time (e.g., [6]). Stevens et al. recognize that the "basal area of the surviving older trees would have increased in the decades between the year implied by the FIA stand age and the measurement date, thus potentially overestimating their past contribution to the stand basal area in the year implied by the FIA stand age." In other words, to the extent that the basal area of surviving trees is overestimated, this translates directly to an under-representation of the potential occurrence of historical high-severity fire. However, Stevens et al. [1] did not subtract the basal area that overestimates the past contributions of surviving trees. The effects can be seen via the following general simulation.

Suppose a plot was burned by high-severity fire 100 years ago with 6.1% basal area surviving fire consisting of 16 m^2 of dead tree basal area. There are 5 live trees of 0.5 m in diameter at breast height (dbh) in the 1-ha FIA plot for a total of 1 m^2 live, surviving basal area. The surviving trees have a higher growth increment in earlier years which decreases as they age. However, when the mean growth rate is calculated using 1594 mature ponderosa pine in dry forests in Oregon [7], the effects of the slower growth at old age is included to give a mean of 0.45 cm dbh/yr. By not considering the growth rates of surviving trees, surviving basal area at the time of the fire would be overestimated by 3.5 times 100 years later. After two hundred years, the age of some FIA plots, the overestimate would be nearly 8 times the actual plot survivorship, with nearly half the basal area incorrectly considered to have survived since prior to the stand age date. Mortality of mature trees after (more recent than) the stand age date could have occurred in some cases, reducing the overestimates by Stevens et al., but this would likely be a small amount compared to the large magnitude of the overestimates. Thus, the potential effects of high-severity fire were greatly underestimated by Stevens et al.

Evidence for historical high-severity fire patches >1,000 ha in size

Stevens et al. [1] suggest that high-severity fire patches >1,000 ha in size in some current fires represent a "departure" from historical conditions. However, DellaSala and Hanson (2015) ([8]: pp. 30–33) present numerous examples of historical data sources documenting high-severity fire patches >1,000 ha occurring before fire suppression in previously unlogged forests in both ponderosa pine and mixed-conifer forest types in every major region of the western U. S. Even though large high-severity patches may have been infrequent, they accounted for most high-severity fire [9].

Combining fire scar data and stand structure data from different plots

Stevens et al. [1] try to test the hypothesis that there would be minimal tree recruitment in the absence of high-severity fire in the FIA plots we studied. However, the locations chosen by Stevens et al. [1] to evaluate recruitment and fire in FIA plots did not actually include any FIA plots. The locations were mostly subjectively selected plots known to not have had severe fire in their long fire-scar history. The plots were up to 1 km away from any FIA plots. Therefore, they do not represent the population of FIA plots we studied.

Fire and tree recruitment

In all six regions we analyzed in Odion et al., the onset of fire suppression about a century ago coincides with a dramatic reduction in the initiation of trees that form the dominant overstory size classes. Thus, the removal of fire had a profound effect on the process of recruitment over vast areas. Recruitment following fire suppression, as hypothesized by Stevens et al., could not account for the pattern of abundant establishment of the dominant size classes of trees before fire suppression. If high-severity fire was a minor process in creating new stand ages, establishment of the dominant overstory trees would not have declined so dramatically with fire suppression.

Stevens et al. claim that "Most" ponderosa pine forests and "many" low/mid-elevation mixed-conifer forests historically were "Low-density" forests with frequent, fuel-limited low/moderate-severity fire regimes is not supported by the evidence

This suggestion by Stevens et al. [1] overstates certain evidence, and does not consider other evidence. The sources cited by Stevens et al. [1] are a biased selection of studies that were mostly conducted at relatively local spatial scales, and were often in old-growth forests that are inherently low-density and by definition have not experienced high-severity fire for centuries. The sources cited by Stevens et al. also include studies of current tree densities that try to determine past tree densities but do not have any way to measure historical trees that died, fell, and decayed, and studies where the past effects of logging or fuel wood cutting (when mining occurred and large amounts of wood fuel was needed) cannot be ruled out [2] or where incomplete historical survey data were used [10]. Additionally, Stevens et al. omit reference to dozens of scientific sources indicating more variable historical ponderosa pine and mixed-conifer forests.

In contrast, Odion et al. (2014)[2] reviewed dozens of historical data sources and reconstructions, finding that historical ponderosa pine and mixed-conifer forests: (1) were highly variable in structure/density; (2) had highly variable fire severity, and most forests were dominated by mixed- and high-severity fire; and (3) consistently had a significant component of open forests dominated by low-severity fire at any given time.

Conclusion

The concern raised by Stevens et al. [1] pertains to only one of the multiple lines of evidence in Odion et al. [2] that together strongly support the historical importance of high-severity fire in ponderosa pine and mixed-conifer forests of the western U.S. Stevens et al.'s comment, specifically on stand age analysis based on Forest Inventory and Analysis field plots, does not refute our study. This is because it is based on a different definition of high-severity fire than the classical definition used by Odion et al. (2014) [2], which is consistent with scientific literature. The new definition proposed by Stevens et al. [1] is based on errors and mischaracterizations of cited sources. Using our definition or theirs of high severity, Stevens et al. [1] found that many FIA plots had demographic structure consistent with a high-severity fire in the 200 years prior to fire suppression and the number of these plots was likely a large underestimate due to the improperly narrow definition of high-severity fire used by Stevens et al., and a major calculation error in their methods.

Acknowledgments

We appreciate the comments of Jens Stevens and two anonymous reviewers.

Abstract: The Northern Spotted Owl (*Strix occidentalis caurina*) is an emblematic, threatened raptor associated with dense, late-successional forests in the Pacific Northwest, USA. Concerns over high-severity fire and reduced timber harvesting have led to programs to commercially thin forests, and this may occur within habitat designated as "critical" for spotted owls. However, thinning is only allowed under the U.S. Government spotted owl guidelines if the long-term benefits clearly outweigh adverse impacts. This possibility remains uncertain. Adverse impacts from commercial thinning may be caused by removal of key habitat elements and creation of forests that are more open than those likely to be occupied by spotted owls. Benefits of thinning may accrue through reduction in high-severity fire, yet whether the fire-reduction benefits accrue faster than the adverse impacts of reduced late-successional habitat from thinning remains an untested hypothesis. We found that rotations of severe fire (the time required for high-severity fire to burn an area equal to the area of interest once) in spotted owl habitat since 1996, the earliest date we could use, were 362 and 913 years for the two regions of interest: the Klamath and dry Cascades. Using empirical data, we calculated the future amount of spotted owl habitat that may be maintained with these rates of high-severity fire and ongoing forest regrowth rates with and without commercial thinning. Over 40 years, habitat loss would be far greater than with no thinning because, under a "best case" scenario, thinning reduced 3.4 and 6.0 times more dense, late-successional forest than it prevented from burning in high-severity fire in the Klamath and dry Cascades, respectively. Even if rates of fire increase substantially, the requirement that the long-term benefits of commercial thinning clearly outweigh adverse impacts is not attainable with commercial thinning in spotted owl habitat. It is also becoming increasingly recognized that exclusion of high-severity fire may not benefit spotted owls in areas where owls evolved with reoccurring fires in the landscape.

Keywords: Fire rotation, forest regrowth rate, forest thinning, future habitat, habitat loss, late-successional forest, policy implications, severe fire, spotted owl.

INTRODUCTION

Conservation of the emblematic Northern Spotted Owl (*Strix occidentalis* ssp. *caurina*) in the Pacific Northwest of North America has become a global example of balancing conflicting land management goals (DellaSala and Williams 2006). Concern over degradation of the owl's dense, late-successional forest habitat led to the 1994 Northwest Forest Plan (NWFP). The NWFP shifted management on ~100,000 km^2 of federal USA forestlands from an emphasis on resource extraction to embrace ecosystem management and biodiversity conservation goals. Under the NWFP, ~30% of federal lands traditionally managed for timber production were placed in late-successional reserves that emphasized conservation goals and limited timber harvesting (USFS/USDI 1994).

Over the last decade, managers and policy makers have become increasingly concerned about high-severity fire and reduced timber harvesting in NWFP dry forests (e.g., Spies *et al.* 2006, Power 2006, Thomas *et al.* 2006, Ager *et al.* 2007, USFWS 2011). Forest thinning has been viewed as a solution for controlling fires in dry forests throughout western North America (Agee and Skinner 2005, Stephens and Ruth 2005) and commercial criteria have been included to pursue timber harvest goals (Johnson and Franklin 2009, Franklin and Johnson 2012). Commercial thinning prescriptions currently being implemented under these

1874-2130/14 2014 Bentham Open

criteria may remove up to one-half of forest basal area, and may also include patch cutting or small clear cuts (USDI 2011). Commercial thinning is now proceeding rapidly without a full understanding of the long-term risks.

For spotted owls, thinning and associated activities often remove or reduce key habitat features in direct proportion to the intensity of the commercial prescription. Key spotted owl habitat features that may be reduced or removed directly or indirectly include high tree density and canopy cover (King 1993, Pidgeon 1995), recently killed pines (*Pinus* spp.) and abundant snags (Pidgeon 1995), multiple tree layers, with abundant medium and small white fir (*Abies concolor*) or Douglas-fir (*Pseudotsuga menziesii*) (King 1993, Pidgeon 1995, Everett *et al.* 1997, Irwin *et al.* 2012), large volume of mature-sized down logs (Pidgeon 1995), shrubs (King 1993, Pidgeon 1995, Irwin *et al.* 2012) and trees with heavy mistletoe infections (Hessburg *et al.* 2008), which are essential for spotted owl nesting (USFWS 2011). Thinning or contemporary harvest near the nest or activity center has been shown to displace Northern Spotted Owls (Forsman *et al.* 1984, King 1993, Hicks *et al.* 1999, Meiman *et al.* 2003). Telemetry studies on California Spotted Owls (*Strix occidentalis* ssp. *occidentalis*) in the Sierra Nevada found that owls avoided Defensible Fuel Profile Zones (an intensive thinning treatment) (USFS 2010). Unoccupied California Spotted Owl territories had a lower probability of re-occupancy after timber harvest, even when habitat alterations comprised <5% of a territory (Seamans and Gutiérrez 2007). In addition, Barred Owls (*S. varia*), which out-compete spotted owls (Dugger *et al.* 2011), use younger and more open forests compared to Northern Spotted Owls (Wiens 2012).

Studies also have found negative impacts of thinning to northern flying squirrels (*Glaucomys sabrinus*), the primary prey of Northern Spotted Owls in most of its range (Waters and Zabel 1995, Waters *et al.* 2000, Carey 2001, Ransome and Sullivan 2002, Gomez *et al.* 2005, Ransome *et al.* 2004, Bull *et al.* 2004, Meyer *et al.* 2007, Wilson 2008, Holloway and Smith 2011, Manning *et al.* 2012). Negative effects may persist for 15 years or longer (Wilson 2008). In addition, openings between trees from thinning may create barriers, due to predator avoidance, for flying squirrels to cross using its gliding locomotion (Manning *et al.* 2012). Thinning has also been found to have negative effects on the abundance of other main prey species for Northern Spotted Owls such as red-backed voles (*Myodes californicus*) (Suzuki and Hayes 2003) and woodrats (*Neotoma cinerea, N. fuscipes*) (Lehmkuhl *et al.* 2006).

Because of the many conflicts between thinning and spotted owl conservation, some authors have recommended that treatments aimed at controlling fire avoid spotted owl habitat and instead treat vegetation elsewhere that is the most flammable and strategic for accomplishing fuel treatment goals (Gaines *et al.* 2010). The 2011 Recovery Plan for the Northern Spotted Owl, the blueprint for management of this species on federal lands in the region (USFWS 2011), contains the proviso that long-term benefits to spotted owls of forest thinning treatments must clearly outweigh adverse impacts (USFWS 2011). The U.S. Fish and Wildlife agency that developed the plan suggested that benefits over time might accrue from a net increase in habitat because fire disturbances would be reduced (USFWS 2011). But whether the benefits would outweigh the impacts remains uncertain due to limitations of previous assessments.

Previous assessments of the efficacy of thinning treatments in reducing fire disturbances in spotted owl habitat (Wilson and Baker 1998, Lee and Irwin 2005, Roloff *et al.* 2005, 2012, Calkin *et al.* 2005, Hummel and Calkin 2005, Ager *et al.* 2007, Lehmkuhl *et al.* 2007) have not incorporated the probability of high-severity fires occurring during the treatment lifespan. The effect of this is to overestimate treatment efficacy in potentially controlling fire or fire behavior (Rhodes and Baker 2008). Nor have the effects of recruitment of dense, late-successional forest that act to offset loss from fire been included in prior assessments. In addition, impacts of the kind of commercial thinning treatments being implemented to address dry forest concerns have not been fully considered for the owl or its prey (e.g., Ager *et al.* 2007, Lehmkuhl *et al.* 2007, Roloff *et al.* 2012). Current commercial thinning prescriptions being implemented in dry forests specifically identify desired future conditions to be maintained (e.g. Johnson and Franklin 2009) that have basal area and other structural targets mostly well below the minimum levels that have been found in spotted owl nesting, roosting and foraging habitat (NRF) in dry forests. For example, basal area targets in a project in southwest Oregon designed to demonstrate the thinning prescriptions in dry forest spotted owl habitat were 13.75-27.5 m^2/ha (USDI 2011), while stands < 23 m^2/ha very rarely support spotted owl nesting territories (Buchanan and Irwin 1995). In addition, the Recovery Plan (USFWS 2011) permits thinning in core areas, but emphasizes treating areas outside of core areas, so there is a need for assessment of impacts outside core areas as well. Areas outside cores may be essential for foraging and be part of the breeding season home range. Furthermore, owls often move outside core areas (USFWS 2011). Lastly, available habitat outside existing cores may become important to owl recovery, particularly if spotted owls are displaced from higher quality habitat by Barred Owls (Dugger *et al.* 2011).

To assess whether benefits of commercial thinning outweigh adverse impacts to spotted owls in dry forests (USFWS 2011), quantitative assessments are needed that allow for direct assessment of the amounts of any dense, mature or late-successional habitat that would be reduced by both commercial prescriptions and severe fire. Accordingly, we calculated these amounts by projecting them over 40 years and incorporated into our calculations the effects of forest regrowth. For our calculations, we used empirical data on fire and forest regrowth from the potential habitat within the two dry forest regions where spotted owls occur, the Klamath and dry Cascades of California, Oregon, and Washington, that are subject to thinning. We analyzed each region separately using region-wide data. Conservation planning for spotted owls commonly occurs at the scale of these regions. For our thinning treatment, we chose a "best" scenario for minimizing the amount of dense, late-successional forest to be treated (Lehmkuhl *et al.* 2007); while we used an optimistic scenario for treatment efficacy, assuming that a 50% reduction in high-severity fire would occur (Ager *et al.* 2007). We also illustrate the effects of varying treatment amount and efficacy. To calculate rotations of severe fire in the forests of the study area, we used available fire data from a time period, 1996-2011, which includes exceptionally large, rare fire events. Our approach may be useful to managers interested in maintaining habitat for other species that rely on dense forests in fire-prone regions (Odion and Hanson 2013).

METHODS

Study Area

We analyzed fire and forest recruitment trends in 19,000 km^2 of dry forests in the Klamath and 18,400 km^2 in the Cascades provinces. As in Hanson *et al.* (2009), we analyzed only late-successional, or "older" forests present in 1995, as mapped by Moeur *et al.* (2005). This is a small fraction of the dry forest regions. Our analysis was further restricted to federal lands. Mapping by Moeur *et al.* (2005) corresponds to mid-montane forest zones where Northern Spotted Owls occur. These montane forest zones include forests dominated mainly by true firs (*A. grandis, A. concolor*), Douglas-fir (*Pseudotsuga menziesii*), and Ponderosa pine (*P. ponderosa*): Other conifers found in the central and northern Cascades in dry forests frequented by spotted owls are western hemlock (*Tsuga heterophylla*), western larch (*Larix occidentalis*), and limited amounts of western red cedar (*Thuja plicata*) and Engelmann spruce (*Picea engelmannii*). Forests in the Klamath are noted for high conifer diversity, with species such as incense cedar (*Calocedrus decurrens*) commonly found in the range of spotted owls. A variety of broad-leaved evergreen trees, such as madrone (*Arbutus menziesii*) and tanoak (*Lithocarpus densiflorus*) are also characteristic of these forests (Whittaker 1960).

Quantifying Future Habitat

We determined existing rates of dry-forest redevelopment following stand initiation in the forests of the study regions as delineated by Mouer *et al.* (2005) using the extensive U.S. Forest Service Forest Inventory and Analysis (FIA) forest monitoring data (http://www.fia.fs.fed.us/tools-data/). FIA is a monitoring system based on one permanent, random plot per ~2400 ha across forested lands. We excluded plots from forests not used by spotted owls (e.g. lodgepole pine, oak forest) and from non-conifer vegetation and non-federal lands. Most of these plots were already excluded by the mapping by Mouer *et al.* (2005) that delineated the study area.

An FIA plot consists of a 1-ha area. For tree measurements, this area is sub-sampled with four circular subplots that are 0.1 ha for large-tree sampling and 0.017 ha for smaller-tree sampling (defined by region). The diameter-at breast-height (dbh) and crown position of each tree and the ring count from two cores from dominant/codominant trees are measured in each subplot (USFS 2010). Stand age for an FIA plot is determined from the average of all ring counts from sub-plot samples, weighted by cover of sampled trees, and 8 years are added for estimated time to grow to breast height (1.4 m). We used live-tree dbh data to prepare regressions with stand age.

FIA data were available from 2001-2009, comprising 90% of the plots available within our study area. A total of 581 plots from the Klamath and 441 from the dry Cascades were considered, representing 13,944 and 10,680 km^2 in each region, respectively. The number would be higher, but we eliminated 139 plots in the Klamath and 141 in the Cascades that had different stand-initiation dates from different subplots of the main FIA plot. This situation occurs throughout the study area due to the patchy nature of mixed-severity fire. Including all the subplots as individual plots creates a larger sample size, but we chose not to do this because some individual locations would be overrepresented. Most importantly, both approaches lead to the same results.

We analyzed fire severity from 1996-2011 in late-successional, or "older" forests mapped by Moeur *et al.* (2005). For 1996-2008, we used the Monitoring Trends in Burn Severity (MTBS) (http://www.mtbs.gov/) data. We used the ordinal classification from MTBS, as MTBS analysts determine for each fire where significant thresholds exist in digital prefire and postfire images, supplemented with plot data and analyst experience with fire effects. In plot data, a composite burn index that sums mortality by vegetation stratum is used to identify high fire severity (see http://www.mtbs.gov/). For 2009-2011, we obtained U.S. Forest Service digital data (http://www.fs.fed.us/postfire-vegcondition) and classified these data following Miller and Thode (2007). We could not use pre-1996 MTBS fire severity data because the pre-burn map of spotted owl forest habitat is from 1995 (Moeur *et al.* 2005). From severity data we calculated high-severity fire rotation (FR^{hs}), the expected time to severely burn an area equivalent to the area of interest once, or the landscape mean interval for severe fire (Baker 2009).

We calculated annual high-severity fire and forest regrowth rates to future proportions for early-, mid- and mature or late-successional forests, denoted herein by "E," "M," and "L," respectively, using annual time steps. We defined late-successional forests by selecting a value, 27.5 m^2/ha. This amount corresponds with the maximum basal area that would be left according to currently implemented thinning prescriptions (USDI 2011). This is somewhat higher than the minimum basal area where spotted owls have been found to nest in dry forests. For example, the mean value minus one standard deviation in all the dry forest stands studied by Buchanan *et al.* (1995) was 23 m^2/ha. However, we did not want to identify the rate of regrowth to the very minimum basal area that constitutes habitat, but regrowth to a basal area more likely to function as habitat. Mid- and early-successional forests were defined as 13.5-27.5 and <13.5 m^2/ha tree basal area, respectively. We separated mid-successional from early-successional forest because, mid-successional forests may be included in thinning treatments, but early-successional forests may not. Thinned forest ("T") was our fourth vegetation state. The forest states are diagramed in Fig. (**1**). The proportion of each state in the landscape at time *t,* defined a vector (P_t^E, P_t^M, P_t^T, P_t^L). Transition probabilities ϕ_t^{rs} equaled the probability that any portion of state *r* at time *t* transitions to

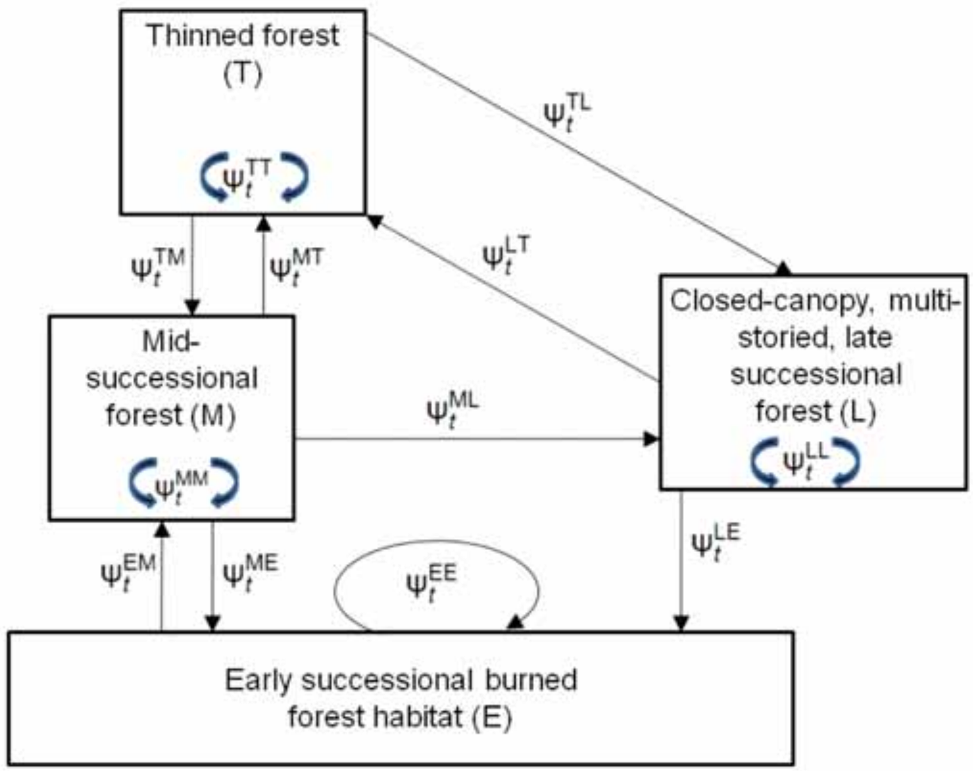

Fig. (1). State (boxes) and transition (arrows) model for dry Pacific Northwest Forest vegetation with fire disturbances and thinning. Variables are the transition rates between states indicated by the associated arrow.

state *s* at time *t* + 1, allowing calculation of future amounts of each forest type using the following equation:

$$\begin{bmatrix} \phi_t^{EE} & \phi_t^{ME} & \phi_t^{TE} & \phi_t^{LE} \\ \phi_t^{EM} & \phi_t^{MM} & \phi_t^{TM} & \phi_t^{LM} \\ \phi_t^{ET} & \phi_t^{MT} & \phi_t^{TT} & \phi_t^{LT} \\ \phi_t^{EL} & \phi_t^{ML} & \phi_t^{TL} & \phi_t^{LL} \end{bmatrix} \begin{bmatrix} P_t^{E} \\ P_t^{M} \\ P_t^{T} \\ P_t^{L} \end{bmatrix} = \begin{bmatrix} P_{t+1}^{E} \\ P_{t+1}^{M} \\ P_{t+1}^{T} \\ P_{t+1}^{L} \end{bmatrix} \quad (1)$$

The initial proportions, $P_{t=0}^{E\text{-}L}$ of the three natural-forest states were from the FIA basal-area analyses, with thinned forests considered zero for simplicity and because of lack of data. The annual transition from mid- and late- to early-successional forest from high-severity fire (ϕ_t^{LE}, ϕ_t^{ME}) was $1/FR^{hs}$. Early-successional forests also burned at this rate (ϕ_t^{EE}). Annual rates of forest redevelopment were from the inverse of the growth period ($1/G^{EM}$) to reach 13.5 m^2/ha live-tree basal area, or to grow from 13.5 to 27.5 m^2/ha live-tree basal area ($1/G^{ML}$), calculated from the regression of live basal area on age (see results). Lower-severity fire can reduce basal area from >27.5 m^2/ha basal area to <27.5 m^2/ha. However, this transition is already considered in the regrowth rate, which also incorporates the effects of lower-severity fires that have occurred on rates of forest redevelopment. Because natural disturbances that may temporarily lower basal area are captured in the transitions from early- to late-successional forest, the transition from late to mid-successional forest was set to zero. Transition rates to thinned forest were based on treatment within 20 years, beginning in year *t* + 1, of the mid- and late-successional forests present at *t* = 0 (see Table **1** for annual rate). Based upon the empirical FIA and MTBS data described above, we used these transitions (Table **1**) and Eq. 1 to project forward 40 years (see sample calculation in the Supplementary Materials). We chose this time interval because it represents one cycle of thinning and forest recovery.

Next, we calculated the effects of varying levels of thinning, and treatment efficacy (in terms of the effect on high-severity fire rotation intervals), over the study period. According to an analysis of a spotted owl landscape by Lehmkuhl *et al.* (2007), a "best" scenario for minimizing the short-term adverse impacts of thinning while reducing fire frequency and severity was one that treated only 22% of the landscape, and limited thinning in nesting, roosting, and foraging habitat to 21% of the area of this habitat. We used this prescription in our calculations to illustrate the effects under a best-case scenario. In our calculations, the amount of mid-successional forest thinning differed between the two regions because amounts of both mid- and late-successional forests were not the same. We also considered the effects of treating from 0 to 45% of forests, holding constant the proportions of treatments that were in late-successional vs. mid-successional forests.

We assumed that there would be no high-severity fire in treated forests over the treatment lifespan. We additionally assumed that thinning 22% of the landscape would lower the amount of high-severity fire in the unthinned landscape by half. This is based on the findings of Ager *et al.* (2007) who simulated the effects of wildfire ignitions following strategic

Table 1. Annual transition probabilities used in transition matrices for each scenario analyzed for dry provinces within the range of the Northern Spotted Owl. FR^{hs} is the high-severity fire rotation. G is the time required for stands to grow from early to mid- (EM) or mid- to late-successional (ML) forest (see Table 2). K = Klamath, C = Cascades. R is the amount that high severity fire is reduced by thinning (50% reduction at 22 percent of late-successional forest thinned).

*Only in effect for the first 20 years.
†Does not take effect until after 20 years.

thinning treatments in a spotted owl landscape. When <22% of the landscape was affected at any given time (such as any time prior to year 20 when the full treatment would be incomplete, or after one-time treatments began to recover, or for scenarios with <22% of the landscape treated) the same ratio of area treated to reduction in high-severity fire (22% treat: 50% reduction in fire) was used to reduce the area burned at high severity (see Supplementary Material for an illustration). Thus, the amount that fire was reduced by thinning increased with each year as a function of the total area thinned (all other variables were constant). Ager *et al.* (2007) found little additional effect of treatments in reducing wildfires as treatment level increased beyond 20%, so we did not calculate greater reductions in fire as treatment levels went from 22-45%. However, we additionally calculated future habitat amounts as a function of fire rotation to evaluate the effects of varying treatment efficacy, in which case we did calculate the reduced amount of habitat burned severely. This amount is the dependent variable in our summary figures. Treatment lifespan was assumed to be 20 years (Rhodes and Baker 2008) for "one-time thinning," or maintained in perpetuity over the 40 years for "maintained." A sample calculation using the model (equation 1) is presented in the Supplementary Material.

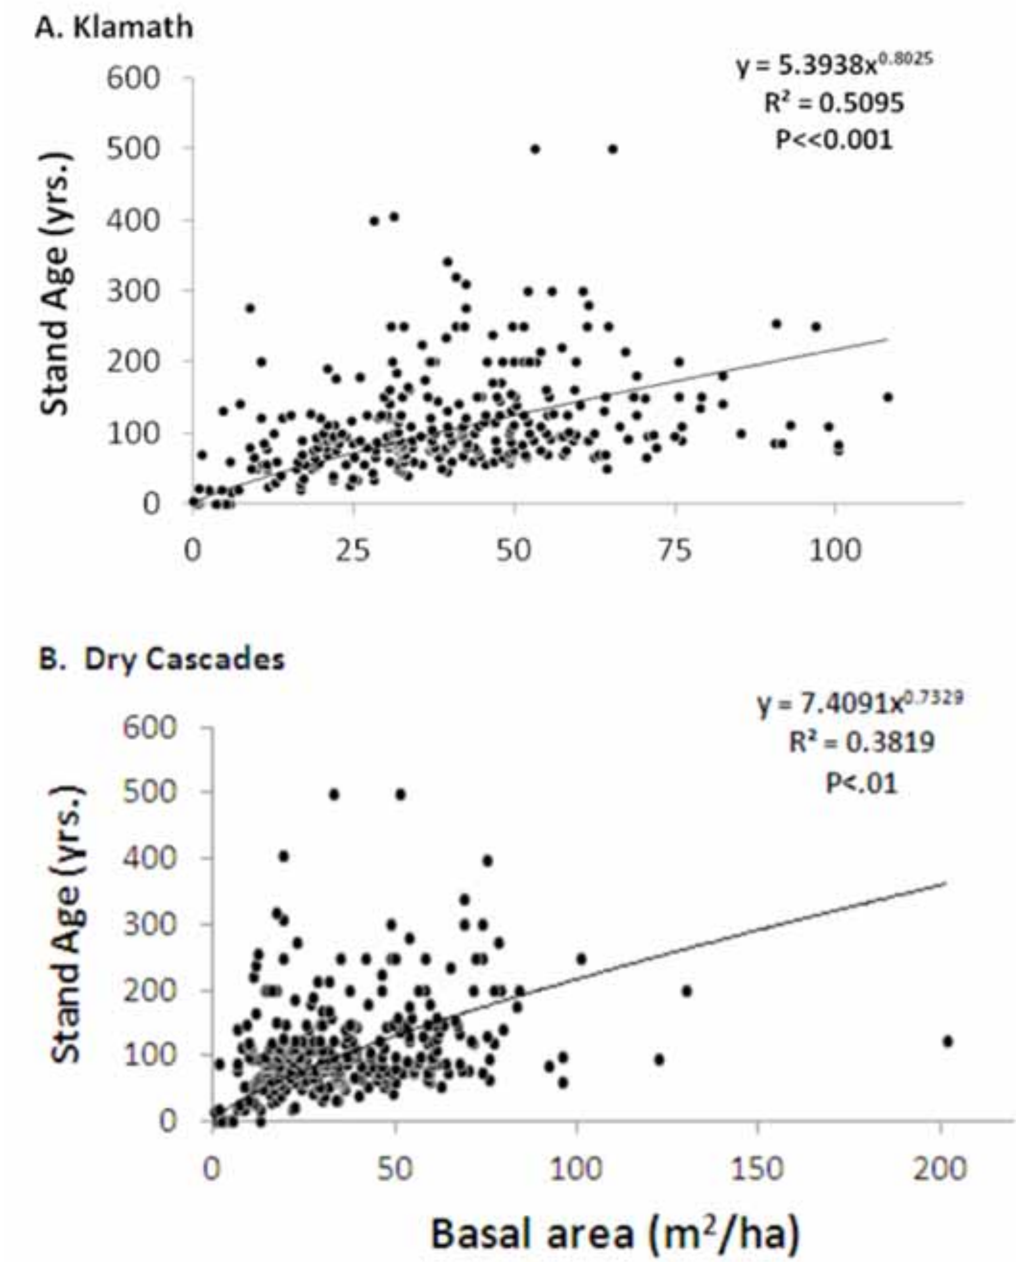

Fig. (2a-b). Scatterplots of live-tree basal area per hectare and stand age from US Forest Service FIA data for the A. Klamath region and B. dry Cascades region.

The only owl habitat we considered for impacts from thinning was suitable nesting, roosting, and foraging (so called NRF habitat). Because treatments aimed at demonstrating the type of thinning to be implemented in spotted owl habitat reduce basal area down to 13.75-27.5 m^2/ha, mostly well-below the minimum amounts for NRF habitat (Pidgeon 1995, Buchanan and Irwin 1998, LeHaye and Gutiérrez 1999), and because treated forests also have reduced amounts of key habitat features like multi-canopy structure, down wood, small firs and mistletoe infections, the area affected by these treatments will largely correspond to the amount of habitat lost. Thinning may also render adjacent, unthinned forest unsuitable or less suitable (Seamans and Gutiérrez 2007), but we did not account for this effect. The lifespan for thinning treatments that we used was 20 years for one-time thinning (Rhodes and Baker 2008), and 40 years for maintained treatments. Transition from late- to early-successional vegetation due to high-severity fire also was considered habitat loss. This may overestimate the impacts of fire on Northern Spotted Owl foraging habitat (Bond *et al.* 2009, USFWS 2011), but the assumption is largely irrelevant due to the low rates of high-severity fire in both study regions in relation to forest regrowth, as described next.

RESULTS

We found a highly significant relationship between live-tree basal area and stand age in both regions (Figs. **2a-b**, Klamath n = 442, dry Cascades n = 304). Much of the variance in the plot data was caused by a modest number of relatively old stands that had much lower basal area for their

Table 2. Forest Inventory and Analysis (FIA) plot parameters for the Klamath and dry Cascades provinces, California, Oregon, and Washington, based on most recent survey data from 2001-2009. Also shown are the amounts of time after fire that is takes forest to regrow to the specified live basal area (BA) thresholds using the regression equations shown in Figs. (2a-b).

age than did other plots. The amount of time following disturbance needed for regenerating forests to reach live-tree basal area >27.5 m^2/ha was 77 and 90 years, respectively, for the Klamath and dry Cascades (Table **2**).

Using the MTBS data, the rotation for high-severity fire from 1996-2011 was 362 to 913 years in the Klamath and dry Cascades, respectively (Table **2**). At these rates, a total of 1,221 and 325 km^2 of high-severity fire would occur in Klamath and dry Cascades late-successional forests, respectively, in 40 years. With annual regrowth rates of late-successional forests that were 4.5 to >10 times greater than the rates of fire disturbances (i.e. (1/77)/(1/362) for the Klamath and (1/89)/(1/913) for the dry Cascades, and no disturbances other than fire, late-successional forests would eventually come to occupy 83% of the potential forested area in the Klamath and 91% in the Cascades. Thus, over 40 years, late-successional forests in the Klamath increased slightly over their current amount of 77% of the forested landscape FIA plots to 81% or from about 10,668 km^2 to 11,335 km^2 (Fig. **3a**). In the dry Cascades, where late-successional forests were 59% of the forested landscape FIA plots, they increased relatively rapidly to 77% of the forested landscape, or from 6,253 km^2 to 8,234 km^2 in 40 years (Fig. **4a**).

Simulated thinning of 21% of dense, late-successional forest of the Klamath landscape meant that a total of 2,225 km^2 would be reduced, while treatments in mid-successional forests would cover 840 km^2 to reach a treatment level of 22% of the whole landscape. After the one-time thinning, late-successional forests returned to slightly lower amounts than occurred without thinning after 40 years (Fig. **3a**). The net effect of the one-time thinning was to reduce late-successional habitat by 10.7% over the 40-year period, or from an average of 11,086 km^2 to 9,996 km^2 over 40 years (i.e., 1,090 km^2 less each year on average, Fig **3b**). The amount of dense, late-successional forest that was prevented from burning at high severity was 16 km^2/year, resulting in 320 km^2 of dense, late-successional forest, which would otherwise have been transformed into early-successional forest, in each year on average over the 40-year period. Therefore, in this scenario, thinning reduced 3.4 times more late-successional forest than it increased. The maintained treatment reduced habitat by 15.3%, from 11,086 km^2 on average over 40 years to 9,396 km^2 (i.e., 1,690 km^2 less each year on average, Fig. **3c**). In both cases, 13% of the habitat loss was from thinning in mid-successional forest that prevented or slowed these forests from developing into dense, late-successional forest. The amount of dense, late-successional forest that was prevented from burning at high severity was 20 km^2/year, resulting in 400 km^2 of dense, late-successional forest, which would otherwise have been transformed into early-successional forest, in each year on average over the 40-year period. Therefore, the combination of thinning and maintenance reduced 4.2 times more late-successional forest than it increased.

In the Cascades, to treat 22% of the landscape, the thinning scenario targeted 1,313 km^2 of dense, late-successional forest, and 1,036 km^2 of mid-successional forest. After the one-time thinning, late-successional forests again returned to slightly lower amounts than occurred without thinning after 40 years (Fig. **4a**). The net effect of the one-time thinning treatment over 40 years was to reduce dense, late-successional forest by an average level of 11.1% (836 km^2 less each year on average, Fig. **4b**). The amount of dense, late-successional forest that was prevented from burning at high severity from the one time treatment was 3.5 km^2/year, resulting in 140 km^2 of dense, late-successional forest, which would otherwise have been transformed into

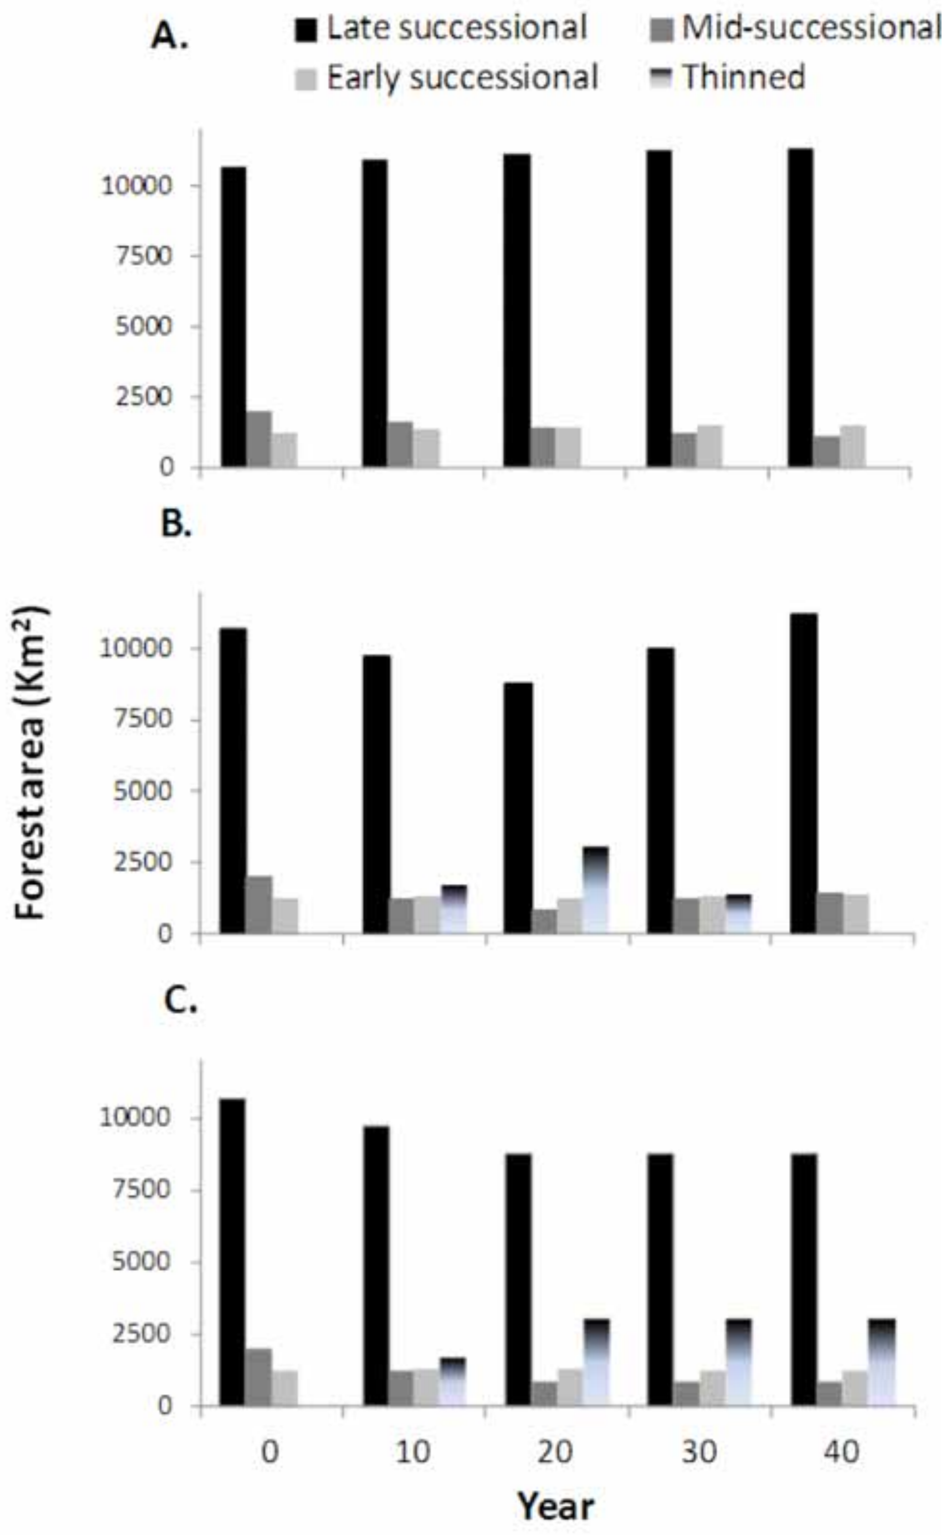

Fig. (3a-c). Amounts of the four forest types (early-, mid-, late-successional, and thinned) in the landscape over a 40-year period based on the states shown in (Fig. **1**) and transition rates (Table **2**) for the Klamath province, California, and Oregon, and the following scenarios: A) no treatment; B) one-time treatment of 21% of late-successional forests (>27.5 m^2/ha live-tree basal area) and 42% of mid-successional forests (= total of 22% of landscape treated) followed by recovery in 20 years to late-successional forest; C) treatment of 21% of late-successional forests (>27.5 m^2/ha live-tree basal area) and 42% of mid-successional (= total of 22% of landscape treated) forests with future maintenance. We converted proportions of forest types from modeling output to km^2 using the area estimate from FIA for the Klamath study region.

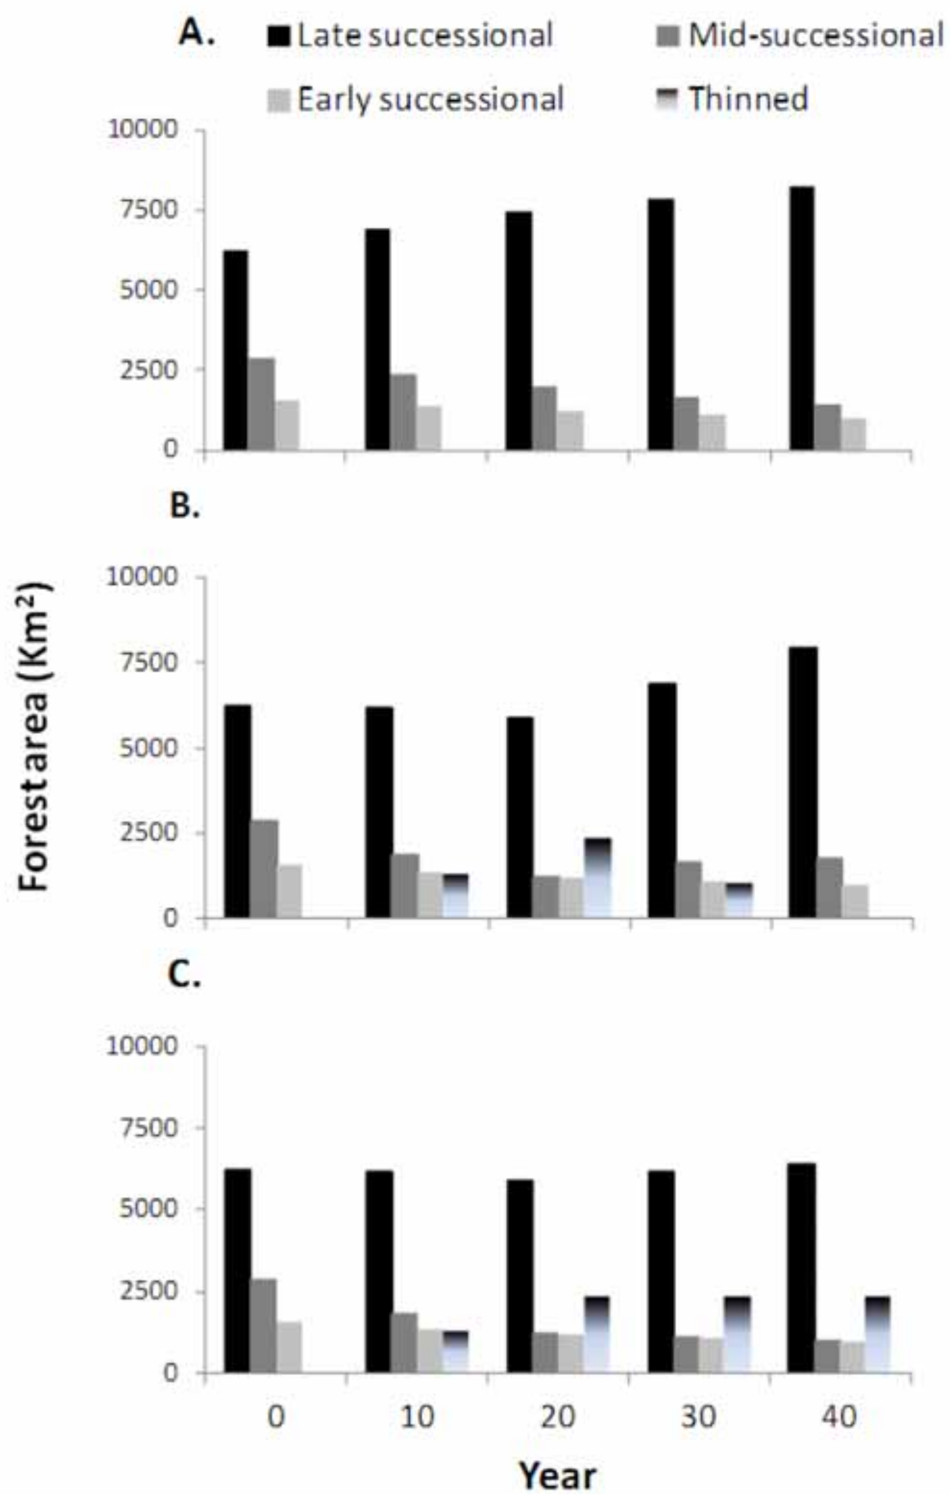

Fig. (4a-c). Amounts of the four forest types (early-, mid-, late-successional, and thinned) in the landscape over a 40-year period based on the states in (Fig. **1**) and transition rates (Table **2**) for the dry Cascades province, California, Oregon, and Washington and the following scenarios: **A**) no treatment; **B**) one time treatment of 21% of late-successional forests (>27.5 m^2/ha live tree basal area) and 36% of mid-successional forests (=22% of landscape treated) followed by recovery in 20 years to late-successional forest; **C**) treatment of 21% of late-successional forests (>27.5 m^2/ha live tree basal area) and 36% of mid-successional forests (=22% of landscape treated) in perpetuity. We converted proportions of forest types from modeling output to km^2 using the area estimate from FIA for the dry Cascades study region.

early-successional forest, in each year on average over the 40-year period. Therefore, thinning reduced 6.0 times more late-successional forest than it increased. The maintained treatment reduced dense, late-successional forest by an average of 16.4% (1,212 km^2less each year on average, Fig. **4c**). Of this reduction, 30% was from the indirect effect of thinning in mid-successional forests, more of which were treated in the Cascades scenario. The amount of dense, late-

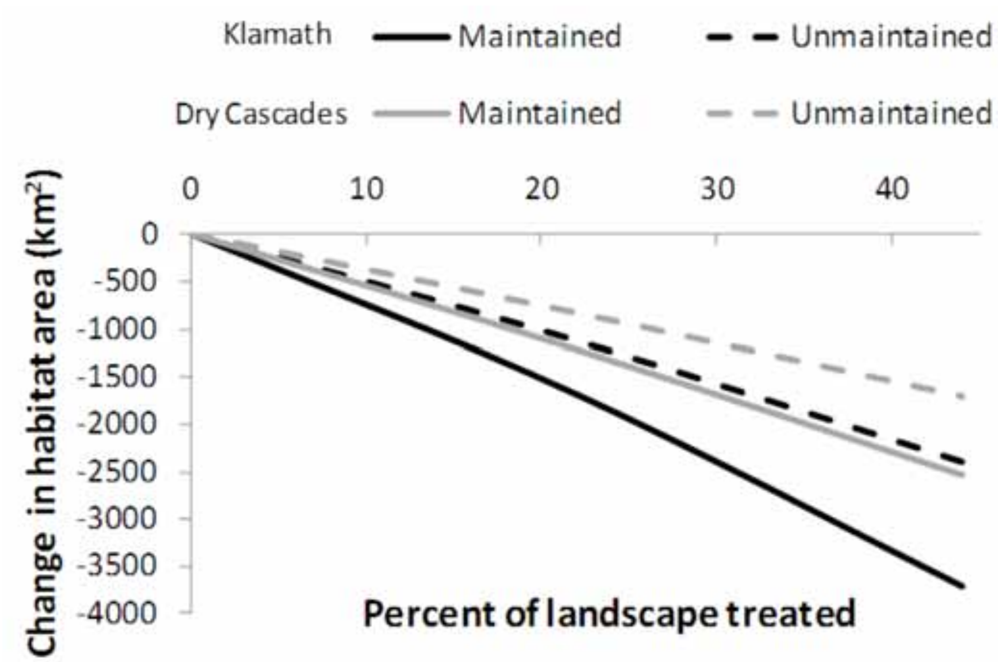

Fig. (5). Net amount of habitat lost over 40 years compared to the no-treatment scenario as a function of treatment of 0-45% of the landscape. The amount of late-successional forest treated was held constant at 21% of the area of this forest, except at very low levels of treatment. The amount of mid-successional forest treated varied from zero at very low treatment levels, to a large proportion of the mid-successional forests when 45% of the landscape was treated, particularly in the Klamath region.

successional forest that was prevented from burning at high severity from the maintained treatment scenario was 4.5 km^2/year, resulting in 180 km^2 of dense, late-successional forest, which would otherwise have been transformed into early-successional forest, in each year on average over the 40-year period. Therefore, the combination of thinning and maintenance reduced 6.7 times more late-successional forest than it increased.

As treatment level increased from 11 to 22%, habitat loss doubled (Fig. **5**). With 22% of the landscape treated, the effect of reducing fire by 50% in the rest of the landscape was reached, and there was no further reduction in fire with increasing treatment amount. With less fire prevented per km^2 treated, the rate of habitat loss increased as treatment went from 22 to 45% of the landscape.

We also assessed the effect of holding treatment level constant and varying the efficacy of treatments. Even if treatment efficacy was considerably greater than we assumed and rotations of high-severity fire substantially longer than twice their current length, the amount of dense, late-successional forest habitat that would be reduced due to thinning would only be slightly lower (Figs. **6a-b**). With complete elimination of fire over 40 years as a result of treatments, the amount of dense, late-successional forest would be 9-10% less than with no treatment. This becomes a large amount of habitat loss over time.

DISCUSSION

We found that the habitat recruitment rate exceeded the rate of severe fire by a factor of 4.5 in the Klamath and 10 in the dry Cascades, leading to a deterministic increase in dense forest habitat over time, assuming no other disturbance events. In contrast, previous published assessments of fire on spotted owls have not explicitly considered fire and forest regrowth rates (Wilson and Baker 1998, Lee and Irwin 2005, Roloff *et al.* 2005, 2012, Calkin *et al.* 2005, Hummel and Calkin 2005, Ager *et al.* 2007, Lehmkuhl *et al.* 2007). Not including the probability of high-severity fire, which is low, leads to highly inflated projections of the effects of thinning versus not thinning on high-severity fire (Rhodes and Baker 2008, Campbell *et al.* 2012).

Our calculations of thinning effects included rates of forest regrowth along with high-severity fire. The calculations illustrate how the requirement that the long-term benefits of thinning clearly outweigh adverse impacts (USFWS 2011) is not attainable as long as treatments have adverse impacts on spotted owl habitat. This is because the amount of dense, late-successional forest that might be prevented from burning severely would be a fraction of the area that would be thinned. Under our "best case" scenario, thinning reduced dense, late-successional forest by 3.4 and 6.0 times more than it prevented such forest from experiencing high-severity fire in the Klamath and dry Cascades, respectively, similar to findings in a recent unpublished report by U.S. Forest Service scientists from the Pacific Northwest Research Station (Raphael *et al.* 2013). This would not be a concern if thinning effects were neutral, but the commercial thinning prescriptions being implemented call for forests with basal area reduced by nearly half to 13.5-27.5 m^2/ha, which is mostly well below the minimum level known to function as nesting and roosting habitat (ca. 23 m^2/ha) (Buchanan *et al.* 1995, 1998). Thus, if dense forests are subjected to these treatments, much of the impacted area would no longer have minimum basal area needed to function as nesting and roosting habitat. Even an immediate doubling of fire rates due to climate change or

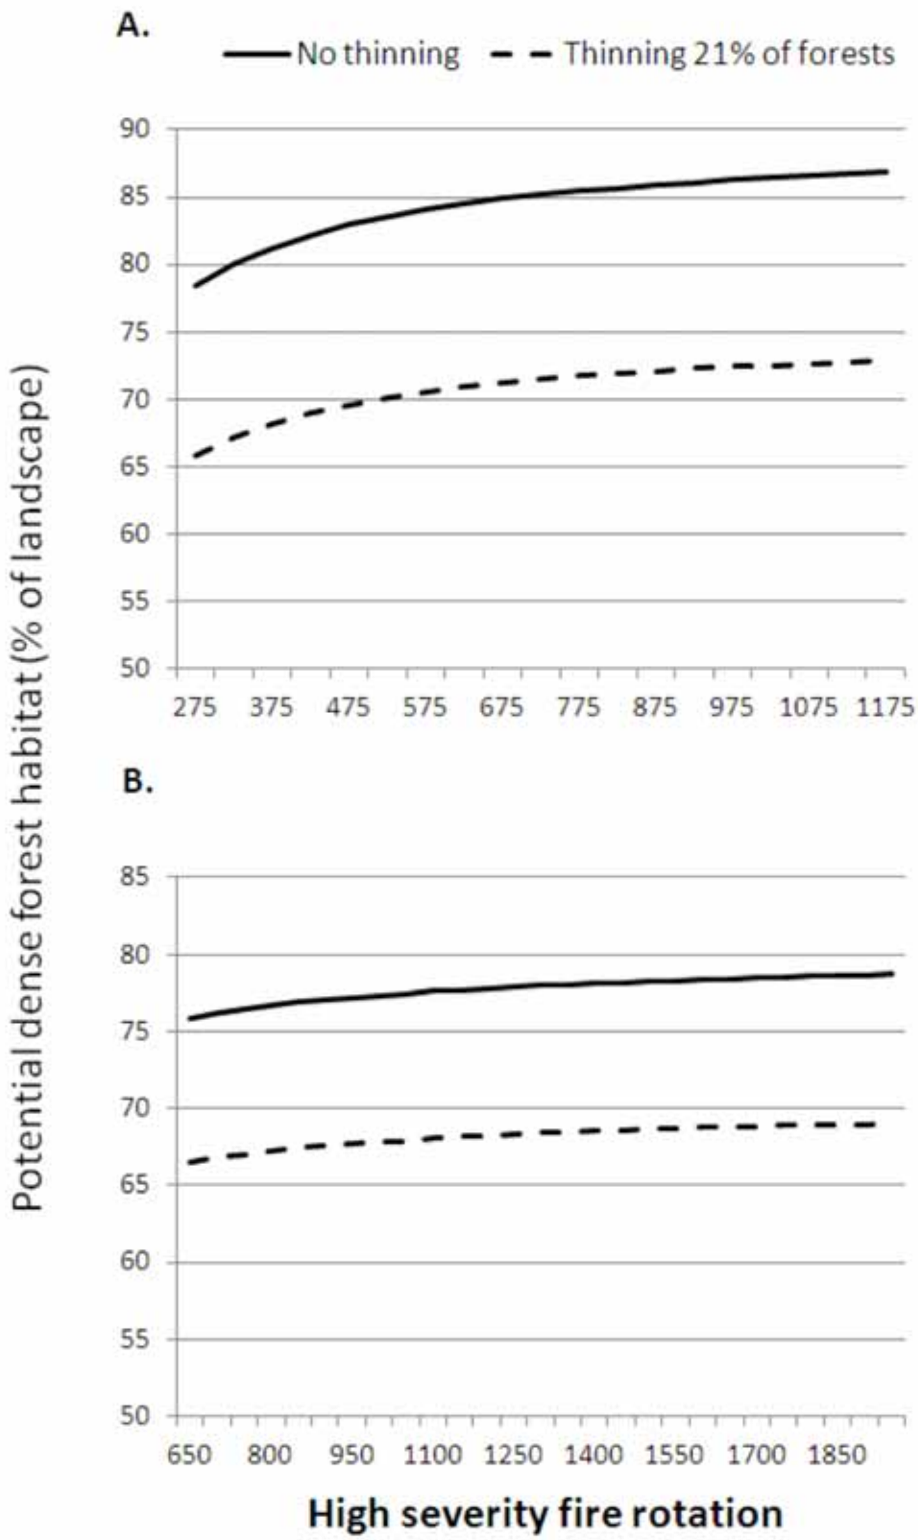

Fig. (6a-b). Amount of forest habitat in the range of the Northern Spotted Owl in the A. Klamath, and B. dry Cascades 40 years in the future as a function of the average high severity rotation over that time period, and longer rotations.

other factors would result in far less habitat affected by high-severity fire than thinning. In addition, much of the high-severity fire might occur regardless of thinning, especially if the efficacy of thinning in reducing high-severity fire is reduced as fire becomes more controlled by climate and weather (Cruz and Alexander 2010). Clearly, the strategy of trying to maintain more dense, late-successional forest habitat by reducing fire does not work if the method for reducing fire adversely affects far more of this forest habitat than would high-severity fire, and the high-severity fire might occur anyway because it is largely controlled by climate and weather.

There may be silvicultural treatments that can be done in spotted owl habitat that may reduce adverse impacts. For example, thinning that maintains at least 23-27.5 m^2 ha basal area. However, given that key habitat elements such as small trees, down wood, and likely some intermediate-sized trees are going to be targeted in any forest fuel reduction treatment, it appears unlikely that any conventional fuels reduction treatment in spotted owl habitat would not have at least some adverse impacts. This is supported by research on thinning that was often less intensive than commercial thinning prescriptions. This research showed negative impacts on spotted owls or their prey, as summarized in our introduction (Waters and Zabel 1995, Waters *et al.* 2000, Carey 2001, Ransome and Sullivan 2002, Gomez *et al.* 2003, Suzuki and Hayes 2003, Ransome *et al.* 2004, Bull *et al.* 2004, Lehmkuhl *et al.* 2006, Meyer *et al.* 2007, Wilson 2010, Holloway and Smith 2011, Manning *et al.* 2012), and how spotted owls have been displaced by even very limited amounts of thinning or contemporary harvest near the nest or activity center (Forsman *et al.* 1984, King 1993, Hicks *et al.* 1999, Meiman *et al.* 2003, Seamans and Gutiérrez 2007). Even if adverse impacts were quite modest, the amount of dense, late-successional forest that might be prevented from experiencing high-severity fire is so much smaller than the area that would be treated in an effort to accomplish this reduction in fire, that the net impact of the thinning would still be much greater. In addition, it is becoming increasingly less clear whether a reduction in high-severity fire below current rates would necessarily be beneficial to spotted owls. The dry forests in which spotted owls are found were historically characterized by mixed-severity fires (see Hessburg *et al.* (2007), Baker (2012), and Odion *et al.* (2014) for historic fire in the dry Cascades of Washington and Oregon, Beaty and Taylor (2001) and Bekker and Taylor (2001, 2010) for the California Cascades, and Wills and Stuart (1994), Taylor and Skinner (1998, 2003), and Odion *et al.* (2014) for the Klamath). Recent research suggests that this historic fire may have neutral and beneficial effects to spotted owls.

Studies on the effects of fire on spotted owls are few and often focused on other owl subspecies and some studies are confounded by post-fire logging effects (Clark *et al.* 2013). Nonetheless, it has long been known that fire in woody vegetation causes an increase in small rodent populations and consequently raptor populations (Lawrence 1966), and studies on spotted owls and fire where no logging occurred suggest that high-severity fire at current rates may confer benefits or be neutral. Bond *et al.* (2009) found that California Spotted Owls in the Sierra Nevada preferentially foraged in severely burned forests more than unburned forests within about 1.5 km of a core-use area. The percentage of high-severity fire in burned Mexican Spotted Owl (*Strix occidentalis* ssp. *lucida*) sites had no significant influence (Jenness *et al.* 2004). Roberts *et al.* (2011) found no support for an occupancy model for California Spotted Owls that distinguished between burned and unburned sites in unmanaged forests; the mean “owl survey area” that burned at high-severity was 12%, with one survey area experiencing up to 52% high-severity fire, which is almost three times the current amount of severe fire in owl habitat, according to the MTBS data. In a longer-term (1997-2007) study of California Spotted Owl site-occupancy dynamics throughout the Sierra Nevada, high-severity fire that burned on average 32% of forested vegetation around nests and core roosts had no significant effect on extinction or colonization probabilities, and overall occupancy probabilities were slightly higher in mixed-severity burned areas than in unburned forest (Lee *et al.* 2012), while other research found no significant difference in home range size between mixed-severity fire areas and unburned forest (Bond *et al.* 2013). Studies on reproduction in occupied sites of all three spotted owl subspecies indicated no difference between unburned sites and mixed-severity burned sites (excluding burn out areas created by fire suppression operations) (Jenness *et al.* 2004), or in some cases reproduction may have been greater in burned sites (Bond *et al.* 2002, Roberts 2008). The longer-term value of fire disturbances is in the creation of landscape heterogeneity with inclusions of young stands, improving habitat at the landscape scale. Fire also plays a vital role in creating snags, large down logs, and other key elements of the highest quality spotted owl habitat at the territory scale (Franklin *et al.* 2000). No assessments of fire and thinning effects on spotted owls, including this one, have accounted for any potential beneficial effects of mixed-severity fire, nor the potential negative effects of lack of mixed-severity fire in treated areas.

While much of the concern about fire and thinning in dry forests of the Pacific Northwest has focused on spotted owls, it may also apply to other biota associated with dense, old forests, including species of conservation concern, such as Pacific fisher (*Martes pennanti pacifica*), which research indicates may benefit from mixed-severity fire (Hanson 2013), the Northern Goshawk (*Accipiter gentilis*), and, following fire, the Black-backed Woodpecker (*Picoides arcticus*), which depends upon higher-severity fire in dense, older forest (Odion and Hanson 2013). Like the spotted owl, studies have documented that this woodpecker is also negatively affected by thinning (Hutto 2008). Also, like the spotted owl, the Back-backed Woodpecker, Pacific Fisher and Northern Goshawk occur in forests where the historic fire regime was not low-severity. Modeling for the fisher, similar to modeling for the spotted owl, has not used the actual rates of high-severity fire and forest regrowth to assess possible impacts of fire, and has assumed that fire represents a loss of fisher habitat (Scheller *et al.* 2011), contrary to more recent empirical findings (Hanson 2013). Not including the actual probability of fire leads to considerably inflated projections of the effects of thinning vs. not thinning in reducing high-severity fire (Rhodes and Baker 2008, Campbell *et al*. 2012). Our findings highlight the need to be cautious about conclusions that thinning treatments are needed for species found in dense forest and that they will not have unintended consequences (e.g., Stephens *et al.* 2012) until long-term, cumulative impacts are better understood. As we found with spotted owls, long-term and unintended consequences may be substantial for species that rely on dense, late-successional forests, especially when these species are sensitive to small amounts of thinning in their territory.

CONCLUSION

We used a quantitative approach that, unlike others, accounted for rates of high-severity fire and forest recruitment, allowing assessment of future amounts of spotted owl habitat at current rates of fire, with and without thinning. We found that the long-term benefits of commercial thinning would not clearly outweigh adverse impacts, even if much more fire occurs in the future. This conclusion applies even if adverse impacts of treatments are quite modest because of the vastly larger area that would need to be treated compared to area of high-severity fire that might be reduced by thinning. Moreover, our results indicate that, even if a longer time interval is analyzed (e.g., 100 years), the declines in dense, late-successional habitat due to thinning would not flatten, as long as thinning is reoccurring. Thus, where spotted owl management goals take precedence, the best strategy for maintaining habitat will be to avoid thinning treatments that have adverse impacts in spotted owl habitat or potential habitat (Gaines *et al.* 2010). There is ample area outside of existing or potential spotted owl habitat where managers wishing to suppress fire behavior or extent may focus their efforts without directly impacting spotted owls (Gaines *et al.* 2010), such as in areas adjacent to homes or in dense conifer plantations with high fuel hazards (Odion *et al.* 2004). In addition, there are management approaches that may be more effective than thinning in helping accomplish these fire prevention goals, such as controlling human-caused fire ignitions (Cary *et al.* 2009). Lastly, emerging research suggests that fire is not the threat it has been assumed to be for spotted owls, suggesting that, rather than management that focuses on suppressing fire behavior, other, no regrets active management may be more appropriate (Hanson *et al.* 2010). Research is needed to determine if these findings might apply to other species that are characteristic of dense forests, particularly given the widespread and growing emphasis on thinning as a management tool for suppressing wildland fires.

CONFLICT OF INTEREST

The authors confirm that this article content has no conflict of interest.

Edited by William H. Schlesinger, Duke University, Durham, NC, and approved January 22, 2018 (received for review November 16, 2017)

Strategies to mitigate carbon dioxide emissions through forestry activities have been proposed, but ecosystem process-based integration of climate change, enhanced CO_2, disturbance from fire, and management actions at regional scales are extremely limited. Here, we examine the relative merits of afforestation, reforestation, management changes, and harvest residue bioenergy use in the Pacific Northwest. This region represents some of the highest carbon density forests in the world, which can store carbon in trees for 800 y or more. Oregon's net ecosystem carbon balance (NECB) was equivalent to 72% of total emissions in 2011–2015. By 2100, simulations show increased net carbon uptake with little change in wildfires. Reforestation, afforestation, lengthened harvest cycles on private lands, and restricting harvest on public lands increase NECB 56% by 2100, with the latter two actions contributing the most. Resultant cobenefits included water availability and biodiversity, primarily from increased forest area, age, and species diversity. Converting 127,000 ha of irrigated grass crops to native forests could decrease irrigation demand by 233 billion $m^3 \cdot y^{-1}$. Utilizing harvest residues for bioenergy production instead of leaving them in forests to decompose increased emissions in the short-term (50 y), reducing mitigation effectiveness. Increasing forest carbon on public lands reduced emissions compared with storage in wood products because the residence time is more than twice that of wood products. Hence, temperate forests with high carbon densities and lower vulnerability to mortality have substantial potential for reducing forest sector emissions. Our analysis framework provides a template for assessments in other temperate regions.

forests | carbon balance | greenhouse gas emissions | climate mitigation

Strategies to mitigate carbon dioxide emissions through forestry activities have been proposed, but regional assessments to determine feasibility, timeliness, and effectiveness are limited and rarely account for the interactive effects of future climate, atmospheric CO_2 enrichment, nitrogen deposition, disturbance from wildfires, and management actions on forest processes. We examine the net effect of all of these factors and a suite of mitigation strategies at fine resolution (4-km grid). Proven strategies immediately available to mitigate carbon emissions from forest activities include the following: (*i*) reforestation (growing forests where they recently existed), (*ii*) afforestation (growing forests where they did not recently exist), (*iii*) increasing carbon density of existing forests, and (*iv*) reducing emissions from deforestation and degradation (1). Other proposed strategies include wood bioenergy production (2–4), bioenergy combined with carbon capture and storage (BECCS), and increasing wood product use in buildings. However, examples of commercial-scale BECCS are still scarce, and sustainability of wood sources remains controversial because of forgone ecosystem carbon storage and low environmental cobenefits (5, 6). Carbon stored in buildings generally outlives its usefulness or is replaced within decades (7) rather than the centuries possible in forests, and the factors influencing product substitution have yet to be fully explored (8). Our analysis of mitigation strategies focuses on the first four strategies, as well as bioenergy production, utilizing harvest residues only and without carbon capture and storage.

The appropriateness and effectiveness of mitigation strategies within regions vary depending on the current forest sink, competition with land-use and watershed protection, and environmental conditions affecting forest sustainability and resilience. Few process-based regional studies have quantified strategies that could actually be implemented, are low-risk, and do not depend on developing technologies. Our previous studies focused on regional modeling of the effects of forest thinning on net ecosystem carbon balance (NECB) and net emissions, as well as improving modeled drought sensitivity (9, 10), while this study focuses mainly on strategies to enhance forest carbon.

Our study region is Oregon in the Pacific Northwest, where coastal and montane forests have high biomass and carbon sequestration potential. They represent coastal forests from northern California to southeast Alaska, where trees live 800 y or more and biomass can exceed that of tropical forests (11) (Fig. S1). The semiarid ecoregions consist of woodlands that experience frequent fires (12). Land-use history is a major determinant of forest carbon balance. Harvest was the dominant cause of tree mortality (2003–2012) and accounted for fivefold as much mortality as that from fire and beetles combined (13). Forest land ownership is predominantly public (64%), and 76% of the biomass harvested is on private lands.

Significance

Regional quantification of feasibility and effectiveness of forest strategies to mitigate climate change should integrate observations and mechanistic ecosystem process models with future climate, CO_2, disturbances from fire, and management. Here, we demonstrate this approach in a high biomass region, and found that reforestation, afforestation, lengthened harvest cycles on private lands, and restricting harvest on public lands increased net ecosystem carbon balance by 56% by 2100, with the latter two actions contributing the most. Forest sector emissions tracked with our life cycle assessment model decreased by 17%, partially meeting emissions reduction goals. Harvest residue bioenergy use did not reduce short-term emissions. Cobenefits include increased water availability and biodiversity of forest species. Our improved analysis framework can be used in other temperate regions.

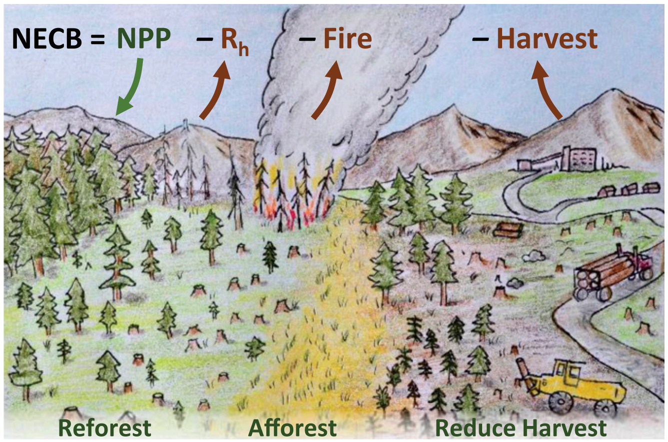

Fig. 1. Approach to assessing effects of mitigation strategies on forest carbon and forest sector emissions. NECB is productivity (NPP) minus Rh and losses from fire and harvest (red arrows). Harvest emissions include those associated with wood products and bioenergy.

Many US states, including Oregon (14), plan to reduce their greenhouse gas (GHG) emissions in accordance with the Paris Agreement. We evaluated strategies to address this question: How much carbon can the region's forests realistically remove from the atmosphere in the future, and which forest carbon strategies can reduce regional emissions by 2025, 2050, and 2100? We propose an integrated approach that combines observations with models and a life cycle assessment (LCA) to evaluate current and future effects of mitigation actions on forest carbon and forest sector emissions in temperate regions (Fig. 1). We estimated the recent carbon budget of Oregon's forests, and simulated the potential to increase the forest sink and decrease forest sector emissions under current and future climate conditions. We provide recommendations for regional assessments of mitigation strategies.

Results

Carbon stocks and fluxes are summarized for the observation cycles of 2001–2005, 2006–2010, and 2011–2015 (Table 1 and Tables S1 and S2). In 2011–2015, state-level forest carbon stocks totaled 3,036 Tg C (3 billion metric tons), with the coastal and montane ecoregions accounting for 57% of the live tree carbon (Tables S1 and S2). Net ecosystem production [NEP; net primary production (NPP) minus heterotrophic respiration (Rh)] averaged 28 teragrams carbon per year (Tg C y^{-1}) over all three periods. Fire emissions were unusually high at 8.69 million metric tons carbon dioxide equivalent ($tCO_2e\ y^{-1}$, i.e., 2.37 Tg C y^{-1}) in 2001–2005 due to the historic Biscuit Fire, but decreased to 3.56 million $tCO_2e\ y^{-1}$ (0.97 Tg C y^{-1}) in 2011–2015 (Table S4). Note that 1 million tCO_2e equals 3.667 Tg C.

Our LCA showed that in 2001–2005, Oregon's net wood product emissions were 32.61 million tCO_2e (Table S3), and 3.7-fold wildfire emissions in the period that included the record fire year (15) (Fig. 2). In 2011–2015, net wood product emissions were 34.45 million tCO_2e and almost 10-fold fire emissions, mostly due to lower fire emissions. The net wood product emissions are higher than fire emissions despite carbon benefits of storage in wood products and substitution for more fossil fuel-intensive products. Hence, combining fire and net wood product emissions, the forest sector emissions averaged 40 million $tCO_2e\ y^{-1}$ and accounted for about 39% of total emissions across all sectors (Fig. 2 and Table S4). NECB was calculated from NEP minus losses from fire emissions and harvest (Fig. 1). State NECB was equivalent to 60% and 70% of total emissions for 2001–2005 and 2011–2015, respectively (Fig. 2, Table 1, and Table S4). Fire emissions were only between 4% and 8% of total emissions from all sources (2011–2015 and 2001–2004, respectively). Oregon's forests play a larger role in meeting its GHG targets than US forests have in meeting the nation's targets (16, 17).

Historical disturbance regimes were simulated using stand age and disturbance history from remote sensing products. Comparisons of Community Land Model (CLM4.5) output with Forest Inventory and Analysis (FIA) aboveground tree biomass (>6,000 plots) were within 1 SD of the ecoregion means (Fig. S2). CLM4.5 estimates of cumulative burn area and emissions from 1990 to 2014 were 14% and 25% less than observed, respectively. The discrepancy was mostly due to the model missing an anomalously large fire in 2002 (Fig. S3*A*). When excluded, modeled versus observed fire emissions were in good agreement ($r^2 = 0.62$; Fig. S3*B*). A sensitivity test of a 14% underestimate of burn area did not affect our final results because predicted emissions would increase almost equally for business as usual (BAU) management and our scenarios, resulting in no proportional change in NECB. However, the ratio of harvest to fire emissions would be lower.

Projections show that under future climate, atmospheric carbon dioxide, and BAU management, an increase in net carbon uptake due to CO_2 fertilization and climate in the mesic ecoregions far outweighs losses from fire and drought in the semiarid ecoregions. There was not an increasing trend in fire. Carbon stocks increased by 2% and 7% and NEP increased by 12% and 40% by 2050 and 2100, respectively.

We evaluated emission reduction strategies in the forest sector: protecting existing forest carbon, lengthening harvest cycles, reforestation, afforestation, and bioenergy production with product substitution. The largest potential increase in forest carbon is in the mesic Coast Range and West Cascade ecoregions. These forests are buffered by the ocean, have high soil water-holding capacity, low risk of wildfire [fire intervals average 260–400 y (18)], long carbon residence time, and potential for high carbon density. They can attain biomass up to 520 Mg C ha^{-1} (12). Although Oregon has several protected areas, they account for only 9–15% of the total forest area, so we expect it may be feasible to add carbon-protected lands with cobenefits of water protection and biodiversity.

Reforestation of recently forested areas include those areas impacted by fire and beetles. Our simulations to 2100 assume regrowth of the same species and incorporate future fire responses to climate and cyclical beetle outbreaks [70–80 y (13)]. Reforestation has the potential to increase stocks by 315 Tg C by 2100, reducing forest sector net emissions by 5% by 2100 relative to BAU management (Fig. 3). The East and West Cascades ecoregions had the highest reforestation potential, accounting for 90% of the increase (Table S5).

Afforestation of old fields within forest boundaries and nonfood/nonforage grass crops, hereafter referred to as "grass crops," had to meet minimum conditions for tree growth, and crop grid cells had to be partially forested (*SI Methods* and Table S6). These crops are not grazed or used for animal feed. Competing land uses may decrease the actual amount of area that can be afforested. We calculated the amount of irrigated grass crops (127,000 ha) that could be converted to forest, assuming success of carbon offset programs (19). By 2100, afforestation increased stocks by

Table 1. Forest carbon budget components used to compute NECB

Flux, Tg C·y^{-1}	2001–2005		2006–2010		2011–2015		2001–2015
NPP	73.64	7.59	73.57	7.58	73.57	7.58	73.60
Rh	45.67	5.11	45.38	5.07	45.19	5.05	45.41

Harvest removals	8.58	0.60	7.77	0.54	8.61	0.6	8.32
Fire emissions	2.37	0.27	1.79	0.2	0.97	0.11	1.71
NECB	17.02	9.17	18.63	9.14	18.81	9.13	18.15

Average annual values for each period, including uncertainty (95% confidence interval) in Tg C y^{-1} (multiply by 3.667 to get million tCO_2e).

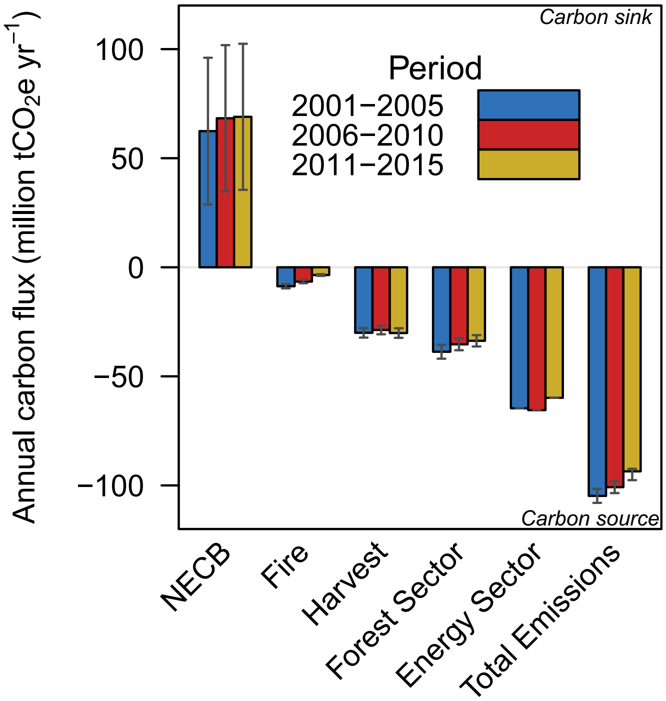

Fig. 2. Oregon's forest carbon sink and emissions from forest and energy sectors. Harvest emissions are computed by LCA. Fire and harvest emissions sum to forest sector emissions. Energy sector emissions are from the Oregon Global Warming Commission (14), minus forest-related emissions. Error bars are 95% confidence intervals (Monte Carlo analysis).

94 Tg C and cumulative NECB by 14 Tg C, and afforestation reduced forest sector GHG emissions by 1.3–1.4% in 2025, 2050, and 2100 (Fig. 3).

We quantified cobenefits of afforestation of irrigated grass crops on water availability based on data from hydrology and agricultural simulations of future grass crop area and related irrigation demand (20). Afforestation of 127,000 ha of grass cropland with Douglas fir could decrease irrigation demand by 222 and 233 billion $m^3 \cdot y^{-1}$ by 2050 and 2100, respectively. An independent estimate from measured precipitation and evapotranspiration (ET) at our mature Douglas fir and grass crop flux sites in the Willamette Valley shows the ET/precipitation fraction averaged 33% and 52%, respectively, and water balance (precipitation minus ET) averaged 910 $mm \cdot y^{-1}$ and 516 $mm \cdot y^{-1}$. Under current climate conditions, the observations suggest an increase in annual water availability of 260 billion $m^3 \cdot y^{-1}$ if 127,000 ha of the irrigated grass crops were converted to forest.

Harvest cycles in the mesic and montane forests have declined from over 120 y to 45 y despite the fact that these trees can live 500–1,000 y and net primary productivity peaks at 80–125 y (21). If harvest cycles were lengthened to 80 y on private lands and harvested area was reduced 50% on public lands, state-level stocks would increase by 17% to a total of ~3,600 Tg C and NECB would increase 2–3 Tg C y^{-1} by 2100. The lengthened harvest cycles reduced harvest by 2 Tg C y^{-1}, which contributed to higher NECB. Leakage (more harvest elsewhere) is difficult to quantify and could counter these carbon gains. However, because harvest on federal lands was reduced significantly since 1992 (NW Forest Plan), leakage has probably already occurred.

The four strategies together increased NECB by 64%, 82%, and 56% by 2025, 2050, and 2100, respectively. This reduced forest sector net emissions by 11%, 10%, and 17% over the same periods (Fig. 3). By 2050, potential increases in NECB were largest in the Coast Range (Table S5), East Cascades, and Klamath Mountains, accounting for 19%, 25%, and 42% of the total increase, whereas by 2100, they were most evident in the West Cascades, East Cascades, and Klamath Mountains.

We examined the potential for using existing harvest residue for electricity generation, where burning the harvest residue for energy emits carbon immediately (3) versus the BAU practice of leaving residues in forests to slowly decompose. Assuming half of forest residues from harvest practices could be used to replace natural gas or coal in distributed facilities across the state, they would provide an average supply of 0.75–1 Tg C y^{-1} to the year 2100 in the reduced harvest and BAU scenarios, respectively. Compared with BAU harvest practices, where residues are left to decompose, proposed bioenergy production would increase cumulative net emissions by up to 45 Tg C by 2100. Even at 50% use, residue collection and transport are not likely to be economically viable, given the distances (>200 km) to Oregon's facilities.

Discussion

Earth system models have the potential to bring terrestrial observations related to climate, vulnerability, impacts, adaptation,

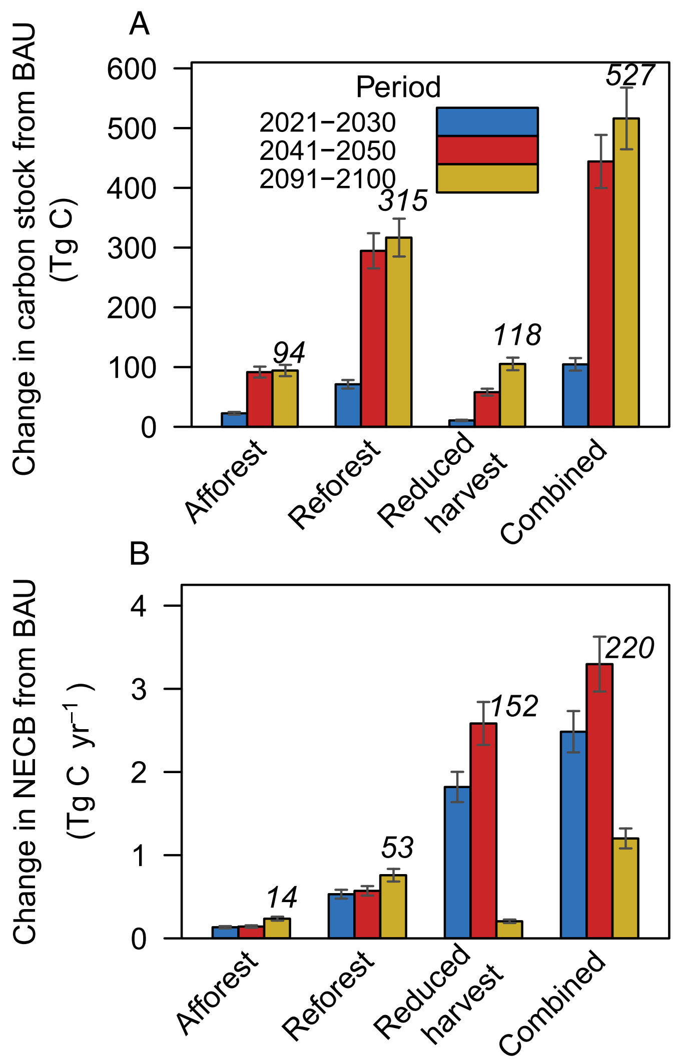

Fig. 3. Future change in carbon stocks and NECB with mitigation strategies relative to BAU management. The decadal average change in forest carbon stocks (*A*) and NECB relative to BAU (*B*) are shown. Italicized numbers over bars indicate mean forest carbon stocks in 2091–2100 (*A*) and cumulative change in NECB for 2015–2100 (*B*). Error bars are ±10%.

and mitigation into a common framework, melding biophysical with social components (22). We developed a framework to examine a suite of mitigation actions to increase forest carbon sequestration and reduce forest sector emissions under current and future environmental conditions.

Harvest-related emissions had a large impact on recent forest NECB, reducing it by an average of 34% from 2001 to 2015. By comparison, fire emissions were relatively small and reduced NECB by 12% in the Biscuit Fire year, but only reduced NECB 5–9% from 2006 to 2015. Thus, altered forest management has the potential to enhance the forest carbon balance and reduce emissions.

Future NEP increased because enhancement from atmospheric carbon dioxide outweighed the losses from fire. Lengthened harvest cycles on private lands to 80 y and restricting harvest to 50% of current rates on public lands increased NECB the most by 2100, accounting for 90% of total emissions reduction (Fig. 3 and Tables S5 and S6). Reduced harvest led to NECB increasing earlier than the other strategies (by 2050), suggesting this could be a priority for implementation.

Our afforestation estimates may be too conservative by limiting them to nonforest areas within current forest boundaries and 127,000 ha of irrigated grass cropland. There was a net loss of 367,000 ha of forest area in Oregon and Washington combined from 2001 to 2006 (23), and less than 1% of native habitat remains in the Willamette Valley due to urbanization and agriculture (24). Perhaps more of this area could be afforested.

The spatial variation in the potential for each mitigation option to improve carbon stocks and fluxes shows that the reforestation potential is highest in the Cascade Mountains, where fire and insects occur (Fig. 4). The potential to reduce harvest on public land is highest in the Cascade Mountains, and that to lengthen harvest cycles on private lands is highest in the Coast Range.

Although western Oregon is mesic with little expected change in precipitation, the afforestation cobenefits of increased water availability will be important. Urban demand for water is projected to increase, but agricultural irrigation will continue to consume much more water than urban use (25). Converting 127,000 ha of irrigated grass crops to native forests appears to be a win–win strategy, returning some of the area to forest land, providing habitat and connectivity for forest species, and easing irrigation demand. Because the afforested grass crop represents only 11% of the available grass cropland (1.18 million ha), it is not likely to result in leakage or indirect land use change. The two forest strategies combined are likely to be important contributors to water security.

Cobenefits with biodiversity were not assessed in our study. However, a recent study showed that in the mesic forests, cobenefits with biodiversity of forest species are largest on lands with harvest cycles longer than 80 y, and thus would be most pronounced on private lands (26). We selected 80 y for the harvest cycle mitigation strategy because productivity peaks at 80–125 y in this region, which coincides with the point at which cobenefits with wildlife habitat are substantial.

Habitat loss and climate change are the two greatest threats to biodiversity. Afforestation of areas that are currently grass crops would likely improve the habitat of forest species (27), as about 90% of the forests in these areas were replaced by agriculture. About 45 mammal species are at risk because of range contraction (28). Forests are more efficient at dissipating heat than grass and crop lands, and forest cover gains lead to net surface cooling in all regions south of about 45° latitude in North American and Europe (29). The cooler conditions can buffer climate-sensitive bird populations from approaching their thermal limits and provide more food and nest sites (30). Thus, the mitigation strategies of afforestation, protecting forests on public lands and lengthening harvest cycles to 80–125 y, would likely benefit forest-dependent species.

Oregon has a legislated mandate to reduce emissions, and is considering an offsets program that limits use of offsets to 8% of

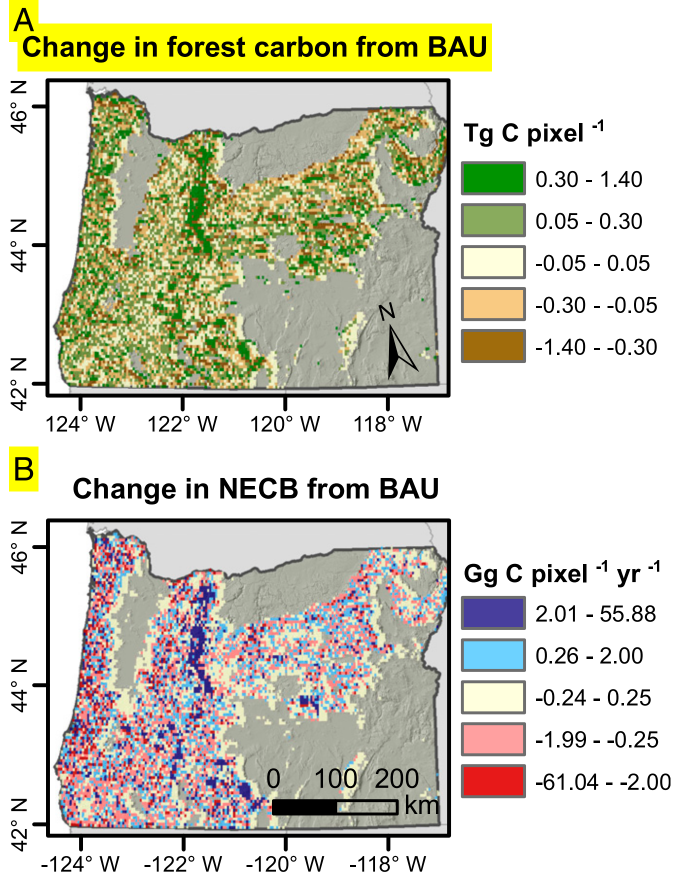

Fig. 4. Spatial patterns of forest carbon stocks and NECB by 2091–2100. The decadal average changes in forest carbon stocks (*A*) and NECB (*B*) due to afforestation, reforestation, protected areas, and lengthened harvest cycles relative to continued BAU forest management (red is increase in NECB) are shown.

the total emissions reduction to ensure that regulated entities substantially reduce their own emissions, similar to California's program (19). An offset becomes a net emissions reduction by increasing the forest carbon sink (NECB). If only 8% of the GHG reduction is allowed for forest offsets, the limits for forest offsets would be 2.1 and 8.4 million metric tCO_2e of total emissions by 2025 and 2050, respectively (Table S6). The combination of afforestation, reforestation, and reduced harvest would provide 13 million metric tCO_2e emissions reductions, and any one of the strategies or a portion of each could be applied. Thus, additionality beyond what would happen without the program is possible.

State-level reporting of GHG emissions includes the agriculture sector, but does not appear to include forest sector emissions, except for industrial fuel (i.e., utility fuel in Table S3) and, potentially, fire emissions. Harvest-related emissions should be quantified, as they are much larger than fire emissions in the western United States. Full accounting of forest sector emissions is necessary to meet climate mitigation goals.

Increased long-term storage in buildings and via product substitution has been suggested as a potential climate mitigation option. Pacific temperate forests can store carbon for many hundreds of years, which is much longer than is expected for buildings that are generally assumed to outlive their usefulness or be replaced within several decades (7). By 2035, about 75% of buildings in the United States will be replaced or renovated, based on new construction, demolition, and renovation trends (31, 32). Recent analysis suggests substitution benefits of using wood versus more fossil fuel-intensive materials have been overestimated by at least an order of magnitude (33). Our LCA accounts for losses in product substitution stores (PSSs) associated with building life span, and thus are considerably lower than when no losses are assumed (4, 34). While product substitution reduces the overall forest sector emissions, it cannot offset the losses incurred by frequent harvest and losses associated with product transportation, manufacturing, use, disposal, and decay. Methods for calculating substitution benefits should be improved in other regional assessments.

Wood bioenergy production is interpreted as being carbon-neutral by assuming that trees regrow to replace those that burned. However, this does not account for reduced forest carbon stocks that took decades to centuries to sequester, degraded productive capacity, emissions from transportation and the production process, and biogenic/direct emissions at the facility (35). Increased harvest through proposed thinning practices in the region has been shown to elevate emissions for decades to centuries regardless of product end use (36). It is therefore unlikely that increased wood bioenergy production in this region would decrease overall forest sector emissions.

Conclusions

GHG reduction must happen quickly to avoid surpassing a 2 °C increase in temperature since preindustrial times. Alterations in forest management can contribute to increasing the land sink and decreasing emissions by keeping carbon in high biomass forests, extending harvest cycles, reforestation, and afforestation. Forests are carbon-ready and do not require new technologies or infrastructure for immediate mitigation of climate change. Growing forests for bioenergy production competes with forest carbon sequestration and does not reduce emissions in the next decades (10). BECCS requires new technology, and few locations have sufficient geological storage for CO_2 at power facilities with high-productivity forests nearby. Accurate accounting of forest carbon in trees and soils, NECB, and historic harvest rates, combined with transparent quantification of emissions from the wood product process, can ensure realistic reductions in forest sector emissions.

As states and regions take a larger role in implementing climate mitigation steps, robust forest sector assessments are urgently needed. Our integrated approach of combining observations, an LCA, and high-resolution process modeling (4-km grid vs. typical 200-km grid) of a suite of potential mitigation actions and their effects on forest carbon sequestration and emissions under changing climate and CO_2 provides an analysis framework that can be applied in other temperate regions.

Materials and Methods

Current Stocks and Fluxes. We quantified recent forest carbon stocks and fluxes using a combination of observations from FIA; Landsat products on forest type, land cover, and fire risk; 200 intensive plots in Oregon (37); and a wood decomposition database. Tree biomass was calculated from species-specific allometric equations and ecoregion-specific wood density. We estimated ecosystem carbon stocks, NEP (photosynthesis minus respiration), and NECB (NEP minus losses due to fire or harvest) using a mass-balance approach (36, 38) (Table 1 and *SI Materials and Methods*). Fire emissions were computed from the Monitoring Trends in Burn Severity database, biomass data, and region-specific combustion factors (15, 39) (*SI Materials and Methods*).

Future Projections and Model Description. Carbon stocks and NEP were quantified to the years 2025, 2050, and 2100 using CLM4.5 with physiological parameters for 10 major forest species, initial forest biomass (36), and future climate and atmospheric carbon dioxide as input (Institut Pierre Simon Laplace climate system model downscaled to 4 km × 4 km, representative concentration pathway 8.5). CLM4.5 uses 3-h climate data, ecophysiological characteristics, site physical characteristics, and site history to estimate the daily fluxes of carbon, nitrogen, and water between the atmosphere, plant state variables, and litter and soil state variables. Model components are biogeophysics, hydrological cycle, and biogeochemistry. This model version does not include a dynamic vegetation model to simulate resilience and establishment following disturbance. However, the effect of regeneration lags on forest carbon is not particularly strong for the long disturbance intervals in this study (40). Our plant functional type (PFT) parameterization for 10 major forest species rather than one significantly improves carbon modeling in the region (41).

Forest Management and Land Use Change Scenarios. Harvest cycles, reforestation, and afforestation were simulated to the year 2100. Carbon stocks and NEP were predicted for the current harvest cycle of 45 y compared with simulations extending it to 80 y. Reforestation potential was simulated over areas that recently suffered mortality from harvest, fire, and 12 species of beetles (13). We assumed the same vegetation regrew to the maximum potential, which is expected with the combination of natural regeneration and planting that commonly occurs after these events. Future BAU harvest files were constructed using current harvest rates, where county-specific average harvest and the actual amounts per ownership were used to guide grid cell selection. This resulted in the majority of harvest occurring on private land (70%) and in the mesic ecoregions. Beetle outbreaks were implemented using a modified mortality rate of the lodgepole pine PFT with 0.1% y^{-1} biomass mortality by 2100.

For afforestation potential, we identified areas that are within forest boundaries that are not currently forest and areas that are currently grass crops. We assumed no competition with conversion of irrigated grass crops to urban growth, given Oregon's land use laws for developing within urban growth boundaries. A separate study suggested that, on average, about 17% of all irrigated agricultural crops in the Willamette Valley could be converted to urban area under future climate; however, because 20% of total cropland is grass seed, it suggests little competition with urban growth (25).

Landsat observations (12,500 scenes) were processed to map changes in land cover from 1984 to 2012. Land cover types were separated with an unsupervised K-means clustering approach. Land cover classes were assigned to an existing forest type map (42). The CropScape Cropland Data Layer (CDL 2015, https://nassgeodata.gmu.edu/CropScape/) was used to distinguish nonforage grass crops from other grasses. For afforestation, we selected grass cropland with a minimum soil water-holding capacity of 150 mm and minimum precipitation of 500 mm that can support trees (43).

Afforestation Cobenefits. Modeled irrigation demand of grass seed crops under future climate conditions was previously conducted with hydrology and agricultural models, where ET is a function of climate, crop type, crop growth state, and soil-holding capacity (20) (Table S7). The simulations produced total land area, ET, and irrigation demand for each cover type. Current grass seed crop irrigation in the Willamette Valley is 413 billion $m^3 \cdot y^{-1}$ for 238,679 ha and is projected to be 412 and 405 billion m^3 in 2050 and 2100 (20) (Table S7). We used annual output from the simulations to estimate irrigation demand per unit area of grass seed crops (1.73, 1.75, and 1.84 million $m^3 \cdot ha^{-1}$ in 2015, 2050, and 2100, respectively), and applied it to the mapped irrigated crop area that met conditions necessary to support forests (Table S7).

LCA. Decomposition of wood through the product cycle was computed using an LCA (8, 10). Carbon emissions to the atmosphere from harvest were calculated annually over the time frame of the analysis (2001–2015). The net carbon emissions equal NECB plus total harvest minus wood lost during manufacturing and wood decomposed over time from product use. Wood industry fossil fuel emissions were computed for harvest, transportation, and manufacturing processes. Carbon credit was calculated for wood product storage, substitution, and internal mill recycling of wood losses for bioenergy.

Products were divided into sawtimber, pulpwood, and wood and paper products using published coefficients (44). Long-term and short-term products were assumed to decay at 2% and 10% per year, respectively (45). For product substitution, we focused on manufacturing for long-term structures (building life span >30 y). Because it is not clear when product substitution started in the Pacific Northwest, we evaluated it starting in 1970 since use of concrete and steel for housing was uncommon before 1965. The displacement value for product substitution was assumed to be 2.1 Mg fossil C/Mg C wood use in long-term structures (46), and although it likely fluctuates over time, we assumed it was constant. We accounted for losses in product substitution associated with building replacement (33) using a loss rate of 2% per year (33), but ignored leakage related to fossil C use by other sectors, which may result in more substitution benefit than will actually occur.

The general assumption for modern buildings, including cross-laminate timber, is they will outlive their usefulness and be replaced in about 30 y (7). By 2035, ∼75% of buildings in the United States will be replaced or renovated, based on new construction, demolition, and renovation trends, resulting in threefold as many buildings as there are now [2005 baseline (31, 32)]. The loss of

ENVIRONMENTAL SCIENCES

SUSTAINABILITY SCIENCE

the PSS is therefore PSS multiplied by the proportion of buildings lost per year (2% per year).

To compare the NECB equivalence to emissions, we calculated forest sector and energy sector emissions separately. Energy sector emissions ["in-boundary" state-quantified emissions by the Oregon Global Warming Commission (14)] include those from transportation, residential and commercial buildings, industry, and agriculture. The forest sector emissions are cradle-to-grave annual carbon emissions from harvest and product emissions, transportation, and utility fuels (Table S3). Forest sector utility fuels were subtracted from energy sector emissions to avoid double counting.

Uncertainty Estimates. For the observation-based analysis, Monte Carlo simulations were used to conduct an uncertainty analysis with the mean and SDs for NPP and Rh calculated using several approaches (36) (*SI Materials and Methods*). Uncertainty in NECB was calculated as the combined uncertainty of NEP, fire emissions (10%), harvest emissions (7%), and land cover estimates (10%) using the propagation of error approach. Uncertainty in CLM4.5 model simulations and LCA were quantified by combining the uncertainty in the observations used to evaluate the model, the uncertainty in input datasets (e.g., remote sensing), and the uncertainty in the LCA coefficients (41).

Model input data for physiological parameters and model evaluation data on stocks and fluxes are available online (37).

ACKNOWLEDGMENTS. We thank Dr. Thomas Hilker (deceased) for producing the grass data layer, and Carley Lowe for Fig. 1. Abstract

Understanding the causes and consequences of rapid environmental change is an essential scientific frontier, particularly given the threat of climate- and land use-induced changes in disturbance regimes. In western North America, recent widespread insect outbreaks and wildfires have sparked acute concerns about potential insect–fire interactions. Although previous research shows that insect activity typically does not increase wildfire likelihood, key uncertainties remain regarding insect effects on wildfire severity (i.e., ecological impact). Recent assessments indicate that outbreak severity and burn severity are not strongly associated, but these studies have been limited to specific insect or fire events. Here, we present a regional census of large wildfire severity following outbreaks of two prevalent bark beetle and defoliator species, mountain pine beetle (*Dendroctonus ponderosae*) and western spruce budworm (*Choristoneura freemani*), across the US Pacific Northwest. We first quantify insect effects on burn severity with spatial modeling at the fire event scale and then evaluate how these effects vary across the full population of insect–fire events ($n = 81$ spanning 1987–2011). In contrast to common assumptions of positive feedbacks, we find that insects generally reduce the severity of subsequent wildfires. Specific effects vary with insect type and timing, but both insects decrease the abundance of live vegetation susceptible to wildfire at multiple time lags. By dampening subsequent burn severity, native insects could buffer rather than exacerbate fire regime changes expected due to land use and climate change. In light of these findings, we recommend a precautionary approach when designing and implementing forest management policies intended to reduce wildfire hazard and increase resilience to global change.

1. Introduction

Forest ecosystems play a vital role in the biosphere, but anthropogenic climate change and shifting disturbance regimes threaten to destabilize the ecosystem services that forests provide from local to global scales (Kurz *et al* 2008, Littell *et al* 2010, Seidl *et al* 2011, Turner *et al* 2013). Indeed, the indirect effects of climate change on forests via disturbances (including wildfires, insect outbreaks, introduced species, and pathogens) are expected to exceed the direct but more gradual effects of warmer temperatures (Ayres *et al* 2014, Hart *et al* 2015). In an era of rapid, nonlinear changes in the Earth system, understanding the causes, consequences, and feedbacks of forest disturbances is a crucial scientific and policy frontier.

Disturbance interactions—when one disturbance influences the likelihood, extent, or severity of another (Paine *et al* 1998, Simard *et al* 2011, Buma 2015, Meigs *et al* 2015a)—are a particularly important example of feedbacks that could be reinforced under novel climatic conditions (e.g., persistent drought (Turner *et al* 2013, Harvey *et al* 2014b, Hart *et al* 2015)). In western North America, insect outbreaks and wildfires are the two most ecologically and economically significant natural forest disturbances (Westerling *et al* 2006, Kurz *et al* 2008, Hicke *et al* 2013). Both disturbances have been widespread in recent decades and are projected to increase in response to climate and land use change (Hessburg *et al* 2000, Westerling *et al* 2006, Raffa *et al* 2008, Bentz *et al* 2010, Littell *et al* 2010, Ayres *et al* 2014). By killing trees and redistributing forest fuels, insect outbreaks influence fire regimes in many parts of the world, and recent large outbreaks have sparked acute societal concerns about potential insect–fire interactions and impaired ecosystem resilience (Hicke *et al* 2012, Harvey *et al* 2014b, Jenkins *et al* 2014). For example, based on the implicit assumption that insect outbreaks increase wildfire hazard by generating abundant dead fuels, the 2014 US Farm Bill designated \$200 million annually to support fuel reduction activities across 18 M ha of US National Forest lands affected by diseases and insects (Agricultural Act of 2014, Hart *et al* 2015).

Despite concerns about altered fire regimes and insect–fire interactions, recent studies indicate that insect outbreaks generally do not increase wildfire likelihood (Lynch and Moorcroft 2008, Kulakowski and Jarvis 2011, Flower *et al* 2014, Hart *et al* 2015, Meigs *et al* 2015a). When they do overlap, however, key uncertainties remain regarding the influence of insect outbreaks on subsequent wildfire severity (Hicke *et al* 2012, Harvey *et al* 2014b, Hart *et al* 2015). Specifically, although insect-caused tree mortality may increase the flammability of canopy fuels at fine scales in time and space (Jolly *et al* 2012), a pivotal question in contemporary environmental management is whether these insect-altered fuels increase burn severity (i.e., ecological impact; a major fire regime component) at broader spatiotemporal scales. If insect outbreaks do amplify subsequent fire effects, the resultant compound impacts may hasten climate-induced shifts in disturbance regimes toward more severe fire and altered ecosystem structure and function. Conversely, if insects buffer subsequent fire effects by redistributing fuel density and/or availability, recent widespread outbreaks may bolster ecosystem resistance to shifting fire regimes. Empirical studies that identify particular time lags and locations where insect-altered fuels either exacerbate or dampen fire effects on surviving trees are directly applicable to time-sensitive management activities (e.g., post-insect salvage logging, fuel reduction at the wildland–urban interface) as well as broader policy discussions of forest health in a time of shifting disturbance regimes.

Due in part to data paucity, computational limitations, and the relative rarity of insect–fire co-occurrence, recent empirical assessments of insect effects on burn severity have been limited to specific insect outbreaks, fire events, or insect–fire time lags (e.g., Crickmore 2011, Harvey *et al* 2013, Harvey *et al* 2014b, Prichard and Kennedy 2014). These studies suggest that burn severity is either unaffected by or weakly positively associated with outbreak severity, that insect effects are context-dependent, or that factors like fuel treatments, topography, and weather are stronger predictors of fire effects. To further elucidate general system behavior and inform regional management strategies, it is essential to investigate numerous fire events spanning multiple insect types (e.g., bark beetle versus defoliator), insect and burn severities, and time lags. Here, we leverage recent advances in remote sensing of forest disturbance dynamics (Kennedy *et al* 2010, Meigs *et al* 2015b) to conduct a burn severity census of large wildfires following recent outbreaks of the two most prevalent native forest insects across a large forested region, the US Pacific Northwest (PNW; 40 M ha; Oregon and Washington; figure 1). We focus on all large fire events (⩾400 ha) with substantial overlap of fire perimeters with prior outbreaks of either mountain pine beetle (MPB) [*Dendroctonus ponderosae* Hopkins (Coleoptera: Curculionidae: Scolytinae); a bark beetle] or western spruce budworm (WSB) [*Choristoneura freemani* Razowski (Lepidoptera: Tortricidae); a defoliator] (total $n = 81$; table S1). Our specific objectives are (1) to quantify the fine-scale (30 m) effects of recent insect outbreaks on subsequent burn severity with spatial modeling at the fire event scale and (2) to evaluate the role of insect type, time since outbreak, insect and fire extent, fire season, and interannual drought across the full population of insect–fire events.

2. Methods

2.1. Study area and recent insect dynamics

Conifer forests of the PNW vary across gradients of climate, topography, soil, and management history (Franklin and Dyrness 1973, Hessburg *et al* 2000, Meigs *et al* 2015a). Despite climatic variability, a common feature is that low precipitation during summer months (Franklin and Dyrness 1973) yields conditions conducive to periodic insect and wildfire disturbances, particularly in mixed-species conifer forests east of the crest of the Cascade Range (Meigs *et al* 2015a). In general, these forests occur in remote, mountainous terrain and are managed by US federal agencies for multiple resource objectives. Given the extent of similar geographic conditions, vegetation types, and anthropogenic pressures, recent PNW insect and wildfire patterns are broadly representative of contemporary disturbance dynamics in conifer forests of western North America.

Bark beetles, especially MPB outbreaks, have altered forest composition and structure across tens of millions of hectares of North American forests in recent decades (Raffa *et al* 2008, Bentz *et al* 2010). MPB adults attack pine tree stems [*Pinus spp.*, particularly mature lodgepole pine (*Pinus contorta* Douglas ex Louden)], inducing variable but relatively rapid tree mortality during major outbreaks (Raffa *et al* 2008, Meigs *et al* 2011). In contrast, WSB larvae typically consume the current year's foliage of host trees {particularly true firs [*Abies spp.*], spruces [*Picea spp.*], and Douglas-fir [*Pseudotsuga menziesii* (Mirb.) Franco]},

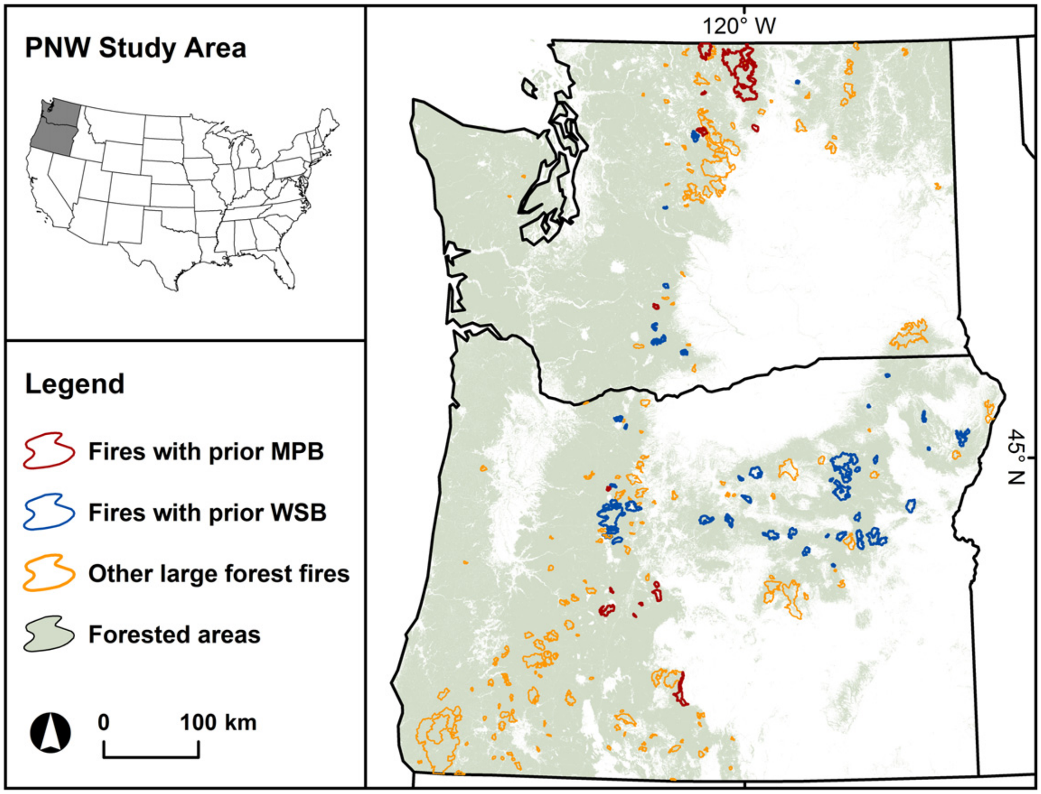

Figure 1. Distribution of large forest fires affected by prior outbreaks of mountain pine beetle (MPB; red; $n = 19$) and western spruce budworm (WSB; blue; $n = 62$) within the US Pacific Northwest study area (Oregon and Washington; inset). Note that 29% of large wildfires during the study period (⩾400 ha; 1987–2011; $n = 277$) had ⩾10% prior insect damage, highlighting that these potential compound disturbance events are limited to drier, interior conifer forests. We include only large wildfire perimeters with ⩾50% forest cover (see methods). Oregon and Washington encompass ca. 40 M ha, half of which is forested (forest cover from Ohmann *et al* 2012).

and multiple years of WSB defoliation can result in tree mortality, often in conjunction with secondary bark beetles (Hummel and Agee 2003, Meigs *et al* 2011). Across the PNW, both insects have erupted in multiple outbreaks since 1970, with WSB exceeding MPB in cumulative extent and tree mortality (Meigs *et al* 2015b). Importantly, WSB host forests are more widespread and occur in relatively warmer, more productive locations than MPB host forests in the study area.

2.2. Insect and fire census data

Recent advances in remote sensing of forest dynamics across the PNW (Kennedy *et al* 2010, Meigs *et al* 2015b) provide an unprecedented opportunity to investigate relationships between insect outbreaks and wildfire severity in a retrospective, empirical, census-based framework. We used regional maps of insect and fire effects developed with LandTrendr time series analysis, which is described in detail by Kennedy *et al* (2010). Briefly, we acquired georectified images from the USGS Landsat archive and applied a series of steps —pre-processing (atmospheric correction, cloud masking), processing (temporal segmentation), and analysis (disturbance attribution, regional mosaicking)—to reduce multiple sources of uncertainty and assess trajectories of vegetation change (Kennedy *et al* 2010, Meigs *et al* 2015b).

We accounted for insect activity with LandTrendr-based maps of the cumulative magnitude, cumulative duration (count of years), and time since onset of MPB and WSB outbreaks developed by Meigs *et al* (2015b). These insect maps improve on regional aerial surveys by capturing fine-scale variation of insect impacts (30 m) and constraining maps to locations with durable vegetation change in known insect host forests from 1985 to 2012. The maps also quantify the impacts of MPB and WSB in consistent units of spectral change as seamless mosaics across the PNW study area (including all or part of 35 Landsat satellite scenes (Meigs *et al* 2015b)).

We accounted for burn severity by combining LandTrendr-based regional mosaics of spectral change (Kennedy *et al* 2010) with fire perimeters from a database of large wildland fires in the western US (⩾400 ha; 1985–2012 (available online: http://mtbs.gov)). We first compiled annual time series (temporally stabilized at the pixel scale) of the normalized burn ratio (NBR; which combines near-infrared and mid-infrared wavelengths of the Landsat TM/

ETM + sensor (Miller and Thode 2007)). Importantly, the Landsat time series are anchored in time near the median date of each scene (generally 1 August), which reduces seasonal variability associated with phenology and sun angles. We then computed the relative differenced normalized burn ratio (RdNBR (Miller and Thode 2007)) in two-year intervals to ensure pre- and post-fire coverage for all pixels within a given fire event. By capturing the relative change in dominant forest vegetation, RdNBR enables the assessment of burn severity across numerous fire events spanning heterogeneous vegetation (Miller and Thode 2007, Cansler and McKenzie 2014) or variable prefire disturbances (including insect outbreaks (Harvey *et al* 2013, Prichard and Kennedy 2014)). Although remotely sensed spectral change indices such as RdNBR have inherent limitations and do not measure very fine-scale fire effects and responses (e.g., tree charring, forest floor combustion, or postfire regeneration (Harvey *et al* 2014b)), they provide the only spatially and temporally consistent metric of burn severity encompassing all fires since 1985. Furthermore, because NBR is at the core of many current fire monitoring protocols (e.g., Key and Benson 2006), our RdNBR-based analysis is directly applicable to contemporary fire research and management.

We conducted a regional insect–fire severity census by focusing on large fire events with the following characteristics: total fire extent $\geqslant$400 ha; $\geqslant$10% of fire extent affected by prefire insect outbreaks (either MPB or WSB); $\geqslant$50% forest cover (30 m resolution (Ohmann *et al* 2012)). Because this forest cover map targets conditions in the year 2000 and classifies some previously burned areas as non-forest, we manually included several fires ($n = 8$) with mapped forest cover <50%. To avoid potential confounding effects, we excluded fire polygons with prior outbreaks of both MPB and WSB ($n = 8$), fires in 1986 with only one full year of prefire insect data ($n = 5$), fires in 2012 without postfire imagery for RdNBR calculations, and one fire classified as a prescribed fire. With these criteria, we refined the total population of forest fires ($n = 425$ spanning 1985–2012) to our final census of large wildfires with prefire insect activity ($n = 81$ spanning 1987–2011; figure 1).

2.3. Statistical analysis

We developed a hierarchical framework to investigate insect effects on burn severity within and among all wildfires in our census (i.e., at the individual and population level). Within each large insect–fire event, we assessed fine-scale (30 m) insect effects on burn severity with sequential autoregression (SAR), a powerful spatial modeling approach advanced recently for wildfire analysis (e.g., Wimberly *et al* 2009, Prichard and Kennedy 2014). SAR incorporates the inherent spatial autocorrelation in dependent and independent variables with a spatial error term (Haining 1993, Wimberly *et al* 2009). This spatial error term also accounts for spatially autocorrelated variables not included explicitly, resulting in more robust inferences than traditional approaches like ordinary least squares regression (Wimberly *et al* 2009, Prichard and Kennedy 2014).

We conducted all analyses in the R statistical environment (R Core Team 2015), constructing SAR models with the spautolm function in the spdep package (Bivand *et al* 2013) in the form:

$$Y = X\beta + \lambda W(Y - X\beta) + \varepsilon,$$

where Y is the vector of the dependent variable, X is the matrix of independent variables, β is the vector of parameters, λ is the autoregressive coefficient, W is the spatial weights matrix, and ε is the uncorrelated error term. W is based on the spatial structure of the dependent and independent variables and is defined by an inverse distance rule that assigns a weight of zero to all pixels outside the focus pixel neighborhood and weights equal to the inverse of the distance within the focus pixel neighborhood. We determined the most parsimonious inverse distance rule of W by selecting the neighborhood that minimized both the Akaike information criterion (AIC) and residual spatial autocorrelation of the SAR model (Moran's I) (Kissling and Carl 2008, de Knegt *et al* 2010). Specifically, we ran SAR models with all dependent and independent variables (described below) across seven neighborhood distances (30–210 m in 30 m increments) for a subset of fires ($n = 15$) spanning the range of conditions in the large fire census. We then calculated AIC and Moran's I of the SAR residual values (moran.test function in Bivand *et al* 2013), which indicated an optimal neighborhood distance of 30 m, consistent with previous SAR burn severity modeling in the study area (Prichard and Kennedy 2014) and typical for a spreading disturbance phenomenon such as fire.

Following these initial steps, we quantified insect effects on subsequent burn severity at the individual fire level (Objective 1) by running a SAR model for each large insect–fire event in the regional census ($n = 81$). We used all 30 m pixels within each fire perimeter to predict burn severity (RdNBR) with the same set of independent variables related to forest fuels and topography (table 1). We included the insect damage and duration variables described above as well as pixel-level estimates of prefire biomass from annual Landsat time series and nearest neighbor imputation with forest inventory data derived for a regional analysis of carbon trajectories (http://lemma.forestry.oregonstate.edu/projects/cmonster).

Although our primary focus was insect effects on burn severity via their impacts on vegetation/fuels, we recognize that topography and weather are fundamental drivers of fire behavior and effects. We thus included a set of five topographic variables (aspect, elevation, slope, and topographic position index at 150 and 450 m; derived from a 30 m digital elevation model) associated with burn severity in the region

Table 1. List of variables used in sequential autoregression modeling of burn severity (RdNBR spectral index) of all fire events affected by prior mountain pine beetle or western spruce budworm. All data were compiled as regional mosaics encompassing the Pacific Northwest study area (figure 1) and processed at 30 m resolution.

Variable	Description	Source
Burn severity (response)	Relative differenced normalized burn ratio (RdNBR, two year interval)	(Miller and Thode 2007)
Prefire insect damage	Cumulative prefire vegetation change due to insect activity from Landsat time series (NBR)	(Meigs *et al* 2015b)
Prefire insect duration	Count of years with prefire insect activity from Landsat time series (y)	(Meigs *et al* 2015b)
Prefire biomass[a]	Prefire tree biomass from imputation mapping (kg ha^{-1})	
Aspect[b]	Cosine transformed aspect (°)	
Elevation[b]	Elevation (m)	
Slope[b]	Slope steepness (%)	
Topographic position index (150 m)[b]	Difference between a pixel's elevation and the mean elevation of pixels within 150 m	
Topographic position index (450 m)[b]	Difference between a pixel's elevation and the mean elevation of pixels within 450 m	

[a] Annual biomass maps were derived from Landsat time series and nearest neighbor imputation with forest inventory data as part of a regional analysis of carbon trajectories (http://lemma.forestry.oregonstate.edu/projects/cmonster).

[b] Topographic variables derived from 30 m digital elevation model.

Table 2. List of population-level predictor variables used to assess drivers of insect effects on burn severity across all fire events affected by prior mountain pine beetle or western spruce budworm.

Variable	Description	Source
Insect type	Mountain pine beetle (bark beetle) or western spruce budworm (defoliator)	(Meigs *et al* 2015b)
Time since outbreak	Time since onset of insect outbreak according to Landsat time series (y)	(Meigs *et al* 2015b)
Area affected by insect	Area of fire extent affected by prior mountain pine beetle or western spruce budworm according to Landsat time series (cumulative %)	(Meigs *et al* 2015b)
Fire size	Extent of fire event (ha)	http://mtbs.gov
Fire season	Day of year of fire ignition	http://mtbs.gov
Interannual drought	Palmer drought severity index (mean June–August PDSI) by fire year and state	http://www.wrcc.dri.edu/wwdt/time/

(Thompson *et al* 2007, Dillon *et al* 2011, Prichard and Kennedy 2014). Unlike these spatially static covariates, fire weather is a dynamic variable that needs to match SAR model resolution in both space and time. Recent advances in the development of gridded meteorological data (e.g., Abatzoglou 2013) have great potential for such analysis but must be combined with accurate fire progression maps to assign fire weather conditions to each pixel for the day it burned. Because consistent fire progression maps are a recent development in North American wildfire monitoring, they are not available for most fires in our census, precluding the use of fire weather covariates in our SAR analyses. Nevertheless, a major strength of SAR is that the spatial error term captures unmeasured but spatially structured variables at the pixel scale (Haining 1993, Wimberly *et al* 2009), including fire weather.

To evaluate key drivers of insect–fire effects at the population level (Objective 2), we assessed the distribution of SAR regression coefficients derived for each fire event with a set of predictor variables not included in the SAR models (table 2). Because the large variability and range of the independent SAR variables precluded direct comparison across model coefficients, we first standardized the coefficients by calculating *z*-scores based on the standard deviation of the mean across all SAR models. We then investigated whether insect effects on burn severity (*z*-scores of prefire insect damage coefficients) varied with insect type (MPB versus WSB), time since outbreak, total area affected by prior insect outbreaks (%), fire size (total extent), fire season (inferred from fire ignition date), or drought condition of each fire year (Palmer drought severity index; PDSI). We derived these predictor variables from the insect and fire census data described above, with the exception of state-level PDSI values (available online: http://www.wrcc.dri.edu/wwdt/time/), which we assigned to each fire, averaging June–August after Heyerdahl *et al* (2008). We estimated time since onset of insect outbreak at the fire event scale as the majority year of first detection in the Landsat-based insect atlas (Meigs *et al* 2015b), recognizing that actual insect activity begins one year before vegetation changes are detected (Meigs *et al* 2015a) and that outbreak initiation varies within a given fire perimeter, depending on outbreak and fire extent. Finally, we computed linear models to assess univariate relationships between these population-level predictors and the insect–fire coefficients.

We evaluated uncertainty in the SAR models for each fire event as well as the distribution of model accuracy across all fire events (table S1). Specifically, we

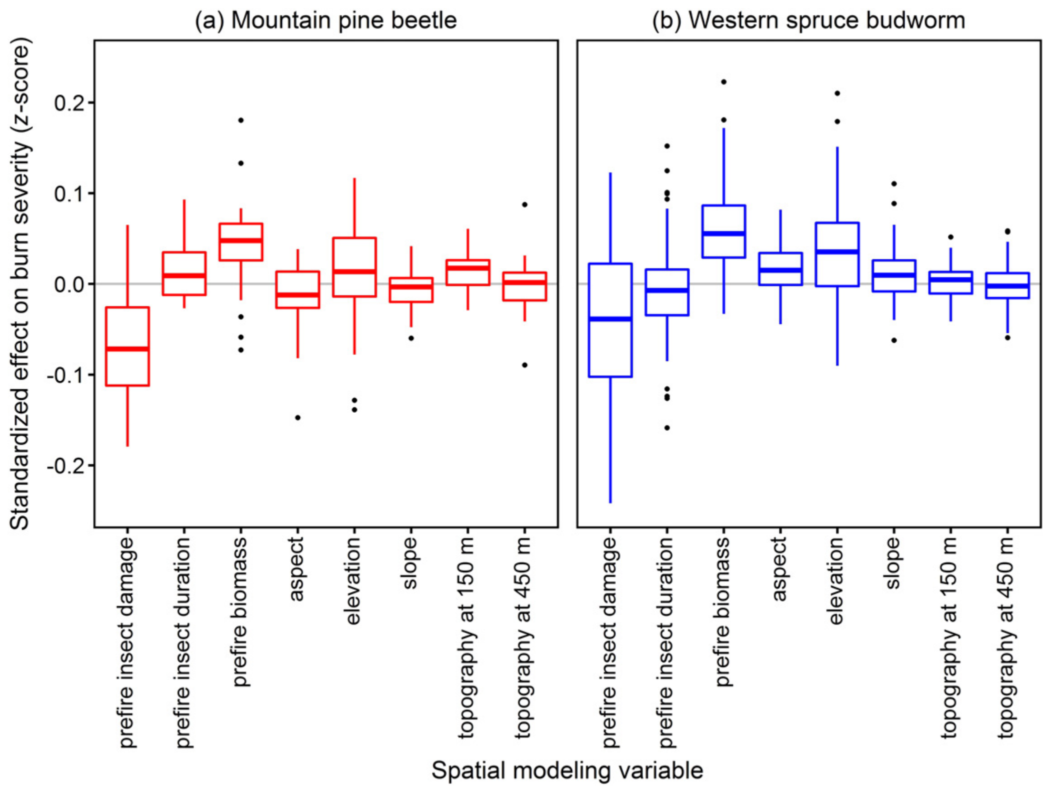

Figure 2. Effect of insect, vegetation, and topography drivers on remotely sensed burn severity across fire events with prior mountain pine beetle (a, $n = 19$) or western spruce budworm (b, $n = 62$). The standardized z-scores from spatial modeling (sequential autoregression; SAR) of each large fire event indicate that burn severity (RdNBR spectral index) is lower in forests with higher cumulative prefire insect damage and lower prefire biomass. The SAR models also account for prefire insect outbreak duration and five potential topographic drivers of severity (table 1). The box and whisker plots show the median as a horizontal line, 25th and 75th percentiles as box edges, 1.5 times the interquartile range as whiskers, and outliers as points.

graphed SAR model coefficients of determination (R^2) by insect type and across the same key predictor variables used in the population-level analysis. Recognizing additional uncertainties inherent to these spatial datasets, we emphasize general patterns across the regional census and the relative effects of insect outbreaks. For example, because the insect outbreak year is offset by one year and uncertain for any given pixel within a fire perimeter, we focus on the relative time since insect outbreak across all fires rather than the specific time lag for a given fire event.

3. Results

Our census of recent insect–fire events across Pacific Northwest forests reveals that, after accounting for prefire biomass and topography, burn severity is generally lower in forests with higher cumulative prefire insect damage (figure 2). Notably, this negative effect of prior insect damage on burn severity is strong enough to emerge without directly accounting for weather conditions at the time of burning.

Following both MPB and WSB outbreaks, burn severity is lower across most time lags (figure 3). The two insects exhibit divergent temporal trajectories, however, revealing differential insect effects on tree mortality, vegetation response, and associated fuel dynamics. Specifically, whereas burn severity decreases with time following MPB outbreaks (figure 3(a)), severity increases with time following WSB outbreaks, eventually recovering to a neutral effect within 20 years (figure 3(b)).

In addition, insect effects on burn severity do not depend on the other population-level predictor variables. Specifically, the insect–fire coefficients are not associated with the proportion of fire extent affected by insects (%), total fire extent (ha), fire season (ignition date), or interannual drought condition (PDSI) for either insect species (figures S1–S4). This lack of association underscores the importance of time-since-outbreak as an emergent predictor of fine-scale insect effects on burn severity (figure 3).

In general, SAR model accuracy is high (MPB mean $R^2 = 0.64$; WSB mean $R^2 = 0.72$; table S1), indicating that the insect, vegetation, and topography variables—as well as the inherent spatial patterning represented by the spatial error term—explain a large proportion of variation in estimated burn severity. In addition, the coefficients of determination are generally evenly distributed across the regional predictor

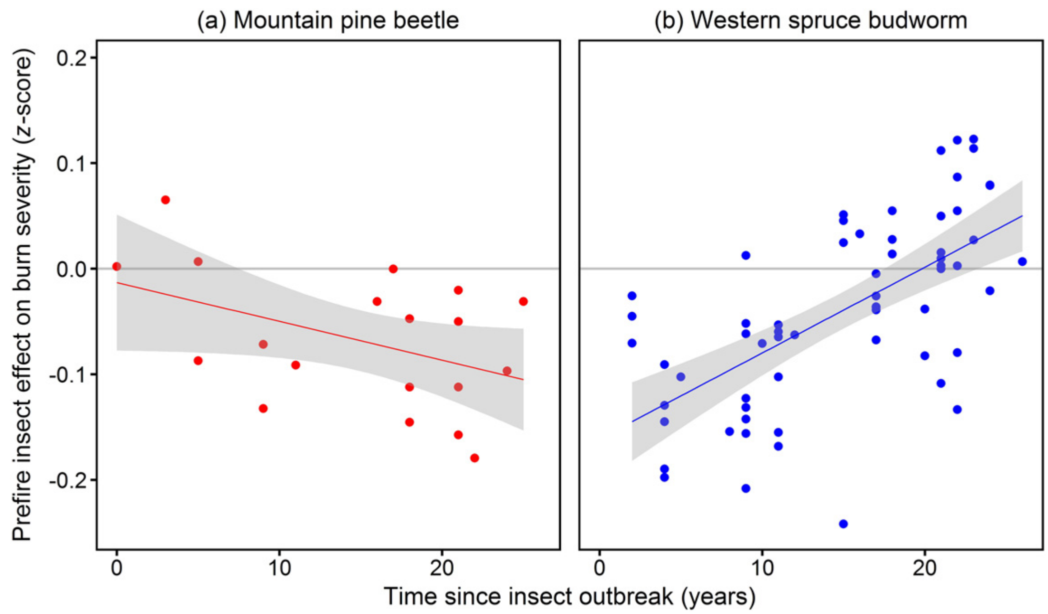

Figure 3. Relationship between prefire insect effect on burn severity (RdNBR spectral index) and years since onset of insect outbreak across fire events (individual points) with prior mountain pine beetle (a) or western spruce budworm (b). For both insects, burn severity is lower in forests with higher prefire insect damage across most time lags, although the two insects exhibit divergent trajectories. Whereas burn severity decreases with time following mountain pine beetle outbreaks ($R^2 = 0.19, P = 0.06, n = 19$), severity increases with time following western spruce budworm outbreaks ($R^2 = 0.40, P < 0.0001, n = 62$), recovering to a neutral effect within 20 years.

variables, which encompass a broad range of insect, fire, and drought conditions (figures S5–S9). Finally, other recognized drivers of burn severity that we did not model explicitly, particularly fire weather and firefighting response at the event scale, contribute to the spatially autocorrelated variance captured indirectly by the SAR spatial error term associated with each fire.

4. Discussion

By quantifying the fine-scale effects of insect outbreaks on burn severity within all large insect–fire events across a heterogeneous forest region, this study demonstrates a general pattern of lower burn severity following outbreaks of both bark beetles and defoliators, in contrast to recent findings that burn severity is either unaffected by or weakly positively associated with outbreak severity (e.g., Crickmore 2011, Harvey *et al* 2013, 2014a, 2014b, Prichard and Kennedy 2014). We suggest that higher severity insect outbreaks reduce the abundance of live vegetation susceptible to wildfire while altering vertical and horizontal fuel distributions, particularly as trees defoliate, die, and transition from canopy to surface fuels (Hummel and Agee 2003, Simard *et al* 2011, Hicke *et al* 2012, Cohn *et al* 2014, Harvey *et al* 2014a).

In the case of MPB, this forest thinning effect results in a lasting reduction of fire impacts on residual vegetation (figure 3(a)). Moreover, the continuing decline in post-beetle burn severity indicates that the thinning effect may persist until vegetation and fuel distributions recover to pre-insect conditions. Because there were relatively few fire events within the first few years following MPB outbreak in our census (figure 3(a)), future studies should continue to investigate the transient yet highly flammable red stage of outbreak (Jolly *et al* 2012). Nevertheless, our finding of generally lower burn severity in forests affected by MPB outbreaks—as well as the relative rarity of red-stage fire events in recent decades despite major beetle outbreaks in the study region (Meigs *et al* 2015b)—highlights the need for discretion in forest and fuel management following beetle outbreaks.

In the case of WSB defoliation, lower initial burn severity is consistent with reduced potential fire behavior and effects due to fine-scale canopy thinning and mortality dynamics (Cohn *et al* 2014). The relatively rapid increase of the budworm-fire coefficient with time (figure 3(b)) indicates that the thinning effect on fuel profiles is less persistent for the defoliator (WSB) than for the bark beetle (MPB). In addition to relatively lower per-unit-area tree mortality impacts (Meigs *et al* 2011), WSB affects host forests that are more productive than those affected by MPB in the study region (Meigs *et al* 2015b), leading to more rapid accumulation of live overstory and understory vegetation. Thus, as time elapses following WSB outbreaks, fuel density and connectivity likely increase in multiple strata, including dead surface fuels (Hummel and Agee 2003) and total live biomass, the latter of which is associated with higher burn severity (figure 2). The potentially synergistic budworm-fire effects in older outbreaks have important implications for current forest management in the US Pacific Northwest, where regional WSB outbreaks peaked 25–30 years ago, exceeding recent MPB outbreaks in cumulative extent and impacts (Meigs *et al* 2015b).

Very few studies to date have assessed post-insect burn severity in an empirical, spatially explicit manner, and our census of numerous large fire events occurring up to 26 years following bark beetle and defoliator outbreaks provides a broader context for assessments of specific insect outbreaks, wildfires, locations, and time lags. In so doing, our analysis demonstrates generally negative feedbacks, in comparison with the neutral or relatively transient positive effects quantified with field observations in wildfires occurring up to 15 years following MPB outbreaks in Northern Rocky Mountain forests (Harvey *et al* 2014a, 2014b). In addition, our results differ from the positive MPB-fire feedbacks identified via SAR for the 2006 Tripod Fire Complex in northern Washington (Prichard and Kennedy 2014). Finally, analyses of fire effects following WSB defoliation have been especially rare. The post-budworm temporal trend suggests a neutral effect ca. 18–23 years post-outbreak (figure 3(b)), consistent with the lack of association between budworm damage and the severity of the 2003 B&B Fire Complex in central Oregon (18 years post-outbreak (Crickmore 2011)).

Our core finding that insect outbreaks actually dampen wildfire severity across numerous large insect–fire events has direct applications to natural resources management. Specifically, policies based on the assumption that recent insect outbreaks increase the hazard of subsequent wildfires might be unjustified (Hart *et al* 2015). Furthermore, given that insects also can reduce wildfire likelihood (Lynch and Moorcroft 2008, Meigs *et al* 2015a), these findings illustrate the role that a biotic disturbance (i.e., insect outbreak) can play in limiting both the occurrence and impacts of an abiotic disturbance (i.e., wildfire). Because bark beetle and defoliator effects on burn severity appear to diverge over time, however, forest management strategies should recognize the differential and dynamic effects of each insect on fuel conditions and associated fire potential.

Although our regional census reveals negative insect effects on burn severity across a range of conditions that has not been assessed to date, numerous uncertainties and research questions remain, particularly regarding the mechanistic linkages among insects, fuels, and other known drivers of fire behavior and effects. Specifically, our inference is limited to the locations and years captured by the available spatial datasets, and future studies could investigate insect–fire severity relationships over broader spatiotemporal scales. Future studies also could combine our spatially extensive methods with the temporally rich insights provided by tree ring analysis (e.g., Flower *et al* 2014). Such a fusion approach would enable forest researchers and managers to determine whether recent insect and fire patterns represent a departure from historic disturbance regimes. In addition, because our census uses remotely sensed relative spectral change (RdNBR) as a proxy for fire effects, we cannot directly address causal relationships, fine-scale ecological impacts and responses (e.g., soil heating, tree regeneration), fire behavior (e.g., fire intensity, crowning), or operational fire management (e.g., firefighter safety, suppression tactics) (Thompson *et al* 2007, Harvey *et al* 2014b, Jenkins *et al* 2014, Hart *et al* 2015). Moreover, although the SAR spatial error term indirectly captures the effects of missing variables (Haining 1993, Wimberly *et al* 2009), future studies could explicitly address the effects of other key drivers like fire weather on a subset of events where fine-scale, consistent, and accurate weather and fire progression data are available (e.g., Harvey *et al* 2014b, Prichard and Kennedy 2014). Similarly, topography and climate are known drivers of burn severity in the western US (Dillon *et al* 2011), and future research could further investigate the generally positive association between elevation and burn severity in our SAR modeling (figure 2) and lack of association between drought and insect–fire effects across this census, which spans a range of drought conditions (figure S4). Finally, our analysis is limited to the relatively rare events where wildfires occur within the initial decades following insect outbreaks, and future studies should continue to evaluate the pervasive ecological and economic impacts of these and other disturbance agents separately (e.g., Westerling *et al* 2006, Kurz *et al* 2008, Hicke *et al* 2013).

5. Conclusion

Contrary to common assumptions of positive feedbacks, recent forest insect outbreaks actually dampen subsequent burn severity at multiple time lags across the US Pacific Northwest. Indeed, by altering forest structure and composition from forest stand to regional scales (Raffa *et al* 2008, Flower *et al* 2014, Meigs *et al* 2015b), these native insects contribute to landscape-scale heterogeneity, potentially enhancing forest resistance and resilience to wildfire. Because insect outbreaks do not necessarily increase the severity of subsequent wildfires, we suggest a precautionary approach when designing and implementing forest management policies aimed at reducing wildfire hazard in insect-altered forests.

In addition, by dampening subsequent burn severity, insect outbreaks could buffer rather than exacerbate some fire regime changes expected due to global change (e.g., climate warming, drought, invasive species (Littell *et al* 2010, Ayres *et al* 2014)) and forest response to land use (e.g., fire exclusion, timber harvest, livestock grazing (Hessburg *et al* 2000)). However, each of the disturbances assessed here (bark beetle, defoliator, wildfire) influences more forest area separately than in combination (Meigs *et al* 2015a), and it will remain a high priority to monitor and adaptively manage their individual impacts on forest health and ecosystem services. Given projected increases in the activity of both wildfires and insects (Raffa *et al* 2008, Bentz *et al* 2010, Littell *et al* 2010), the potential for disturbance interactions will continue to increase, as will the potential for ecological surprises like the negative feedbacks apparent in this census.

Acknowledgments

Learning to coexist with wildfire

Max A. Moritz[1], Enric Batllori[1†], Ross A. Bradstock[2], A. Malcolm Gill[3], John Handmer[4], Paul F. Hessburg[5], Justin Leonard[6], Sarah McCaffrey[5], Dennis C. Odion[7], Tania Schoennagel[8] & Alexandra D. Syphard[9]

The impacts of escalating wildfire in many regions — the lives and homes lost, the expense of suppression and the damage to ecosystem services — necessitate a more sustainable coexistence with wildfire. Climate change and continued development on fire-prone landscapes will only compound current problems. Emerging strategies for managing ecosystems and mitigating risks to human communities provide some hope, although greater recognition of their inherent variation and links is crucial. Without a more integrated framework, fire will never operate as a natural ecosystem process, and the impact on society will continue to grow. A more coordinated approach to risk management and land-use planning in these coupled systems is needed.

Fire is unique among the natural hazards that affect human communities and the ecosystems on which we depend[1]. Although humans sometimes intentionally ignite and manage fires, our main focus is on fighting them. For other natural hazards, such as earthquakes, hurricanes and floods, there is much more emphasis on identifying vulnerabilities and adaptations. The 'command and control' approach[2] typically used in fire management neglects the fundamental role that fire regimes have in sustaining biodiversity and key ecosystem services[3–6]. Unless people view and plan for fire as an inevitable and natural process, it will continue to have serious consequences for both social and ecological systems.

Over the past two decades, wildfires around the world have increasingly affected human values (for example, lives, views or sacred environments) and assets (for example, damage to homes or public infrastructure) and ecosystem services (for example, air quality and long-term carbon storage). The growing list of negative outcomes and their financial effects have complex causes and consequences[7]. The natural range of fire sizes and resultant frequencies, timings and intensities — the 'fire regime' — varies greatly among ecosystems, as do the ways in which human activities have altered them (for example, through timber harvesting, fire suppression, urban or agricultural encroachment, novel ignition patterns and invasive species). Not surprisingly, policy strategies to address wildfires often emphasize fuel reduction[8,9]. However, even where strategies recognize interacting cultural, environmental and economic dimensions of wildfire[10–12], few tackle the difficult land-use issue of where and how humans choose to build their communities in the first place. The prospect of widely increasing fire activity with climate change[13] intensifies the need for a new path forward.

Viewing fire-related problems in the context of coupled socioecological systems (SESs)[14], which explicitly recognize links between humans and their natural environments, provides insights into achieving a more sustainable coexistence with wildfire. We have learned a great deal about fire as an essential ecosystem process and the human dimensions of living on fire-prone landscapes. Synthesis of this knowledge through a coupled systems approach can highlight specific vulnerabilities and trade-offs, and facilitate adaptation strategies across widely varying public and private landscapes (Fig. 1). In this Review, we summarize research on fire-prone ecosystems and fire effects on human communities through the lens of SESs, identify links in these coupled systems, and discuss recommendations for greater resilience. We emphasize insights from three regions (Fig. 2) where major fire-related losses have occurred in recent decades: the Mediterranean basin, the western United States and Australia.

Socioecological systems and fire

Sustainable solutions to most environmental problems will be impossible if the links and interdependencies between humans and ecosystems are ignored[14]. In the context of wildfire, the most well-developed SES research that incorporates this coupling concerns climate-change effects on Alaskan boreal forest ecosystems and rural indigenous communities[15,16]. Case studies in rural communities of New Zealand[17] and California[18] also exist. Remarkably, a coupled wildfire SES framework has yet to be adopted for the more densely developed wildland–urban interface (WUI; area in which communities intermix with or abut natural vegetation), where most of the human fatalities, home losses and fire-suppression expenditures occur.

The complexity of how wildfire operates in different ecosystems and how humans interact with it indicates that place-based hazards and risks should be addressed as a coupled SES[16,19]. Reframing the problem to minimize harmful effects as the climate changes and humans increasingly inhabit fire-prone landscapes identifies an integrated set of coupled SES linkages (Fig. 1). Importantly, this allows us to recognize how the geographic context of the coupling itself contributes to impacts and losses of assets throughout the wildfire SES. Local characteristics of the WUI, and the components on either side of it, will largely determine the degree to which fire may be accommodated and how communities will be affected. The spatial scale of the coupling may also be broad in some cases, such as when fires compromise recreation values (for example, trail access, camping facilities or fishing habitat) and water supplies of distant urbanized areas, or when concerns over human exposure to drifting smoke influence management decisions about fires that are burning relatively far away. Although this framing does not intrinsically address connections between fire and global-scale climate change mitigation[13,15,20], it helps to

reveal geographically relevant solutions for decreasing harmful effects and increasing the positive benefits of fire on the landscape. The institutional complexity that underlies many aspects of this coupled SES framework — agency mandates, property rights, building ordinances, indigenous governance, economic subsidies and political pressures — will also feed into a particular set of solutions, often creating challenging constraints.

Sustainable coexistence with wildfire is both a process and a long-term goal, such that policy, planning and management are adapted and refined through time (Fig. 1). Responsibility must be shared between governments and the people at risk, and the approach integrates building, planning, fuel management, suppression capability, and knowledge of fire and ecosystem dynamics at different scales. Coexistence with wildfire should ultimately allow ecologically appropriate fire regimes to operate on landscapes near and far from the WUI, with relatively low risks to people, property and resources, while also allowing us to enjoy ecosystem services enhanced by fire (for example, habitat maintenance, potential hazard reduction, natural hydrologic functioning, and carbon and nutrient cycling). This outcome should also reduce the costs of fire suppression and the need to put firefighters at risk.

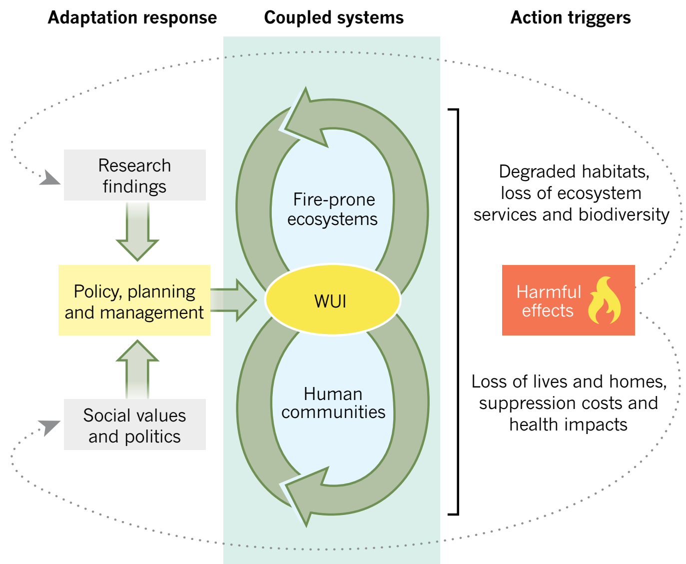

Figure 1 | Links and pathways to resilience in coupled socioecological systems affected by fire. Coexistence with wildfire is strongly influenced by the type of natural fire regimes that operate on a given landscape, and the degree to which communities can reduce exposure and vulnerabilities there. The wildland–urban interface (WUI) is the spatial manifestation of the coupling, and the most proximate scale of exposure and risk mitigation. To learn from and minimize the harmful effects of fire in both the ecosystem and the community, links between systems and scales of interactions must be recognized. Doing so will trigger, through research and in response to changing social values and political context, further adaptation and change in policy, planning and management.

Fire and ecosystems

The role of fire in different ecosystems varies by the degree of current landscape modification, relative to natural or historical patterns and processes. Some regions have large expanses of semi-wilderness where maintenance or restoration of certain fire regimes is crucial to ongoing habitat characteristics or ecosystem services (for example, the western United States and Australia). Here the links between fire characteristics and ensuing ecological effects, or fire 'severity', are often emphasized. Other regions have been so completely altered for various human needs that what is 'natural' is no longer a clear consideration (for example, the Mediterranean basin). Furthermore, climatic controls on fire regimes (for example, frequency of droughts or high-wind events, or length of fire season) tend to dominate in some ecosystems, whereas local controls (for example, topography, fuel loads and ignitions) strongly influence others. Fire resilience is thus context-dependent, varying with the biophysical environment and desired future conditions. Accordingly, our capacity to avoid ecosystem degradation and catastrophic shifts[21] (Fig. 1) depends on the ecosystem in question and how climate change will manifest there.

Mediterranean basin

Mediterranean landscapes are mosaics of various shrublands and oak- and pine-dominated woodlands intermixed with extensive pastures, cultivated lands and abandoned agricultural fields[22]. Despite fire's ecological influence there[4], no reference conditions exist for fire management or restoration, and traditional use of fire for rangeland and game management has strongly influenced historical landscape dynamics[23]. Pronounced biophysical and land-use gradients have recently resulted in contrasting fire and vegetation dynamics. The southern and eastern regions are subject to land over-exploitation and reduction in vegetation cover that increases the risk of desertification and loss of ecosystem services. By contrast, socioeconomic drivers are increasing fire hazards and losses over Mediterranean Europe (northern region) owing to rural depopulation, increased WUI exposure and land-cover changes that are sometimes promoted through afforestation policies[24]. Most shrublands and woodlands in the northern region are becoming dense enough to support climate-driven high-intensity 'crown' fires[22,25].

Wildfire in European Union countries is addressed in national and regional forest policy plans, but consensus on fire and ecosystem management is lacking. In spite of large expenditures, increased preparedness and greater firefighting abilities, extreme fire-weather conditions have caused devastating fires in several Mediterranean countries[26]. A new framework to regulate and promote traditional fire practices, accommodating diverse territorial contexts and operational use of fire, has thus been advocated[27]. Currently limited to local management, prescribed burning is increasing across Europe as a tool that aims to reduce fuel loads and diminish the risk of high-intensity fires[28]. Modest changes to regional and national wildfire policies have therefore included long-term preventive actions, but fire management is still primarily centred on short-term fuel- and suppression-oriented measures[8]. There are concerns over the ecological consequences of recent fire patterns[29], but human-centred fire exclusion generally prevails on most Mediterranean-basin landscapes.

Western United States

Fire management in many western US ecosystems is informed by research on the historical role of fire[30], especially through dendrochronology[31] and landscape reconstructions[32]. Before modern management, different types of fire occurred among vegetation types and maintained important natural structures and functions, with great variation geographically[5,32–35].

In western US forests, high-severity fires that kill overstory trees are typical of cool, high-elevation, subalpine environments[36,37]. Although severe fires may seem catastrophic from a human perspective, in these forests they stimulate vegetation regeneration, promote landscape diversity in terms of vegetation types, provide habitat for many species and sustain other ecosystem services[5]. The many organisms and propagules that may survive the fire, combined with heterogeneity in age, structure and species composition across landscapes, confer resilience against shifts to non-forest types. High-severity fires predominate across about 30% of western US forests, naturally mixing with low-severity fires through time and space across another ~45%[36]. Key regional controls of high-severity fire regimes are extreme drought and high winds[37], and local (for example, topographic) influences on severity patterns can emerge during less dry conditions[38]. Fuels tend to be naturally abundant in these ecosystems, so modern fire suppression may have decreased historical levels of landscape fragmentation, but it has not increased fuel loads[5,39].

By contrast, many dry and mesic, low-elevation and mid-montane forests historically experienced more frequent low-severity fires that maintained relatively open forest structures of fire-resistant

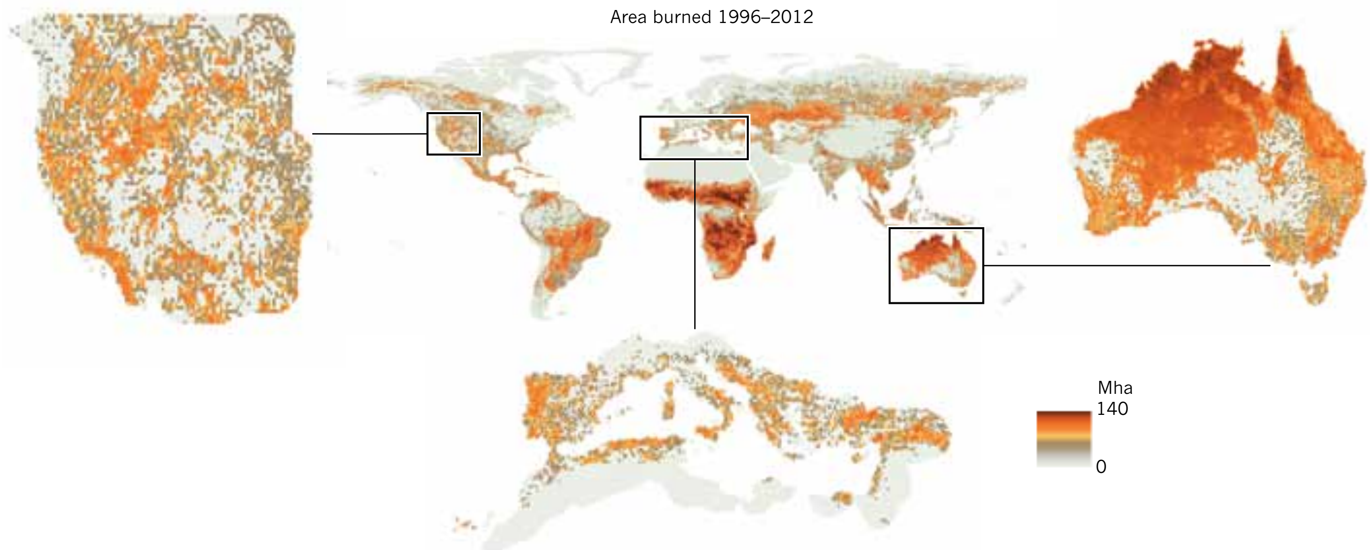

Figure 2 | Area burned patterns and locations of fire-prone regions. The cumulative area burned between 1996 and 2012 in millions of hectares (Mha) per mapped cell. The western US region consists of the 11 western states in the conterminous United States (left), the Mediterranean basin (middle) contains the Mediterranean-climate biomes and the Australian region (right) encompasses the entire continent (see Supplementary Information).

trees[33,34,40], across about 25% of western US forests[36]. Ignition patterns, vegetation structure and fuel amount exert a strong control on regimes of frequent low-severity fire, making them more sensitive to modern human perturbations and also more amenable to fuel-management techniques[33,39–41]. Unlike high-severity fire regimes, timber harvesting and decades of fire suppression in drier forests have lengthened intervals, increased densities of smaller trees and shifted regimes of mostly low-severity fires to include more high-severity, stand-replacing fires. The extent to which this has happened is a topic of debate, raising questions about how widespread 'mixed severity' fire regimes were prehistorically[32,35,42]. Regardless, reducing accumulated fuels in these forests is often a high management priority. Only where such departures from natural fire regimes have led to denser, multilayered, fire-intolerant forests, however, may fuel-reduction treatments restore more characteristic forest structure and function (Box 1).

There is a general consensus regarding the importance of fire, including the need for prescribed burning, to maintain native grasslands and open woodlands. Woody plant encroachment in many ecosystems with sparse tree cover, driven by a lack of fire and replacement of native herbivores, has reduced plant biodiversity, altered vegetation structure and threatened the fauna that depend on those habitats[43,44]. Fire also plays a crucial part in regeneration for some of the vast shrublands of the western United States, especially California's densely urbanized chaparral ecosystems. Similar to high-elevation forests, fire in chaparral is stand-replacing and under strong climatic control (patterns of drought and extreme fire weather)[45], meaning that fuel-reduction efforts have limited effect except in strategic locations[46,47]. Increased fire frequencies, due to abundant human ignitions and non-native grasses that support rapid reburning, threaten to convert many native shrublands to degraded habitats[48]. Invasive grasses also cause very frequent and often large fires across parts of the Great Basin in the western United States[34,49], driven by the 'grass-fire cycle' positive feedback[50] and bringing serious management challenges even to fire-sensitive desert ecosystems[51].

Australia

Fire is ubiquitous in Australian ecosystems, including deserts and tropical forests, and a wide range of fire regimes have been mapped using remote sensing[52]. Annual pulses of relatively intense fire dominate the extensive savannahs of northern Australia, with less frequent, massive fires in the arid zone occurring after above-average rainfall[53]. By contrast, large fires in the temperate forests of the south, although intense, are less extensive and also less regular (decadal occurrence). Biophysical models of fire-regime controls[54] and analysis of trade-offs in fuel characteristics and fire types[52] confirm the primary role of climate, especially the gradient in summer monsoonal precipitation. Thus, fire frequencies tend to vary with latitude, decreasing towards the south and especially the arid interior. Most fire activity on the Australian continent is in grass fuels and of relatively low intensity.

Although palaeo-charcoal deposits document fire's very long history in Australia[55], fine-scale understanding of fire-regime variability through dendrochronology is generally lacking, hindering detailed perspectives on long-term variations in fire regimes. Comprehensive fire management initiatives focus on key environmental objectives, such as biodiversity conservation[20] and emissions reduction[56], as a function of local context. Maintenance of contemporary fire regimes for biodiversity conservation is a priority in most regions, as opposed to the emphasis on restoration that dominates western US approaches.

Australia's productive eucalyptus forests, which can burn at very high intensities and low–moderate frequencies, are largely restricted to southern and eastern edges of the continent. Although these forests are characteristically Australian, their proximity to urbanized areas has probably fed the continent's reputation for high-intensity fire events (see 'Where do people live?'). Debates over the degree to which fuel reduction, whether by mechanical or prescribed fire treatment, can alter the probabilities of high-intensity events[57,58] are similar to those that occur for western US forests.

Prescribed burning in Australia is extensive, but controversial. Fuel reduction burning can partially reduce risk to human life and economic assets, although trade-offs with risks to environmental assets such as biodiversity and ecosystem services are not well understood[3,59]. However, functional responses of species to fire frequencies, sizes, timings and intensities provide a measurable basis for predicting how ecological diversity will respond to management and climate change[60,61].

Resilience and climate change

Ecosystem managers in the three regions covered here (Fig. 2) may have limited ability to alter the numbers, sizes and characteristics of fires occurring in different ecosystems[5,34,39,59]. As already discussed, this is because coarse-scale climatic influences tend to control fire regimes in many ecosystems, especially those that are naturally prone to large and high-severity fires. Except under the most extreme conditions, fire regimes typically constrained by more local-scale controls, such as ignition frequencies and biomass accumulation rates, may respond more strongly to prescribed fire and mechanical fuel reductions. This characterization of two opposing types of fire regimes is, however, a vast over-simplification — idealized end points along a spectrum of variation within and between fire-prone ecosystems[62] — and management prescriptions need to somehow accommodate such complexity. Furthermore, fire-related sensitivities and responses vary among plant and animal species, so fire management for the persistence of one important group of organisms may not favour that of the others.

The potential for climate change to cause 'novel' or 'no analogue' environmental conditions in some ecosystems presents new challenges for management, policy and planning. An obvious goal is to have ongoing fire regimes that minimize the risk of biodiversity loss[59]. Yet, what adaptation responses are appropriate (Fig. 1) if we do not know how future climates and related biophysical processes will differ from the recent past? These uncertainties have resulted in somewhat similar recommendations about fire and ecosystem resilience[63–65]. Heterogeneity in vegetation types, stand structures and successional age classes at all spatial scales and environmental settings is emerging as a strategy for enhancing ecosystem resilience to climate change. This essentially facilitates diverse initial conditions for multiple future ecological trajectories, the most likely and successful of which will not be known for decades. The role of diverse topography in creating microclimate refugia, or 'holdouts'[66], as well as in influencing fire sizes and severity characteristics within large fires[38,67], comprises the physical template for resilience in more mountainous regions. In ecosystems with a recent paucity of burning, fire management that fosters burning under diverse conditions may be useful for achieving this desired heterogeneity and reducing fuel accumulations[41]. Not all fire-generated heterogeneity is ecologically significant, however, so understanding the effects of specific types of 'pyrodiversity' is important[68].

Where do people live?

The WUI is the most proximate spatial manifestation of the coupling in a wildfire SES (Fig. 1). Understanding and addressing vulnerabilities related to the WUI in fire-prone areas is therefore crucial to long-term solutions. As distances between urbanized areas and those protected from development decrease globally[69], a growing WUI will expand the scope of coupling in wildfire SESs worldwide. Negative fire effects that were once due to 'distant' fires (for example, the impacts of smoke on human health) will be increasingly common, making coexistence with wildfire much more challenging.

The current WUI of the western United States is relatively well characterized, with over 60% expansion since 1970 (ref. 70) and about 70% in private ownership[71]. The WUI in this region also predominantly occurs where fire severities are high[70]. Only 14% of private land in the western US WUI is developed, so substantial increases in human exposure to fire may occur as the remaining portions become populated[72]. Although less well characterized, there is growing awareness of expanding WUI in Mediterranean Europe[24,73,74] and Australia[19,75].

Global systematic analyses of human settlement in fire-prone environments is important, but lacking[76]. Coarse-scale characterization of how population densities relate to various fire-prone environments (Fig. 3) provides some insight. Although often characterized as a 'forest fire' problem, western US patterns indicate that highly fire-prone locations with large numbers of people tend to be associated with sparse or no tree cover (for example, the chaparral shrublands of southern California); locations with both high population densities and denser forests exhibit the least area burned (Fig. 3, left). Australia exhibits greater area burned over a broader range of environments, with intermediate population densities being more fire-prone regardless of the amount of forest cover (Fig. 3, middle). The Mediterranean basin is unique because the greatest area burned coincides with the highest population densities (Fig. 3, right), although this too occurs in locations with relatively low forest cover (for example, abandoned agricultural lands[26]).

Acknowledging the diversity of the fire-prone environments and vegetation types where people live is important, because it has implications for the types of fuel treatments that may or may not work to mitigate fire hazards within or near the WUI, and it could help to guide future resource allocation decisions (for example, among vegetation removal, evacuation planning and home vulnerability retrofits)[77]. Awareness of the institutional and social diversity of different human communities is also important, as we discuss in the next section, because it influences their capacity for preparation and mitigation of hazards such as wildfires[18].

Fire and human communities

This section reviews research on how fires affect human communities and is organized by the scale of coupling in a wildfire SES (Fig. 1), ranging from individuals to landscapes. Social science research on wildfire, primarily undertaken in Australia and the United States,

BOX 1

What can 'thinning' of fuels achieve?

There is intense pressure on land-management agencies to reduce fire hazards (for example, rates of spread or flame lengths if a fire occurs). Treatments should be prioritized, however, where they may help to protect communities or reduce fuel loads in the areas that are most likely to experience uncharacteristically severe burns[36,71]. Mechanical fuel-reduction treatments are most suited to certain dry and fire-prone mesic forests[34,39–41,77], where thinning the density of smaller understory trees and removing surface fuel residues (non-merchantable tree tops and limbs) created by these treatments can reduce fire intensities and rates of spread[40]. Not treating the additional surface-fuel by-products can actually increase fire intensity and severity when a wildfire does occur[41].

Some of the most basic trade-offs that limit the widespread use of mechanical fuel reductions involve their economic viability. Often, larger commercial trees will be harvested to help offset operational costs, but this typically generates more surface-fuel residues. Moreover, opening up the overstory canopy and increasing sunlight penetration can increase growth of highly flammable understory vegetation. Controlling this growth response is an ongoing endeavour, the economic feasibility of which is unknown.

Uncertainty about when and where treatments might actually perform as desired must also be considered. Although there are many examples of fuel treatments reducing fire behaviour when conditions are not extreme, recently treated forests can experience a stand-replacing crown fire when wind speeds exceed 30 km h^{-1} and when fuel moisture is low[102]. When the probability of fire occurring in a particular area is relatively low, the odds of a fuel treatment influencing the behaviour of a wildfire there, within the time frame that treatments are effective, is also low[103]. The degree of protection provided by a particular mechanical treatment may thus depend on uncertain parameters (for example, ignition patterns and extreme wind frequencies).

In many areas, ecological restoration and fuel-management goals may be best balanced and accomplished through fire[4,41], which creates natural heterogeneity and provides for fire-dependent species.

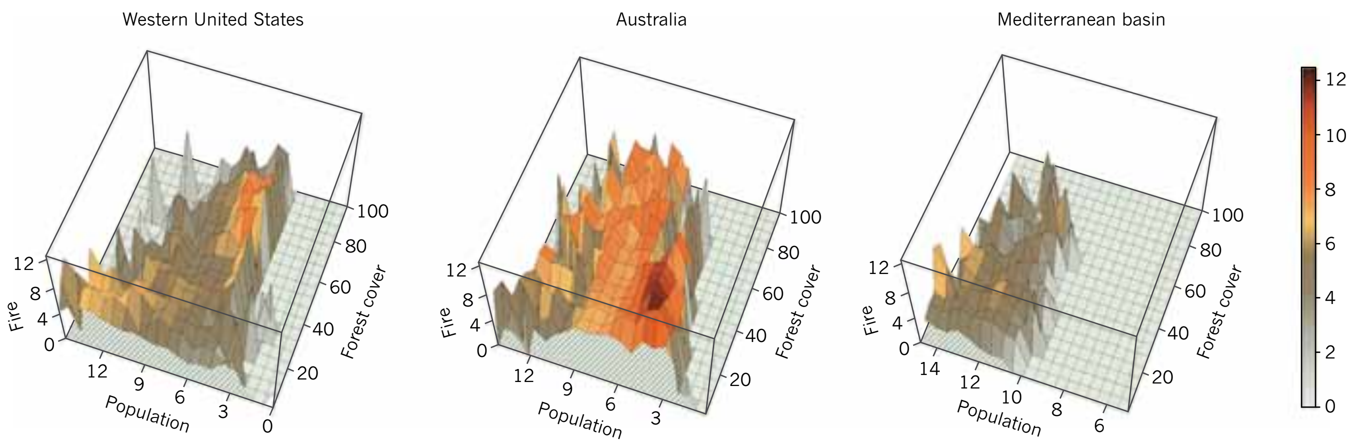

Figure 3 | Relationship between forest cover, population density and area burned in fire-prone regions. Locations with both higher human populations and greater amounts of burning tend not to be consistently characterized by high forest cover. Patterns vary greatly among regions, reflecting the different contexts in which each side of the wildfire socioecological system have intersected. (Data were aggregated from original sources (see Supplementary Information) to 0.25° resolution cells and plotted as density surfaces.) Forest cover is the percentage area covered by trees (>5 m height) per cell in 2000; population is number of people per cell (log transformed) in 2000; and fire is total area burned in hectares per cell (log transformed) between 1996 and 2012. The colour scale for fire is to help differentiate higher peaks in area burned.

is relatively sparse and not easily generalized. Work in the United States emphasizes social acceptance of techniques to mitigate fire risk (for example, fuel reduction on public and private lands) and, more recently, public response during and after fires[78]. In Australia, where many people do not evacuate during fires, risk perception, homeowner preparedness and response during fires, and community safety[79] are key areas of research. We also include studies outside the social sciences that have examined the role of vegetation and fuel treatments linked with losses and the built environment itself.

Risk perception and public response

Public response to wildfire is shaped by numerous factors, such as local context and individual personality and experience, so simple explanations for action or inaction do not exist. For instance, many researchers and managers assume that individuals do not understand fire risk. But US studies show that most people living in high-fire-risk areas understand their exposure, but there is a tenuous link between understanding risk and taking action to mitigate it; whereas recognizing risk might be necessary to consider mitigation, perceived efficacy of mitigation and resource constraints can be more influential[80]. Similarly, whereas around 80% of people in the fire risk areas of Victoria, Australia, know they are in a hazardous area[81], this does not necessarily translate to safer actions. After the devastating 2009 Black Saturday fires in Victoria, most people in high-fire-risk areas were aware of what new fire warnings meant and how to ensure their safety, but few acted on the knowledge when the highest-level warning was issued[81]. A deeper understanding of the influences on preparedness, evacuation decisions and support for hazard mitigation is needed.

Specific cultural and institutional systems affect public response to wildfire, as do psychological and social dynamics. For example, institutional structures in the United States and Australia are quite different, but key social dynamics have many similarities. In both countries, trust is a key factor shaping public support for agencies, whether they provide information or engage in fire-management activities[82]. US studies of public acceptance of prescribed fire reveal that trust in the personnel implementing the burn, along with familiarity with the practice, are associated with higher acceptance levels[83]. In terms of the US public response during fires, evacuating has long been the norm, often with mandatory evacuation orders; until Black Saturday, Australians were urged to either prepare to stay and protect their properties, or to leave early, on the basis that either option was safer than leaving late[79]. Despite this difference, the range of public behaviours in both countries is similar, with some residents leaving early, some staying to defend and a substantial number waiting to see how the situation develops. Furthermore, individual actions do not necessarily reflect a consistent response, as some household members may leave and some stay, while others go back and forth to check on property, animals or those who stay[84]. Although historically 'stay or go' seems to have worked reasonably well in Australia[79], the approach was questioned after the Black Saturday fires, as it was widely seen to have contributed to many of the 173 deaths. However, roughly half the people (around 3,000 households) in the burnt areas seemed to have stayed and defended their properties successfully and about half left, almost as the fire front was approaching. Most were satisfied with their decision and said they would do the same thing again[84]. Most also stated that they would like to be better prepared. The post-fire effort naturally concentrated on fatalities, with official advice after Black Saturday inquiries shifting to leaving early.

When the public response is to evacuate, key elements to success include environmental conditions (especially fire-weather severity), patterns of roads, neighbourhoods and topography. In Australia, public warnings have been based on a fire-weather danger scale, which was revised after Black Saturday to capture the most extreme conditions, along with altered warning messages and advice for these extremes. There is some public understanding of the reclassification, but little evidence of altered behaviour[81] or understanding that weather conditions well below the extreme level are still dangerous. Analogous fire-weather warnings are issued regularly in other parts of the world, but are not standardized and rarely trigger evacuation orders. Similar to many regions, fatalities during evacuations in the Mediterranean basin tend to occur during the most severe weather conditions, when fires have already begun and people choose to evacuate too late[85]; in addition, such extreme events seem to be on the rise[26]. A growing public safety challenge associated with evacuating people from fire-prone communities in mountainous terrain is limited road access. For example, housing densities are increasing in many WUI regions of the western United States without commensurate increases in the road network to support their evacuation[86]. Emergency planning, including preparation of structures and training for those who choose to stay or simply cannot evacuate safely[87], is thus increasingly important to the resilience of many communities in the regions reviewed here.

Structures and surrounding vegetation

To mitigate the risk of structure losses during wildfires, there is increasing evidence from many regions that it is best to focus on the house first and move outward from there[77]. Most structure losses are due to ember attack[88,89], when flaming or smoldering plant material is lofted by winds and blown inside or against the building or adjacent elements, often long before the flaming front arrives. Embers can cause structure ignition by entering through gaps as small as

2 mm[90] or accumulating outside against flammable building (or surrounding) features. Once ember ignition is addressed through structural design or retrofitting, less prevalent modes of structure loss are important, such as radiant heat and flame exposure. To address these, both building design and surrounding vegetation management are normally considered in unison[19], with the balance of these treatments being site specific. Similar to evacuation success, an understanding of the local fire-weather conditions and expected types of fires is required[91]. Hence, the building design strategy is to either consider all possible extremes and the weakest link in the system[88] or to pick a threshold level beyond which the structure may not survive. By relating these to a corresponding fire-weather severity, the occupant has the information for deciding when it is necessary to leave early. As a contingency, egress paths from the building interior to another building or area of minimal fuel could improve safety, but preparation for such a fallback is needed long before a wildfire arrives.

Vegetation reduction is most effective immediately adjacent to structures[88,92–94], as it can eliminate the most immediate sources of combustible material. Vegetation overhanging the structure[91] and ornamental plants[95] have been strongly associated with structure loss. Vegetation clearances more than about 30 m away, however, seem to provide no significant additional benefit in shrubland environments of southern California, even on steep slopes[94], reflecting an important trade-off between hazard reduction and habitat values (for organisms dependent on the vegetation removed). Although these findings may only apply to similar shrubland environments, a similar distance to heavily vegetated areas has also been identified for some forested environments, based on radiant heat exposure to structures[77,96]. In Australia, however, a distance from forest edges of more than 30 m was found to influence home losses[93], indicating that this buffer distance may vary substantially (for example, with fuels, weather and construction types). Another key reason to reduce vegetation near the home is to provide a relatively safe place to engage in structure protection, in case home owners or firefighters are present. It is notable, however, that some species of well-maintained trees (litter removed and high foliar moisture) near the home can actually provide protection, screening embers[19] and acting as a heat sink[96] for an approaching wildfire.

Landscape-scale patterns

Although fuel treatments seem to provide the greatest protection when located near human communities[19,88,93,94,97], landscape-scale characteristics of the WUI itself are important. For this reason, a long-term

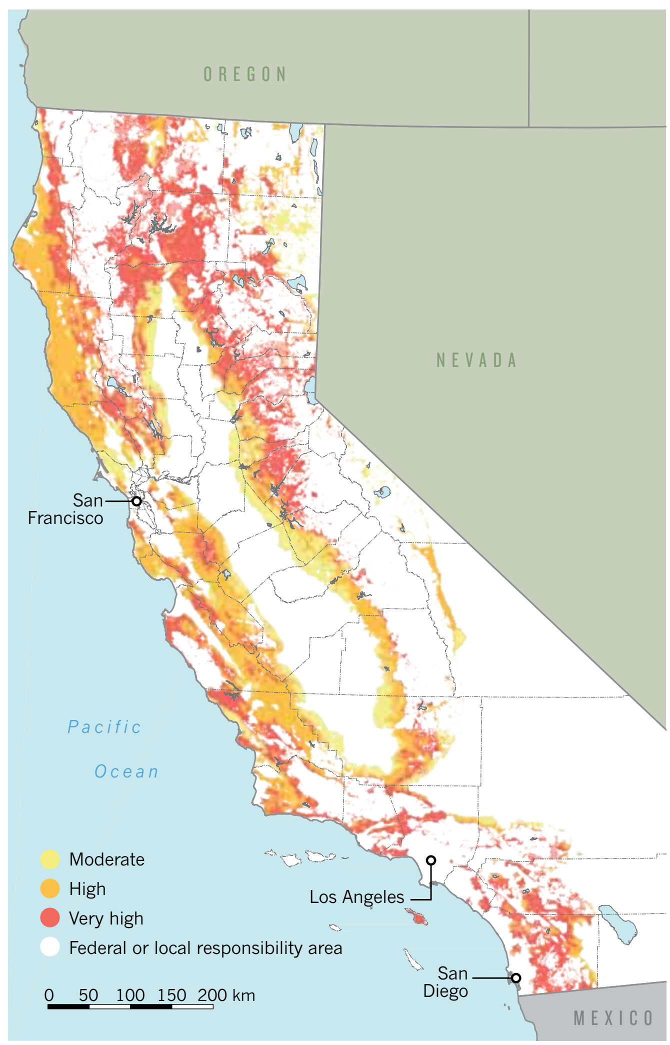
BOX 2

Adaptation measures and fire-hazard mapping

Regardless of the surrounding ecosystem conditions, all communities can better coexist with fire by taking several steps: retrofitting homes against ember attack, effectively managing fuels around homes, developing household and community plans for evacuation compared with stay-and-defend decisions, and participating in risk awareness continuing education. For existing high-hazard wildland–urban interface (WUI) areas, landowners may need to take primary responsibility for pursuing the optimal combination of adaptation measures, based on their local vulnerabilities and wildfire exposure. For development of new communities in high-hazard WUI areas, governments need to take a leadership role in planning. Regardless of responsibility, however, all of these efforts will be guided by better mapping of the fire hazard itself.

The fire hazard severity zone (FHSZ) maps (Box Fig.) of California are an official product of the state Department of Forestry and Fire Protection based on a consistent statewide methodology for estimating potential fire behaviour under a set of relatively dry and high wind conditions. Variables that affect modelled fire behaviour include local topography and potential fuel loads, although weather conditions in the current iteration of maps are not tailored to local extremes. Future updates to the FHSZ methodology will incorporate locally varying wind patterns, better reflecting conditions that cause the worst fire-related losses of lives and homes[45,98].

Fire-resistant residential construction standards are determined by the FHSZ rating of the location in question. In addition, FHSZ classifications must be disclosed at the time of home sales; although this may not deter a sale, it can affect the cost of insuring the home against fire losses. FHSZ maps are thus an incremental but important step towards treating fire like other natural hazards (for example, land-use restrictions associated with flood-plain and earthquake fault maps). Similar mapping methods and codes are produced in Victoria, Australia. Such maps do not explicitly restrict development from occurring — a constraint that should be considered in extremely hazardous locations. Comprehensive approaches should, however, help to better design communities within a complex matrix of both risk and resilience that such maps could reflect spatially. (See Supplementary Information).



approach involving land-use planning offers great potential for reducing wildfire impacts in human communities. A greater understanding is needed concerning building configuration in the WUI and how it relates to risk of losses and fatalities in various environments[73,74]. In some shrubland-dominated landscapes, the arrangement and location of homes have been the most important factors for explaining structure loss: landscape factors such as low housing density, isolated clusters of residential development and long distances to major roads are better predictors of house loss than local factors such as defensible space, fuel or terrain[94,98]. Whether these findings apply to fire-prone landscapes in general or whether there are variations between development patterns and fire regimes needs further research. Although isolated clusters of development and low housing density mean that homes are embedded within, and more exposed to, a matrix of wildland vegetation[19], ignition-prone homes that are closely spaced in neighbourhoods can also facilitate the spread of house-to-house fire, especially during extreme fire weather.

Achieving a sustainable coexistence with wildfire

A coupled SES view of wildfire highlights the variation in each half of the SES, as well as how they come together at the WUI, to create many permutations of hazards and vulnerabilities for both human and natural systems. As such, there will be different thresholds for how harmful effects trigger action before, during and after wildfires, and competing societal pressures will influence the degree to which scientific findings are able to guide adaptive responses (Fig. 1). Despite such complexity, some priorities for future work emerge from the extensive research reviewed here.

Context-specific and place-based approaches will be needed to address many existing and future coupled wildfire SES problems. This is because certain fire regimes are inherently more amenable to management activities than others, and also due to the institutional and social diversity that influences human capacity for mitigating risks to individuals and their communities. It is possible, however, that the permutations mentioned above collapse into characteristic typologies that could inform more systematic analyses. If so, are there mutually resilient combinations that are well matched or somehow compatible? Some fire regimes might dictate the degree to which evacuations should be mandatory or how resources might be allocated (for example, training homeowners to protect homes compared with fuel reduction or structure retrofits). A deeper understanding of the variation, links and scales of causes and effects in coupled wildfire SESs is therefore vital.

Governments have a primary responsibility in the long-term evolution of the WUI and the degree to which it limits or amplifies trans-boundary threats in coupled wildfire SESs, so much greater attention to land-use planning is warranted. Land-use regulations to guide fire-related building codes (Box 2) or restrict development in the most fire-prone locations[2,26,99,100] are clearly important steps that government agencies could take to manage the coupling in a wildfire SES. Agencies have a deeper role, however, in the growth of these trans-boundary threats. For example, the ‘safe development paradox’ applied to flood and hurricane protection demonstrates that making hazardous areas safer for human habitation in the short term actually increases the potential for severe losses over longer time scales[101]. Given that government agencies around the world have focused on reducing fire hazards (for example, through subsidized fire suppression and/or fuel reduction), much less attention has been paid to the ways in which vulnerable WUI development might have been designed from the start. As further development occurs and the WUI expands, so does the need for increased hazard reduction. A perverse consequence of the typical human reaction to fire — to fight it instead of accommodate it — thus contributes to a deepening of coupled wildfire SES problems.

Strategically addressing threats at the WUI maximizes the potential for both effective risk mitigation within developments and management for sustainable fire regimes over the broader sweep of landscapes. Ultimately, trade-offs and sacrifices must be made to balance these competing demands, but concentration of management effort for risk mitigation in the WUI minimizes the area where adverse effects on environmental assets are likely. Better maps of fire hazards, ecosystem services and climate change effects are thus important for assessing these and other related trade-offs. Addressing all social, economic and environmental assets at risk will necessarily focus on separating those that require exclusion of fire from those where fires of some sort are desirable or inevitable. However, it is unlikely that any planning or management regime will completely exclude fires from vulnerable developments on many landscapes (considerable residual risk to people and property will endure). The capacity for communities to cope with the inevitability of fire, as well as its effects at multiple scales, will therefore be essential.

There is a great deal of research to support better policy, planning and management in all aspects of the coupled wildfire SES problem. Viewing fire as a natural and inevitable hazard should be central to most solutions, so we can anticipate its important positive and negative effects on both human and natural systems. Given that combustion is one of the most basic and ongoing natural processes on Earth, we must continue to learn from our experiences to achieve a sustainable coexistence with wildfire. ■

The Holocene record of fire and erosion in the southern Sacramento Mountains and its relation to climate

Grant A. Meyer and *Jedediah D. Frechette,* Department of Earth and Planetary Sciences, University of New Mexico, Albuquerque, New Mexico 87131, gmeyer@unm.edu

Introduction

As highlighted in this issue's Gallery of Geology on page 24, large, severe wildfires have become part of the New Mexico late spring and early summer experience in the last few decades. Such fires have considerable relevance to geomorphologists, as erosion rates in mountainous landscapes are often dramatically increased in the several years after severe fires. Erosion and sediment transport often take place during major debris flows and flash floods (Fig. 1). These events are most commonly triggered by intense thunderstorm rainfall, as in New Mexico's summer monsoon, and very rapid runoff from slopes devoid of vegetation or forest litter. Although water-repellent soils formed by fire effects are often cited as the primary cause of increased runoff, the creation of extensive bare, smooth soil surfaces alone is more than sufficient—for example, consider the erosion that would occur on a plowed, smooth farm field at slope angles of 15–30° or more! The extreme flows that are generated can entrain huge volumes of sediment as they course down slopes and channels. Events of this nature affected a number of small, steep drainages in the Sacramento Mountains southeast of Cloudcroft after the 2002 Peñasco fire. Large quantities of mud- to boulder-sized sediment may be deposited on alluvial fans along the valley margins, and in some cases deep gullies are also cut in the fans. Major damage to roads, buildings, and property resulted in several locations in the Peñasco fire area, as valley-side alluvial fans are common sites for residential and other development.

Along with their importance in understanding geologic hazards and watershed impacts, sediments deposited on alluvial fans by postfire debris flows and floods also provide a means of assessing the timing and spatial distribution of past forest fires, and relations between fire and climate, in particular episodes of severe drought. These sediments are often rich in charcoal fragments from the burned area, which allows radiocarbon dating of fire-related sedimentation events thousands of years into the past, providing an important supplement to the more commonly available tree-ring fire histories. Tree-ring dating has provided a wealth of information on low-severity surface fires that scar trees, but leave them living. Such fires swept through the understory of many southwestern forests every few years to a few decades before European settlement and intensified grazing, logging, and fire suppression in the late 1800s (e.g., Brown et al. 2001). However, tree-ring fire-scar records extend back about 500 yrs at most, and do not provide data on severe fires that kill large stands of trees. Stand-destroying fires can be dated via the ages of living trees that germinated after fire, but this reveals the last such fire only, and again is limited to about the last 500 yrs. Therefore, alluvial sediments can greatly extend fire histories, albeit with greater uncertainty in ages. Climatic change on time scales of a thousand years or more has strongly affected Earth environments over the Holocene Epoch, the ~12,000 yrs since the last episode of continental glaciation. Thus, the sensitivity of fire activity to climate change over such time scales is of great interest. It is also critical to understanding the potential impacts of future droughts on New Mexico's mountain forests, given that predicted warming over the next century has no precedent on the short time scales covered by tree-ring fire chronologies.

FIGURE 1—Deposits of a debris flow from a tributary basin of lower Cox Canyon in the Sacramento Mountains. The tributary basin was severely burned in the 2002 Peñasco fire. Debris-flow deposits partially filled and dammed the main valley arroyo at this location (the arroyo wall is visible across the center of the photo). The surface deposits lack mud because of reworking by later flood flows.

Fire and alluvial history in the Sacramento Mountains

South of Cloudcroft, the Sacramento Mountains are essentially a broad eastward-dipping cuesta, where the range crest and ridges on the eastern slope are capped by resistant limestone and dolomite of the Permian San Andres Formation. Below the San Andres Formation, the highly erodible Permian Yeso Formation forms slopes that have contributed large volumes of fine-grained Holocene alluvium to valleys. Abundant exposures of these alluvial sediments are present in both deep main valley arroyos that predate the Peñasco fire (Fig. 2), and in gullies cut in alluvial fans by recent postfire debris flows and floods (Fig. 1). Deposits of modern postfire events helped us to define criteria for recognition of fire-related sediments in the Holocene alluvium. Conifer forests of the Sacramentos range from spruce and fir near the range crest, through ponderosa pine and mixed conifers at middle elevations, to piñon-juniper stands near the lower forest border.

We focused our investigations along the valleys of the Rio Peñasco and lower Cox Canyon in the eastern Sacramentos (Frechette and Meyer 2009), and in Caballero Canyon west of the range crest (New 2007). Fire-related deposits dating to as much as 8000 yrs ago were discovered, interbedded with deposits with no clear evidence of an origin in a burned area. The most active period of fire-related sedimentation occurred from about 6000 to 4000 yrs ago, as is highlighted in Figure 3. Although it does not stand out markedly as a dominant peak in the fire-related sedimentation curve, this interval saw fans build rapidly with several meters of accumulated sediment including thick, charcoal-rich debris-flow deposits (Fig. 2, inset). This evidence for severe fires is consistent with a generally warmer middle Holocene climate, characterized by widespread and persistent drought conditions in the Southwest and in the interior western United States in general (Buck and Monger 1999; Shuman et al. 2009). However, it may also reflect a higher variability in precipitation and (or)

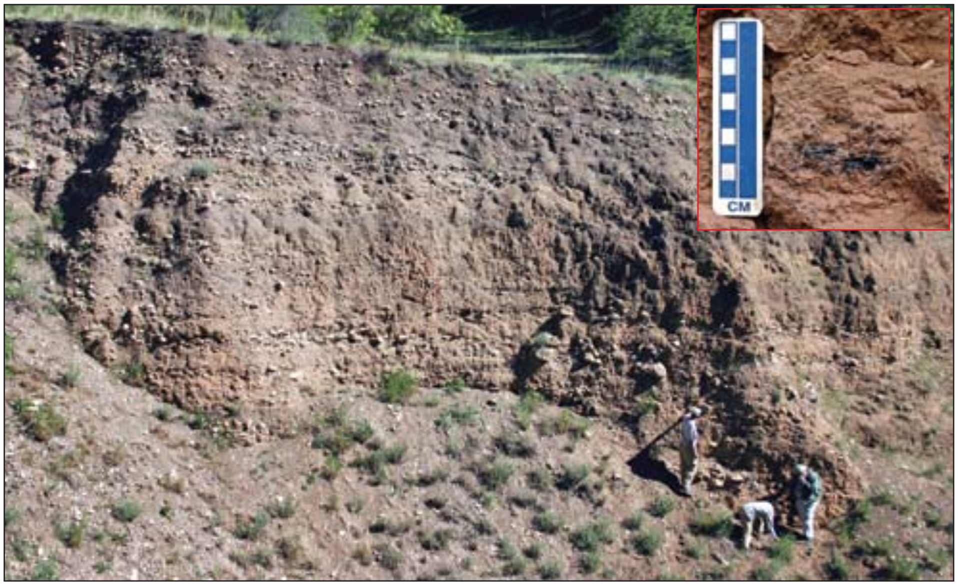

FIGURE 2—More than 10 m (32 ft) of sediment in the toe of an alluvial fan is exposed in this main valley arroyo along the Rio Peñasco. The fan deposits range in age from about 8000 to 650 yrs before present. Darker layers represent organic-enriched soils that developed during times of slow sediment accumulation. The middle part of the section with little soil development starting above the persons' heads dates to about 6000–4000 yrs ago, when rapid fire-related aggradation occurred. Inset shows abundant charcoal fragments in a muddy, poorly sorted fire-related debris-flow deposit from this section.

temperatures at this time (e.g., Asmerom et al. 2007), which would allow forests to grow more dense during wetter intervals that minimize the occurrence of surface fires. Severe crown fires would then be more likely during major droughts.

Evidence for severe fires in charcoal-rich debris flows in the Sacramento Mountains became substantially less common after 4,000 yrs ago, probably because of the climatic cooling associated with declining summer solar radiation in the Northern Hemisphere, and advances of mountain glaciers in the western USA and elsewhere known as the Neoglacial. However, episodic fire-related sedimentation punctuated this time interval, most notably around 650 yrs ago (Fig. 3). This peak in fire-related sedimentation is associated with the "Great Pueblo Drought" of AD 1276–1297, a period of persistent, severely dry conditions that was noted in some of the earliest climate reconstructions using tree rings (Douglass 1929). This megadrought centered on the Four Corners area but affected a much larger region of the Southwest (Cook et al. 2007). It came at the end of a period of generally warmer climate in the western USA from about AD 900–1300 known as the Medieval Climatic Anomaly (Fig. 3). There is also substantial evidence from tree rings, lake levels, and other paleoclimatic records of unusually large fluctuations between wet and dry conditions during this time, which could again promote dense growth of conifer stands followed by extensive severe fires. Prior work in Yellowstone National Park and in central Idaho has also shown the Medieval Climatic Anomaly to be a time of major fire-related debris-flow activity and building of alluvial fans (Meyer et al. 1995; Pierce et al. 2004), illustrating the widespread effects of drought in this interval. The most prominent episode of postfire debris flows in these areas, however, is correlated with the AD 1140–1162 megadrought, considered to be the worst in North America in the last two millennia (Cook et al. 2007). Fire-related deposits dating to the time of the mid-1100s megadrought are found in the Sacramento Mountains (Fig. 3), but are less common than those emplaced after fires in the late AD 1200s. Overall, the occurrence of major droughts, severe fires, and debris flows across the interior western USA is consistent with an inference of generally higher temperatures during the Medieval Climatic Anomaly.

The effects of warmer climate and severe drought notwithstanding, fire-related sedimentation in the Sacramentos over most of the Holocene is characterized by relatively small and sporadic events, consistent with a regime of low-severity surface fires, with the occasional patch of higher-severity crown fires. Likewise, tree-ring fire-scar records in the Sacramentos show that frequent, low-severity surface burns dominated fire activity throughout the range of forest types, from the beginning of the record about AD 1580 to the late 1800s (Brown et al. 2001). This period falls within the generally cooler and effectively moister climate of the Little Ice Age (e.g., Cook et al. 2007) (Fig. 3). A regime of low-severity fires makes sense during the Little Ice Age, as reduced temperatures and evapotranspiration would promote grass growth to fuel surface fires, as well as limit the potential for reducing moisture levels in the forest canopy to the point where extensive, high-severity crown fires could occur. Since the late 1800s, fire suppression and other land uses greatly limited surface fire activity, and the resulting denser forest stands—along with a warming climate, especially in the last several decades—have created conditions that are ripe for extensive stand-destroying crown fires.

An interesting aspect of Sacramento Mountains forests are the large, dense stands of Gambel oak that are especially prominent on the upper western slopes of the range. Professor Thomas Swetnam of the University of Arizona Laboratory of Tree-ring Research has hypothesized that these brushy patches represent areas where severe crown fires destroyed conifer stands and Gambel oak recolonized. Identification of charcoal fragments found in soils under oak brush in Caballero Canyon suggest that some past fires at these sites were indeed in conifer stands (New 2007), but further work is necessary to test this hypothesis.

Another question we considered in our Sacramento Mountains work is whether the deep arroyos found along many valley reaches may, at least in part, stem from land uses such as railroad logging and intensive grazing, especially along the eastern flank of the range. The main valley arroyos predate modern severe wildfires, but the timing of their initiation is largely unknown. At lower elevations in the Southwest and on the Colorado Plateau, most valley-filling alluvial sequences show clear evidence of alternating episodes of arroyo cutting and valley filling, especially in the last 4000 yrs (e.g., Waters and Haynes 2001; Love 1983). We found no clear evidence of past arroyo incision in the exposures examined for fire-related deposits in the eastern Sacramento Mountains. We also found no place where gravelly deposits filled a deep paleochannel in finer-grained valley fill, as occurred in modern times after the Peñasco fire (Fig. 1). Such a relationship should have been obvious despite imperfect exposures along many present arroyos. Some evidence exists for paleo-arroyo cutting in Caballero Canyon on the west slope, however. The lack of clear precedence for modern arroyos in the eastern Sacramentos suggests that 19–20th century land use may have been an important factor. However, we again need to investigate this question further, including dating the initiation of the present episode of arroyo cutting, and conducting a focused search for paleochannels.

Implications of long-term fire-climate relations

As in other studies of Holocene fire-climate relations (e.g., Pierce et al. 2004), our work in the Sacramento Mountains shows that fire behavior is highly sensitive to relatively modest climatic change. With the high probability of increased temperatures and episodes of severe drought over the next century, catastrophic wildfires and their accompanying debris flows and flash floods will become even more likely in New Mexico's mountain forests. Thinning of over-dense stands that have resulted from fire suppression, especially in ponderosa pine forests, can reduce

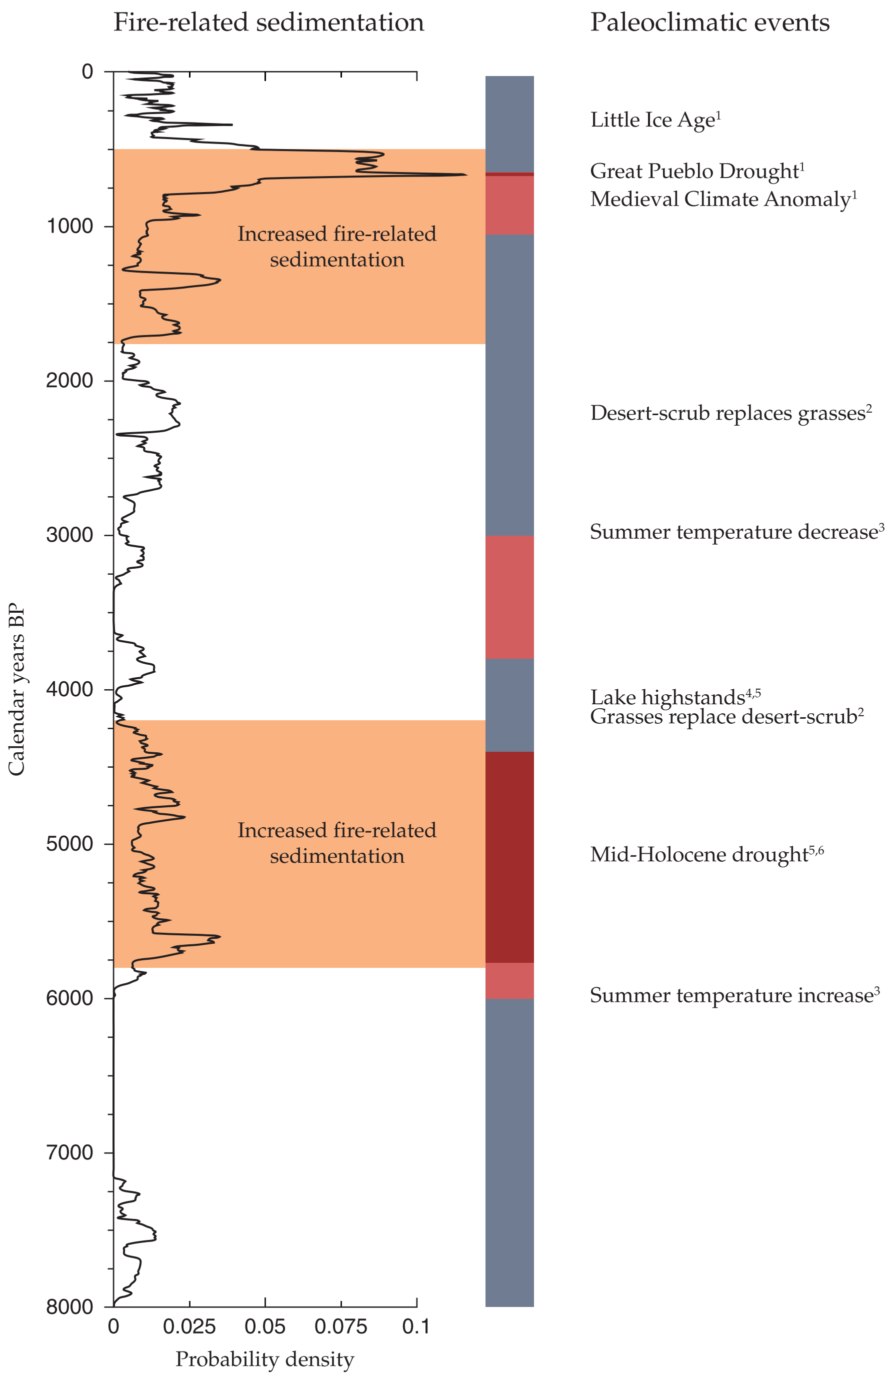

FIGURE 3—Record of fire-related sedimentation in the Sacramento Mountains compared to simplified Holocene paleoclimatic events from the western USA. The curve at left shows the relative probability of fire-related sedimentation, and was constructed by summing probability distributions for calibrated radiocarbon ages on individual fire-related sedimentation events. Periods of increased fire-related sedimentation are inferred based on both radiocarbon age distributions and the nature of stratigraphic evidence for fires. the impact of wildfires, but this is a very large and expensive task that can have impacts of its own, for example, in roadless areas, and there is limited commercial value to the small-diameter trees that must be removed. Public awareness of the hazards that stem directly from development in fire-prone forests, as well as those from postfire debris flows and flash floods on alluvial fans, is key to reducing risks to life and property.

Acknowledgments

We thank Jennifer New, Kristin Frechette, and Erica Bigio for assistance with fieldwork and analyses, and Tim Jull, Todd Lange, and others at the NSF-Arizona AMS Laboratory for help with radiocarbon analyses. We also benefited greatly from discussions of Sacramento Mountains fire ecology and climate with Tom Swetnam and Chris Baisan of the University of Arizona Laboratory of Tree-ring Research, and review comments by Dave Gutzler and Jane Love improved the manuscript. This work was supported by the University of New Mexico, New Mexico Geological Society, Geological Society of America, and Sigma Xi.

Introduction

Extensive outbreaks of tree-killing insects are occurring in many parts of the West, including Colorado. In combination with recent high-intensity forest fires, these insect outbreaks are raising concerns about the health of our forests and our ability to deal with these issues. The visual impact of a high-severity bark beetle outbreak or fire may give the impression that we are in a crisis situation and that we must take dramatic steps to deal with this "emergency". However, recent scientific research on the ecology of forest disturbances, by scientists in Colorado and elsewhere, leads us to interpret these recent events in a much more nuanced manner.

We believe that the responses to insect outbreaks and fires will not produce beneficial results unless those responses are consistent with the basic ecology of the affected forest ecosystems. Hence, we have written this brief synthesis of the current state of knowledge about forest insects and fires in Colorado to help inform effective management options. Our emphasis is on the ecological aspects of the insect outbreaks now affecting thousands of acres in the state. We do not deal extensively with other dimensions of insect outbreaks and fires, although we acknowledge that aesthetics, economics, wildlife management, recreation, watersheds, and fuels are all important considerations in making decisions about forest policy and management.

This report is organized into two sections. The first section addresses nine key questions about the basic ecology of insect outbreaks in Colorado forests; the second section evaluates six possible treatment options. We do not advocate any particular policy or management treatment, but instead describe the likely ecological effects of each potential option. We also provide a very brief synopsis of each answer or treatment option in italics at the beginning of each section. Our hope is that the information summarized here will aid managers and policy-makers in making decisions about how to deal (or not deal) with different kinds of insect outbreaks occurring in different contexts. As will become clear below, not all forests and not all insects are alike. The authors all have training and research experience in forest ecology or hydrology, both in Colorado and elsewhere.

Questions about the Basic Ecology of Forest Insects

Question #1: Which insects are killing trees across large areas in Colorado?

Summary: *The major insects killing trees in Colorado today include bark beetles (mountain pine beetles, spruce beetles, and piñon ips beetles) and defoliators (notably western spruce budworm). All of these insects are native to Colorado and have co-existed with their host tree species for thousands of years (Figure 1).*

Two major groups of insects have been responsible for killing large numbers of trees over extensive areas under outbreak conditions in Colorado: bark beetles and defoliators (Schmid and Mata 1996). Adult bark beetles bore through a tree trunk and lay eggs within the inner bark. The eggs hatch and the beetle larvae eat the inner bark, killing the tree. After the larvae mature, the new adults fly to new trees, bore through the bark, and continue the cycle. There are several species of bark beetles, each of which feeds on one or several species of trees. For example, the mountain pine beetle feeds on ponderosa, lodgepole, and limber pine; the spruce beetle feeds on Engelmann spruce; and the piñon Ips beetle feeds on piñon pine.

Defoliators are a group of insects having a life cycle very different from the bark beetles. The adult defoliators are tiny moths that lay their eggs in the buds of trees. The eggs hatch into caterpillars that feed on the emerging new leaves in spring and early summer. When numerous, the caterpillars may eliminate essentially all of a tree's annual production of leaves or needles. Small trees, or trees that are stressed by other factors, may die after a few years of defoliation, though usually most of the trees in a stand survive the outbreak of defoliators. The most important defoliator in Colorado forests is the western spruce budworm which feeds on Douglas-fir, white fir, subalpine fir, and spruce. Douglas-fir tussock moth is a less frequent but locally significant defoliator of Douglas-fir, white fir, and spruce. Aspen trees may be defoliated by tent caterpillars and large aspen tortrix.

These insects are usually present in a forest in very low numbers, killing only the occasional weak tree. Such low numbers are referred to as

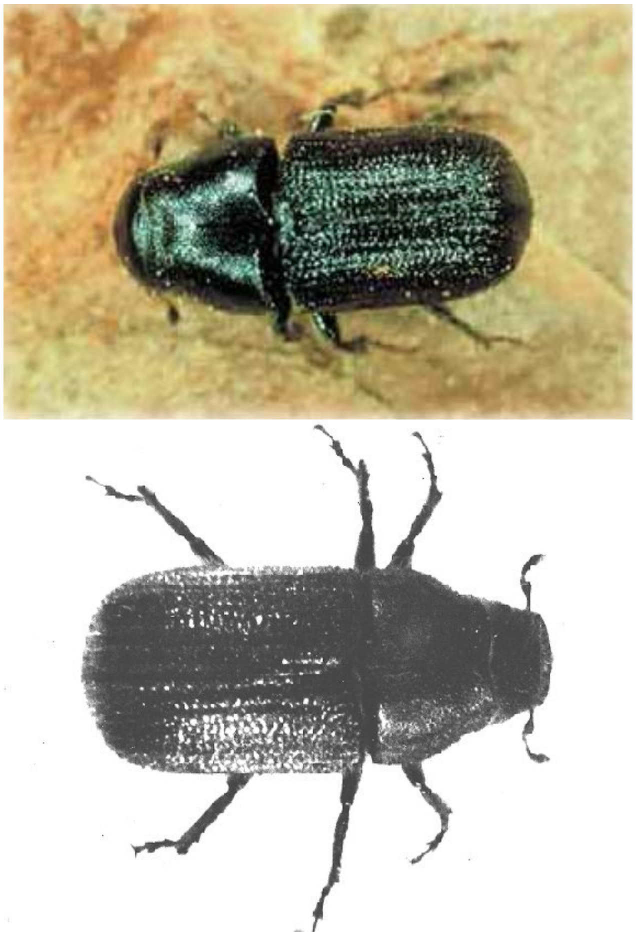

Figure 1. The major insects killing trees in Colorado today include several species of bark beetles (such as the mountain pine beetle above and the spruce beetle below) as well as various species of defoliators. All are native to Colorado and have co-existed with their host tree species for thousands of years. Mountain pine beetle photo from Colorado State Educational Extension Service. Spruce beetle photo from USDA National Agricultural Library.

"endemic" populations. Periodically, however, insect populations grow rapidly and kill large numbers of trees over large areas. This is referred to as an "outbreak" or "epidemic" population. Outbreaks of all of the insect species described above have occurred recently, and have caused extensive mortality events in their respective tree hosts. It is important to note, however, that the trees of Colorado and the Rocky Mountains have coexisted with these native bark beetles and defoliators for thousands of years.

Question #2: Are the insect outbreaks now occurring in Colorado unprecedented in the ecological history of this region, or are they “natural” events similar to outbreaks that occurred in the past?

Summary: *There is no evidence to support the idea that current levels of bark beetle or defoliator activity are unnaturally high. Similar outbreaks have occurred in the past (Figure 2).*

There is no evidence to support the idea that current levels of bark beetle or defoliator activity in Colorado’s lodgepole pine and spruce-fir forests are unnaturally high. The outbreaks now taking place in Colorado are similar in intensity and ecological effects to previously documented outbreaks in the Rocky Mountains. For example, mountain pine beetle outbreaks killed millions of lodgepole pine trees over thousands of square miles in the Cascade and Rocky Mountains during the 1960s, 1970s, and early 1980s (Lynch 2006; chapter 4); and a spruce beetle outbreak in the 1940s killed spruce trees over much of the White River Plateau in western Colorado. Historic photos and tree-ring evidence also document extensive insect outbreaks prior to the 20th century (Baker and Veblen 1990, Veblen et al. 1991, Veblen et al. 1994, Swetnam and Lynch 1998, Eisenhart and Veblen 2000, Veblen and Donnegan 2006). Thus, insect outbreaks are a natural occurrence in almost all of the different kinds of forests in Colorado. Outbreaks do not occur very frequently; the time interval between successive outbreaks in any given area is usually measured in decades. Nevertheless, outbreaks can be expected periodically in almost any place in the state where forests are found.

It is true that bark beetle outbreaks are now

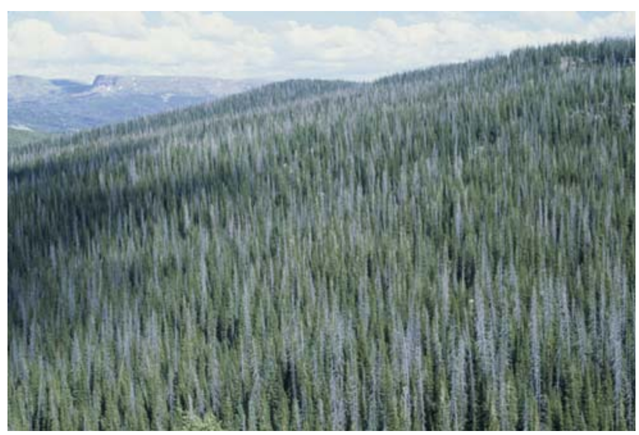

Figure 2. The insect outbreaks now occurring in Colorado are similar in extent and severity to outbreaks of the past. For example, spruce beetles killed millions of trees over thousands of acres in the White River National Forest in the late 1940s and early 1950s. The dead trees (above) are still visible. (Photo by T. T. Veblen).

occurring in parts of Colorado where such extensive insect activity had not been seen at any time during the previous hundred years (e.g., in the Fraser Valley). However, in the absence of tree-ring reconstructions or other spatially detailed information on historical mountain pine beetle outbreaks in Colorado, it is not known if similar outbreaks occurred in the same locations or habitats in the past several centuries. Given the naturally long intervals between recurrent bark beetle outbreaks in Rocky Mountain forests, there is nothing unusual about a hundred-year period of low activity followed by an extensive outbreak. It also is true that mountain pine beetles now are killing trees at unusually high elevations (Wayne Shepperd, personal communication). This may be a significant departure from previous outbreaks. However, it is difficult to know if the current insect activity at high elevations is truly unprecedented, given the lack of data on precise spatial patterns of prehistoric outbreaks. The occurrence of outbreaks today at high elevations, where the insects ordinarily are limited by cold temperatures, is not surprising considering the warm temperatures we have experienced during the past decade, as we discuss in the next question.

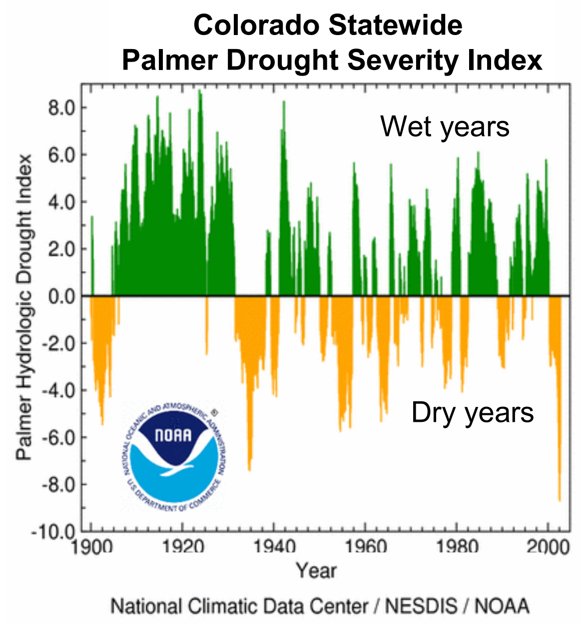

Figure 3. The reason why bark beetle outbreaks are so extensive and severe in Colorado today is because of four interacting ecological factors: (i) long-term drought, as shown above, that stresses trees; (ii) warm summers and (iii) warm winters, which enhance beetle growth and survival; and (iv) abundant food sources (trees) for beetles.

Question #3: Why are the insect outbreaks so severe and so widespread at this time?

<u>Summary</u>: *The ecological factors that control insect populations are complex. Recent bark beetle outbreaks in Colorado probably are a result of four interacting factors: (i) long-term drought, which stresses trees and makes them more vulnerable to insects, (ii) warm summers, which further stress the trees and may accelerate growth of the insects, (iii) warm winters, which enhance survival of insect larvae, and (iv) abundant food (trees) for the insects in Colorado's extensive and often dense forests (Figure 3).*

The factors that control the initiation, spread, and termination of insect outbreaks are complex, and involve a combination of climatic conditions and characteristics of forest stand structure. The relative importance of climate vs. stand structure in any given outbreak is not fully worked out, and in fact may vary from place to place and among the various insect and tree species. Nevertheless, the following is what we know about the interacting influences of drought, temperature, and stand conditions on insect outbreaks.

Evidence from observational, laboratory, and modeling studies indicates that climate is a major controlling factor of bark beetle outbreaks (Bentz et al. 1991, Logan et al. 2003, Carroll et al. 2004, Breshears et al. 2005). The initiation of a bark beetle outbreak is often associated with drought. It is thought that the dry conditions stress the trees and make them less able to defend themselves against the beetles (Carroll et al. 2004). For some insects, the end of the drought usually means the end of the outbreak. However, with mountain pine beetles and spruce beetles, once the beetles have killed a large number of trees and produced abundant offspring, their numbers may become so great that they can overwhelm even healthy trees. If this point is reached, continued drought is not so important: the beetle population continues to grow until it is checked either by a prolonged period of bitter cold weather or until they exhaust their food supply. Low temperatures (around –40 degrees F for about a week), especially in late fall or early spring, may kill the beetle larvae in the trunks of the trees, and thereby terminate the outbreak at any stage in its development.

A warming climate during the last 100 years, particularly in the last few decades, also appears to have played a role in driving recent insect outbreaks. Higher temperatures and a longer frost-free period subject the trees to additional water stress, and may accelerate the growth and development of the beetle larvae. The warming trend of the past few decades (Westerling et al. 2006) may have contributed to the current outbreak of mountain pine beetle in Colorado, as well as recent outbreaks that have occurred outside of Colorado in historically marginal environments for bark beetles, such as at the northern extent of their range in Canada (Carroll et al. 2004) or in high elevations of the northern Rockies (Logan and Powell 2001, Hicke et al. 2006). Furthermore, changing climate conditions are thought to have been responsible for a very severe mortality event in the piñon trees of southern Colorado and adjacent states. Between 2002 and 2004, extensive piñon mortality occurred during a severe drought and an accompanying outbreak of Ips bark beetle (Breshears et al. 2005). Although a more intense drought actually occurred in the 1950s, piñon mortality was far more severe and widespread in 2002 - 2004, apparently because the unusually warm conditions that accompanied the recent drought put additional stress on the trees and allowed more extensive outbreaks of the piñon Ips beetle. Breshears et al. (2005) documented elevated maximum and minimum temperatures at numerous weather stations throughout the Four Corners region during the past decade.

Stand structure also is important in bark beetle outbreaks. The inner bark of very small trees usually is not thick enough to support beetle larvae, and consequently the adult beetles tend to select larger trees to lay their eggs. The minimum tree size for the mountain pine beetle is around four to five inches diameter, but is different for other beetle species (Furniss and Carolin 1977). Thus, stands with large trees are more susceptible to bark beetle outbreaks than are stands with smaller trees. In addition, trees in old or dense stands may be less vigorous and therefore more susceptible to beetles than trees in young or less dense stands, because of competition among trees for limited water and nutrients (Shore and Safranyik 1992). At the landscape scale, if most of the forest is of similar age and has a structure conducive to bark beetle outbreaks, it is likely that outbreaks will be widespread -- if climate conditions are also appropriate. Although fire suppression in the lodgepole pine zone probably reduced opportunities for establishment of young stands since about 1940, young stands have established after timber harvests during this period. The main influence on lodgepole pine age structure in Colorado, however, is widespread burning in the late 1800s that resulted in extensive cohorts of relatively similar age that now are entering a stage that is susceptible to bark beetle outbreaks.

So, why have recent insect outbreaks been so extensive and severe in Colorado? We believe the answer is as follows. The past decade has brought severe drought to many parts of the state (Pielke et al. 2005, Figure 3), accompanied by relatively warm temperatures in both summer and winter (Westerling et al. 2006). The combination of drought and hot summers probably stressed the trees and made them more susceptible to bark beetles; the warm summers may have accelerated the growth and reproduction of some bark beetle species (e.g., spruce beetles and piñon Ips); and the mild winters produced very little mortality of beetle larvae. These climatic conditions probably are the major reason why insect outbreaks have gotten started in many different regions of the state. Once the outbreaks began, the beetles found an abundant food supply (trees) in most of Colorado's forests. Many stands are densely stocked with trees because they have not been disturbed for a very long time by fire, insects, or harvest. All of these factors have combined to create a "perfect storm" of bark beetle outbreaks across much of Colorado.

Question #4: Are the dense forest stands that we see in Colorado today the unnatural consequence of past fire suppression and lack of timber harvesting?

Summary: *The answer to this question depends on the type of forest and its geographic location, as explained below. For example, high density in lodgepole pine and spruce-fir forests is not related to fire suppression; it is simply a natural* *ecological feature of these subalpine forests. It is important to note that not all forests have been affected in the same way by past fire suppression and other human activities (Figure 4).*

Many Colorado forests are very dense, but not all dense forest stands are the unnatural consequence of past fire suppression and lack of timber harvesting. For example, high tree density is a natural condition of most high-elevation forests, including lodgepole pine and spruce-fir. On the other hand, some ponderosa pine forests (but not all) do have unnaturally high tree densities -- higher than would have been seen prior to Euro-American settlement of the region. Thus, it is necessary to distinguish among different forest types in Colorado and elsewhere in the West when considering the effects of past fire suppression and timber harvest (or lack thereof) on current stand density.

Ponderosa Pine Forests Summary: *Tree densities have increased significantly in dry ponderosa pine forests in parts of Arizona, New Mexico, and southern Colorado, largely as a result of fire suppression and other human activities. Ponderosa pine in northern Colorado has been affected to a lesser extent, because fires were historically less frequent in this region than farther south, and the historical landscape was a mosaic of dense and open stands. The proportion of dense vs. open stands is greater in some areas of the Front Range today than historically, in part because of fire suppression, but also because of recovery from 19th century disturbances and because 20th century climate was generally favorable for tree growth.*

Dry ponderosa pine forests in the Southwest were formerly characterized by frequent, low-intensity surface fires, and it is primarily in these forests where fire suppression has contributed to unnaturally dense stands and increased fire severity today (Covington and Moore 1994, Mast et al. 1999, Moore et al. 1999, Allen et al. 2002). Although fire suppression is part of the reason for very dense stands of ponderosa pine in the Southwest, previous grazing, logging, and climate have also contributed to this change in forest structure (Allen et al. 2002). For example, abundant recruitment of pine seedlings typically occurs during moist climatic periods, and the twentieth century has been characterized by several such periods (Savage et al. 1996, Brown and Wu 2005). In the Colorado Rockies, a

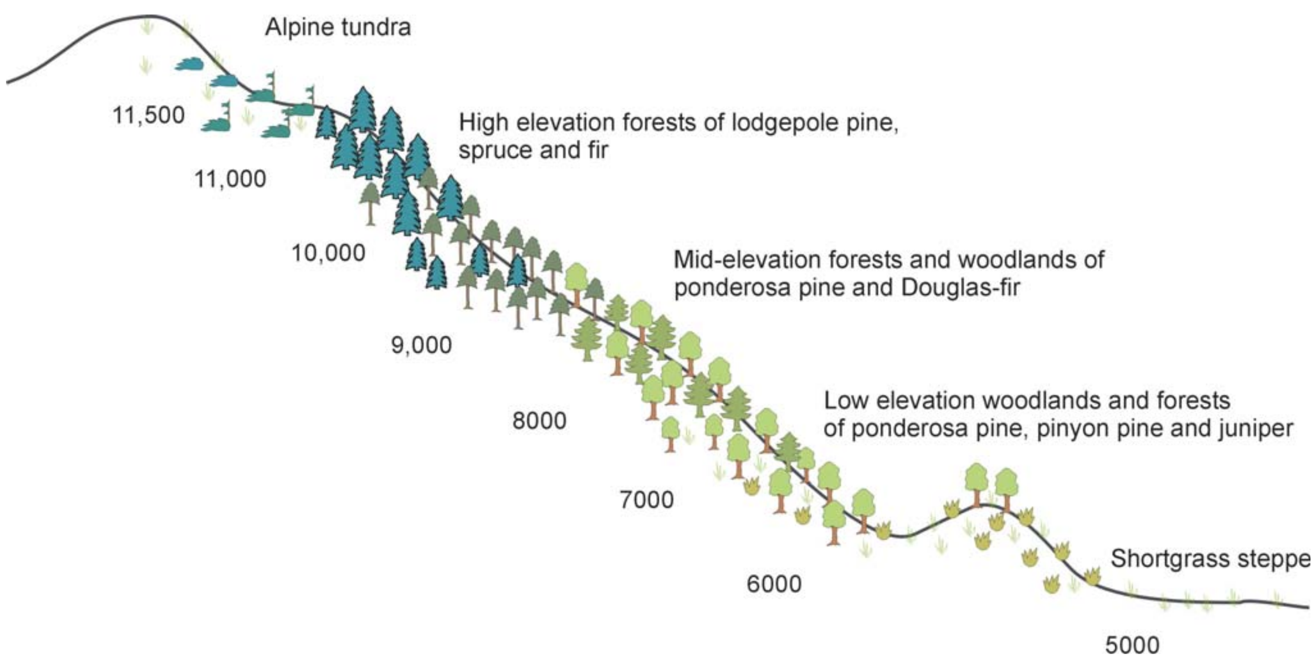

Figure 4. Colorado's forests and woodlands are diverse, ranging from piñon-juniper woodlands in the foothills and basins, to ponderosa pine and Douglas-fir forests at middle elevations, to lodgepole pine and spruce-fir forests at the highest elevations. The natural frequency and effects of forest fires are equally diverse. Tree density in some ponderosa pine forests is greater today than historically because of fire suppression, grazing, and logging during the past century. In contrast, dense stands in high-elevation forests are not related to 20th century fire suppression or land use history; they are simply natural features of these forests where fires have always occurred infrequently. (Figure prepared by L. Huckaby)

model similar to that in the Southwest -- suppression of formerly frequent low-severity fires followed by increased tree density -- applies to some but not all ponderosa pine forests. This "Southwestern ponderosa pine" model appears to be most applicable towards lower elevations and more southerly portions of Colorado.

The Southwestern ponderosa pine model generally does not apply throughout the moister, cooler forests in northern Colorado and at higher elevations, even though ponderosa pine may still dominate (Kaufmann et al. 2006, Baker et al. 2006). For example, in ponderosa pine forests of the Colorado Front Range, tree-ring and other evidence demonstrates that the historical fire regime included both low-severity fire (i.e., surface fires that thin the forests) and high-severity fires (i.e., fires that kill canopy trees and often result in dense regeneration) (Mast et al. 1998, Brown et al. 1999, Kaufmann et al. 2000, Veblen et al. 2000, Huckaby et al. 2001, Ehle and Baker 2003, Sherriff 2004, Kaufmann et al. 2006). In fact, less than 20% of the ponderosa pine zone in the northern Colorado Front Range appears to have been characterized mainly by frequent, low-severity fires. Instead, most of the ponderosa pine zone was characterized by a variable–severity fire regime that included a significant component of high-severity fires (Sherriff, 2004).

The high-severity fires of Front Range ponderosa pine forests tend to occur less frequently than the low-severity fires, and forests naturally grow dense during the long intervals between successive fires. These dense stands are interspersed with more open stands, creating a complex mix of forests. Thus, we conclude that the dense ponderosa pine forests seen in some parts of Colorado's northern Front Range are only partly due to 20th century fire suppression and low rates of timber harvest in recent decades. In contrast to some forests in the Southwest, dense stands of ponderosa pine have always been a component of the Front Range landscape. The proportion of dense vs. more open pine stands has shifted towards more dense stands during the past half-century in many areas, in part because of fire suppression, but also because of climatic conditions conducive to tree growth and natural recovery of forests that were burned or logged in the late 19th century.

Lodgepole Pine Forests <u>Summary</u>: *Dense lodgepole pine stands are not an artifact of fire suppression. These forests have always burned infrequently (intervals of many decades or centuries between fires) and at high intensity, and these fires are naturally followed by development of a dense young stand. Fire suppression has not significantly altered the natural frequency or ecological effects of fire in most lodgepole pine forests.*

Dense stands historically were the norm in lodgepole pine and other high-elevation forests throughout the Rocky Mountain region (Parker and Parker 1994, Kashian et al. 2005, Schoennagel et al. 2004). In these forests in Colorado, fires occur infrequently (on the order of many decades or a century or more between successive fires in any given stand) and naturally tend to be high-intensity fires, usually crown fires, that kill the majority of the trees (Buechling and Baker 2004, Sibold et al. 2006, Veblen and Donnegan 2006). This type of natural fire behavior contrasts strikingly with the frequent surface fires of dry, low-elevation ponderosa pine forests: rather than thinning forests by killing primarily small, fire-intolerant individuals, the naturally severe fires of high-elevation forests typically kill all of the forest canopy and stimulate regeneration of the stand. Post-fire regeneration of lodgepole pine often results in a dense stand, especially where a large proportion of the trees have serotinous cones. Serotinous cones remain sealed by resin until the heat of a fire melts the resin and releases the seeds; thus, even though the adult trees are killed by the fire, they have stored huge numbers of seeds in their cones and those seeds are released into an optimal seed bed created by the fire.

The effect of fire suppression on the structure of individual stands and on the characteristics of stands across the landscape has been relatively minimal in lodgepole pine and other high-elevation forests in Colorado and throughout the Rocky Mountains (Schoennagel et al. 2004). The remote mountainous areas where these forests grow were generally difficult to access for fire-fighting, especially prior to the 1950s. Furthermore, the length of time that fire has been effectively excluded (~50 to 80 years) is short relative to the natural fire return interval (measured in centuries). As a consequence, fire exclusion has not significantly lengthened fire intervals in lodgepole pine forests. Note that this is in marked contrast to frequent, low-severity fire regimes such as Southwestern ponderosa pine.

It is true that a large proportion of the lodgepole pine stands in Colorado are more than 100 years old today (e.g. as reflected in stand age data from USDA Forest Service). However, this pulse of tree establishment was mainly due to widespread severe fires during the second half of the 19th century when climate was conducive to fires in the subalpine zone (Sibold and Veblen 2006). Tree-ring data show that similar pulses of establishment of lodgepole pine followed similar episodes of widespread fire in the 17th and 18th centuries across the subalpine zone of northern Colorado (Kulakowski and Veblen 2002, Kulakowski et al. 2003, Sibold et al. 2006). Thus, the tree-ring record of fire and tree establishment in subalpine forests indicates a high degree of variability in fire extent and stand initiation at time scales of 100 years. This variability included periods of extremely rare fires over 100-year periods of climate unfavorable to fire spread, so that long fire-free intervals such as in the 20th century are not outside the historical range of variability for these forests. Thus, age structures similar to the current dominance of the 100+ year old age class are typical of the historical conditions of lodgepole pine forests.

Because of the natural disturbance regime in lodgepole pine forests, characterized by infrequent but periodically large severe fires and insect outbreaks, these high-elevation forests do not exhibit a static or consistent average age class over time. We know that fires before 1900 in this forest type were infrequent but could grow to very large size under very dry weather conditions (Schoennagel et al. 2004, Sibold et al. 2006). It follows that we should expect large fires in lodgepole pine in the future, and that these future large fires should not be viewed as abnormal from an ecological standpoint. The key point about lodgepole pine forests is that they were dense and burned infrequently historically, and they are dense and burn infrequently today. High density in lodgepole pine forests is not related to fire suppression in any way; on the contrary, it is a natural feature of their ecology.

Spruce-Fir Forests Summary: *Dense spruce-fir stands are not artifacts of fire suppression either. Spruce-fir forests have always burned infrequently (intervals of centuries between fires) and at high intensity, and these fires are naturally followed by development of a dense young stand. Fire suppression has not significantly altered the natural frequency or ecological effects of fire in most spruce-fir forests.*

As in lodgepole pine forests, dense stands are also normal in spruce-fir forests (Veblen and Donnegan 2006). Prior to the beginning of fire suppression efforts in the 20th century, these forests were primarily shaped by large and severe fires that occurred in a given stand, on average, only once per several hundred years (Kulakowski et al. 2003, Buechling and Baker 2004, Sibold et al. 2006). Natural patterns of post-fire stand development resulted in high tree densities. Since long fire-free periods were normal in these forests prior to fire suppression efforts, it is very unlikely that several decades of fire suppression have fundamentally changed the natural fire regime or have resulted in forest structures that could be considered unnaturally dense. Instead, the dense spruce-fir forests today are very much like they have been in past centuries.

Question #5: Are recent wildfires in some of Colorado's dense forest stands unusually severe compared to pre-20th century fire severity?

Summary: *Recent fires have been more severe than historically in some forests, notably dry ponderosa pine forests in parts of Arizona, New Mexico, and southern Colorado. However, recent fires have behaved just as they did historically in most of Colorado's high-elevation forests, such as lodgepole pine and spruce-fir. Large intense fires are the normal fire behavior in these latter kinds of forests, and 20th century fire suppression has not caused them to be unnaturally severe (Figure 5).*

Again we stress the importance of distinguishing among forest types. Recent fires have been more severe, for example, in dry ponderosa pine forests in the Southwest, including some of the forests in southwestern Colorado. However, recent fires clearly are not

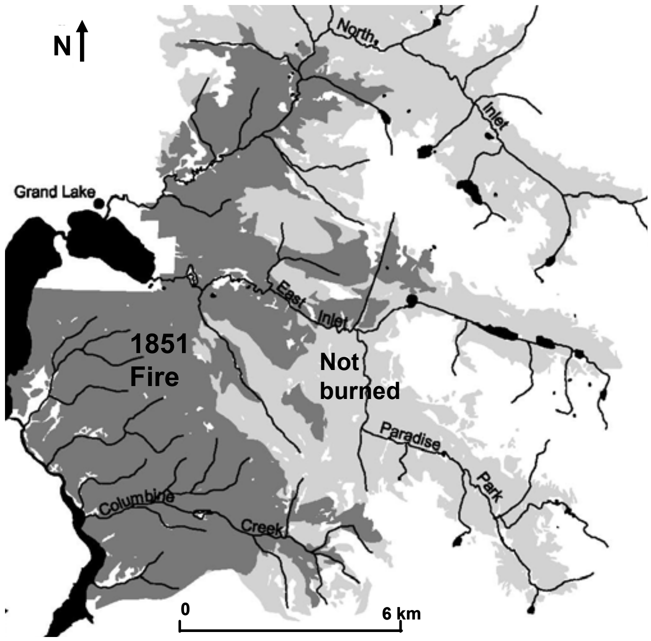

Figure 5. Large, intense forest fires are a natural feature of high-elevation forests in Colorado. For example, much of the country around Grand Lake, Colorado, burned in 1851. Most of the burned area now is covered by 150-year old lodgepole pine forests. (Figure from J. Sibold, 2005 Ph.D. Dissertation, CU Boulder). Some recent fires in ponderosa pine forests have been more severe than would have occurred historically, because of fuels changes associated with fire suppression, grazing, and logging during the past century. However, recent fires in lodgepole pine and spruce-fir forests also have been intense -- but no more intense than occurred historically.

more severe in lodgepole pine or in spruce-fir than fires that occurred in previous centuries. Even in the case of ponderosa pine forests in Colorado, not all areas follow the Southwestern pattern of increased stand densities following the near elimination of fires by grazing and fire suppression in the late 19th and 20th centuries. As noted above, in the Colorado Front Range the ponderosa pine zone was characterized by an historical mixed-severity fire regime in which some areas burned at low severity (as in the Southwest) but other areas, often large, were burned severely and regenerated to dense stands (Mast et al. 1998, Brown et al. 1999, Kaufmann et al. 2000, Veblen et al. 2000, Huckaby et al. 2001, Ehle and Baker 2003, Sherriff 2004, Kaufmann et al. 2006).

Question #6: Do outbreaks of mountain pine beetles and other forest insects increase the risk of severe wildfires?

Summary: *Although it is widely believed that insect outbreaks set the stage for severe forest fires, the few scientific studies that support this idea report a very small effect, and other studies have found no relationship between insect outbreaks and subsequent fire activity. Theoretical considerations suggest that bark beetle outbreaks actually may reduce fire risk in some lodgepole pine forests once the dead needles fall from the trees. It is true that severe fires have occurred recently in some forests following insect outbreaks (e.g., in spruce-fir forests of western Colorado). However, these fires burned under very dry weather conditions, and severe fires are the norm for these kinds of forests even without insect activity. Based on current knowledge, the assumed link between insect outbreaks and subsequent forest fire is not well supported, and may in fact be incorrect or so small an effect as to be inconsequential for many or most of the forests in Colorado (Figure 6).*

Our focus here is on active crown fires, i.e., fires that move from tree crown to tree crown under dry windy conditions. Surface fires also are significant; they can affect soils and understory plants, cause major damage to homes and other structures, and can be difficult to control, especially when burning in heavy fuels. However, in this discussion we emphasize crown fires because these often are the most fast-moving fires, they are the fires that typically cause the most damage to homes and other vulnerable structures, and they are almost impossible to control even with modern fire-fighting technology. It is important to realize that active crown fires do not burn only the dead fuels. On the contrary, crown fires are propagated through both live fuels (needles and small twigs) and dead fuels. Tree-killing insects do not really increase the amount of fuels in a forest stand; what they do is shift some of the live fuels into the dead fuel category. Both live and dead fuels can carry fire under very dry weather conditions.

Although more research is needed to confidently predict the effects of insect outbreaks on subsequent fires in Colorado forests, we offer the following interpretation based on theoretical considerations. Whether beetle-caused mortality enhances fire risk and severity compared to an

Figure 6. Lodgepole pine and spruce-fir forests typically burn at high intensity even without previous insect activity. It is widely believed that insect outbreaks set the stage for intense forest fires, but there is little scientific evidence for such a connection. Some recent Colorado fires have burned intensely in lodgepole pine and spruce-fir forests where insect outbreaks had occurred from a few to 50 years previously (e.g., in the Routt and White River National Forests). However, these fires occurred during extremely dry weather conditions, and forests unaffected by bark beetle outbreaks burned in similar fashion. (Photo by W. H. Romme)

unaffected stand very likely depends on time since outbreak. Post-outbreak stand development and associated fire risk may proceed through three stages. (i) Immediately following an outbreak, when trees are dead and dry needles remain on the trees, the chance of a crown fire getting started may be greater than for live trees. However, the dead needles may not significantly change the likelihood of a crown fire spreading from tree to tree, because crown fire spread is controlled not just by dead fuel quantity, but also by live fuel moisture, wind speed, and canopy bulk density (total amount of live and dead fuels in the canopy). This first stage lasts a relatively short time, because the dead needles usually fall within about two years of a tree's death. (ii) Once the needles fall off the dead trees, the likelihood of both crown fire initiation and spread actually may be reduced in comparison to an unaffected stand, since the dead trees create gaps in the canopy and reduce canopy bulk density. It is known that reducing canopy continuity and bulk density through mechanical thinning or harvesting can reduce crown fire risk (Graham et al. 2004), and it is likely that reductions in canopy continuity and bulk density resulting from insect-caused mortality would have a similar effect. (iii) After the dead snags fall, typically one to several decades after the insect outbreak, it is expected that the risk of crown fire initiation and spread may increase once again through two mechanisms. First, the fallen snags may fuel an intense surface fire, with heat and flame lengths that reach into the crowns of the trees. Second, small trees, which generally survived the outbreak and grew more rapidly in the more open conditions resulting from death of canopy trees, create “ladder fuels” that can carry a surface fire into the canopy. In sum, crown fire risk may be elevated for a brief time during and immediately after the peak of the outbreak, while the trees retain their dead needles; then fall to lower levels for the next few decades while the bare snags remain standing; and finally return to pre-outbreak levels some 20 – 50 years after the outbreak when the snags have fallen and a fast-growing understory has created ladder fuels between the heavy surface fuels and the canopy.

We emphasize again that the interpretation just presented is primarily theoretical and requires further study before definitive conclusions can be drawn. We also stress that this analysis focuses on effects of insect-caused mortality within a single stand. The impact on subsequent fire behavior will be different depending on the proportion of the trees killed in the stand. Moreover, it is important to recognize that a large forest landscape is composed of many individual stands. Substantial changes in stand structure and fire behavior within just one or a few stands may have little influence on fire spread and fire severity across the entire landscape.

A few empirical studies have evaluated subsequent fire activity in areas across the West that have been affected by major insect outbreaks, as summarized below. The general conclusion of these studies has been that the outbreak had no effect or only a small effect on subsequent fire occurrence or severity. However, more research of this kind is needed before we can make definitive statements about insects and fire.

Spruce beetle in subalpine spruce-fir forests. It is well established that in spruce-fir forests, extensive fires are highly dependent on infrequent, severe droughts (Buechling and Baker 2004, Sibold and Veblen 2006). Under those extreme drought conditions, dead fuels from insect outbreaks or other causes appear to play only a minor role, if any, in increasing fire risk. For example, following the 1940s spruce beetle outbreak that resulted in dead-standing trees over most of the subalpine zone of White River National Forest of western Colorado, there was no increase in the numbers of fires compared to unaffected subalpine forests (Bebi et al. 2003). Large fires did not occur in these forests until the drought of 1980, when 10,000 acres burned in the Emerald Lake Fire, and in the very severe drought year of 2002 (Pielke et al. 2005) when 31,000 acres burned in the Big Fish and Spring Creek fires. The 2002 fires in western Colorado affected extensive areas of spruce-fir and lodgepole pine forests that were previously affected by outbreaks of spruce beetle and of mountain pine beetle. Yet despite the expectation that these outbreaks (both the 1940s and an ongoing post-1998 outbreak) would have led to an increased risk of severe fires, the forests that were affected by the outbreaks generally did not burn more extensively or more severely than forests that were not affected (Bigler et al. 2005; Kulakowski and Veblen 2006).

Mountain pine beetle outbreaks in lodgepole pine forests. Turner et al. (1999) evaluated the influence of beetle outbreaks that had occurred 5-15 years previously on the behavior of the 1988 Yellowstone fires in lodgepole pine forests. They found that the likelihood of crown fire was increased somewhat where beetle-caused tree mortality had been high (perhaps because the fallen trees created heavy fuel loads), but was reduced where beetle-caused mortality was only moderate (perhaps because the dead trees interrupted the horizontal continuity of the canopy). Lynch (2006; chapter 3) also examined the influence of previous beetle activity on the 1988 Yellowstone fires by testing whether fire was more likely where the beetles had killed trees than in areas unaffected by the beetles. She found that beetle-affected areas did have a higher probability of burning, but that the increase was only about 11% compared with areas unaffected by beetles.

Spruce budworm defoliation. Massive outbreaks of western spruce budworm affected the Douglas-fir forests of the northern Colorado Front Range in the late 1970s and 1980s, but there is no evidence that they resulted in increased fire occurrence. Widespread fires have occurred recently in these forests, but these fires were associated with the extreme drought of 1998-2002. Therefore, if there was any potential increase in fire risk associated with the spruce budworm outbreaks, that potential was not realized until at least 25 years later when weather conditions were conducive to extreme fire behavior even in the absence of insect effects. In Ontario, Canada, Fleming et al. (2002) found a significant increase in probability of fire 3-9 years after an outbreak (perhaps because of increased vertical fuel continuity between fuels on the forest floor and fuels in the canopy), but probability of fire was not continuously elevated after the outbreak. However, in British Columbia, Canada, Lynch (2006; chapter 2) reported a significant decrease in risk of forest fire for nine years following a spruce budworm outbreak.

The upshot of these few studies of insect effects on subsequent fire risk is that the relationships are complex, and that no simple statements can be made about how outbreaks do or do not increase the risk of fire. One reason for the lack of clear-cut patterns is that spruce-fir and lodgepole pine forests naturally burn very infrequently, and only under very dry weather conditions. When the weather conditions are right for a big fire in spruce-fir or lodgepole pine, fire behavior is naturally intense, whether affected by previous insect activity or not. If insect outbreaks do in fact increase the likelihood of fires getting started or burning intensely through these kinds of forests, the magnitude of increase probably is small and difficult to detect, because fire is so strongly controlled by weather in these forests, and because they naturally burn at high intensity.

Question #7: Are forests with large amounts of insects and dead trees “unhealthy?”

<u>Summary</u>: *"Forest health" is an ambiguous concept, one that is not well defined scientifically. The presence of dead or dying trees does not necessarily mean that the forest ecosystem as a whole is not functioning appropriately, even when such trees are numerous. In fact, dead trees and fallen logs perform some important ecological functions in forests, such as providing wildlife habitat and returning nutrients and organic matter to the soil. Nevertheless, dead trees are unattractive and unappealing to many people, and it can be quite painful to lose trees that have special meaning to an individual, such as large pines surrounding one's home (Figure 7).*

Although it may be relatively easy to ascertain whether an individual tree is healthy or not, the concept of “forest health" is very ambiguous. The presence of unhealthy trees does not necessarily imply that the forest as a whole is unhealthy. On the contrary, standing dead trees and fallen logs (coarse wood) play important roles in wildlife habitat, soil development, and nutrient cycling, and are a defining characteristic of old-growth forests. Bark beetle outbreaks rarely kill all of the trees in a stand, because they preferentially attack the larger trees and generally ignore the smaller trees. These smaller trees may be hidden by the red needles of the large killed trees during the peak of the outbreak, such that one often has an impression of total tree mortality. However, once those needles fall it usually becomes apparent that many small and moderate sized trees survived the outbreak. These smaller trees may grow two to four times more rapidly after the outbreak than they did before, because they are no longer competing with the big trees for light, water, and nutrients (Romme et al. 1986). In mixed forests of lodgepole pine and aspen, the aspen may grow more vigorously after beetles kill the dominant pine trees. Even when all of the trees are killed, as in a severe forest fire, the result usually is stand regeneration, as described above for lodgepole pine. Thus, from a purely ecological standpoint, dead and dying trees do not necessarily represent poor “forest health." They may instead reflect a natural process of forest renewal.

Figure 7. "Forest health" is an ambiguous concept. The presence of dead and dying trees does not necessarily mean that the forest ecosystem as a whole is not functioning appropriately. Dead trees and fallen logs perform important ecological functions, such as providing wildlife habitat and returning nutrients and organic matter to the soil. (photo by W. H. Romme)

Nevertheless, dead trees are unattractive and unappealing to many people, especially when those dead trees are abundant, and it can be quite painful to lose trees that have special meaning to an individual, such as large pines surrounding one's home. The change in the appearance of the forest after an insect outbreak also can have negative economic consequences for a community. Over time, the visual impacts are lessened as aspen and small pines grow larger and more abundant, and the gray trunks of the beetle-killed trees gradually fall to the ground. Nevertheless, the visual evidence of an insect outbreak may persist for a decade or more after the outbreak subsides.

Question #8: Does a large insect outbreak constitute an "emergency?"

Summary: *Forests naturally change slowly, almost imperceptibly, over long periods of time. But periodically this slow process of change is punctuated by rapid change via insect outbreak, fire, or other natural disturbance. The sudden death of thousands of trees may be an emergency for people and communities whose amenities, economic activities, and management plans were based on the slowly changing forest that used to occupy the area. From an ecological perspective, however, insect outbreaks are part of the natural rhythm of change in forest ecosystems, and are followed by a gradual re-development of the forest through natural ecological processes. Where aspen was present before the outbreak, the death of the pines may lead to an increase in the aspen component of the forest (Figure 8).*

The normal development of forests involves very slow changes that continue over decades or centuries. A large-scale insect outbreak or forest fire changes a forest rapidly, over a period of a few weeks or years. Such a rapid change often generates great concern about the health and future of the forest and landscape. Is this an emergency? The sudden death of thousands of trees may be an emergency for people and communities that are accustomed to the slowly changing forest that used to occupy the area. Recreational opportunities and values suddenly change, and long-term plans that relied on only slow changes in the forest (such as estimations of annual wood yield) no longer apply. Thus, these may be emergencies from certain standpoints.

From an ecological perspective, we recognize that the forest will slowly re-develop through natural processes. Many montane landscapes in central Colorado are well suited for both conifers (lodgepole pine, spruce, and fir) and aspen, and several of these species commonly occur in the same forest. A century of forest development without any major disturbance typically leads to decreasing abundance of aspen as the conifers increase in dominance. A bark beetle outbreak that kills many of the conifers may be beneficial to the aspen. Old aspen trees will likely grow faster, and new aspen will become established. An increase in aspen will occur only where aspen clones were present before the beetle outbreak. If there was not aspen already present, then composition of the forest will not change; the surviving conifers (mostly smaller individuals and non-susceptible species) will increase their growth rates and replace the large conifer trees that were killed by beetles.

The terms "ecological emergency" and "insect emergency" suggest that insect outbreaks are unforeseen events. However, insect outbreaks, even extensive ones that kill canopy trees over hundreds of thousands of acres, are natural events in forest ecosystems throughout the Rocky Mountains, and have been occurring for thousands of years (e.g., Swetnam and Lynch 1998, Lavoie 2001). The insects have long been natural components of these forest ecosystems. Therefore, from a purely ecological perspective, an insect outbreak generally would not be regarded as an "emergency," but as an infrequent but normal episode of rapid change within an ecosystem that most of the time is changing only slowly.

Figure 8. Forests naturally change slowly, almost imperceptibly, over long periods of time. But period-ically this slow process of change is punctuated by rapid change via insect outbreak, fire, or other natural disturbance. From an ecological perspective, insect outbreaks are part of the natural rhythm of change in forest ecosystems, and are followed by a gradual re-development of the forest through natural ecological processes. (photo by Dominik Kulakowski)

Question #9: How do insect outbreaks affect streamflow and water quality?

Summary: *An insect outbreak, or any disturbance that reduces the total area of leaf surface in a forest, can potentially increase streamflow by reducing the amount of interception and transpiration. No increase in streamflow is likely when the total annual precipitation is less than 18-20 inches. In areas with more than 18-20 inches of annual precipitation, an increase in streamflow generally will not be detectable unless at least 15-20% of the forest canopy is killed. By themselves, insect outbreaks are unlikely to cause erosion or degrade water quality because they do not disturb the forest soil. Unpaved roads and high-severity wildfires can cause much greater effects on runoff, erosion, and water quality (Figure 9).*

The hydrologic effects of insect infestations vary with the type of forest, the number and size of trees that are killed, and the amount and type of precipitation. The likely effects of a given change in forest density and structure can be predicted with a relatively high degree of confidence because of the long history of plot, process, and watershed scale studies in Colorado and elsewhere (MacDonald and Stednick, 2003). Over the last decade there has been a sharp increase in our understanding of how wildfires, prescribed fires, and thinning affect runoff and erosion rates in Colorado (e.g., Moody and Martin, 2001; Benavides-Solorio and MacDonad, 2005; Kunze and Stednick, 2006).

Removal of all or a part of the forest canopy may potentially increase streamflow via two mechanisms. First, the forest canopy intercepts a portion of incoming precipitation, and this intercepted rain or snow simply evaporates or sublimates back into the atmosphere without ever reaching the soil. A reduction in the forest canopy generally reduces the amount of water that is intercepted and thereby increases net precipitation (but see below for other complicating factors). Second, live trees take up water from the soil and transpire that water into the atmosphere.

Several principles determine whether a particular insect infestation or management action will significantly alter the amount and timing of runoff. First, removing the forest cover from areas that receive less than about 18-20 inches of annual precipitation will have little effect on the amount and timing of runoff as long as there are no significant changes to the infiltration rate of the soil. The primary reason for this lack of change is that any reductions in interception and transpiration are negated by an increase in soil evaporation and transpiration by any remaining vegetation (Bosch and Hewlett, 1982). Once annual precipitation exceeds about 18-20 inches, the reduction in interception and transpiration due to forest harvest or dieback will increase annual runoff, and this increase generally will be proportional to the amount of annual precipitation. Second, at least 15-20% of

Figure 9. An insect outbreak can potentially increase streamflow by reducing the amount of water transpired by trees. However, the increase probably will not be detectable unless total annual precipitation is greater than 18-20 inches and at least 15-20% of the forest canopy is killed. By themselves, insect outbreaks generally do not cause erosion or degrade water quality, because they usually do not disturb the soil. (photo by J. A. Hicke)

the forest canopy has to be killed or removed before there will be any measurable increase in annual runoff. Removing a smaller proportion of the forest cover may still increase the amount of runoff, but this increase probably will not be statistically detectable. Third, the increase in annual runoff due to forest harvest or tree death is roughly proportional to the amount of the forest canopy that is removed or killed. Fourth, the absolute changes in streamflow will be much smaller in dry years than wet years, and become harder to detect as spatial scale increases (MacDonald and Stednick, 2003).

Extrapolation of paired-watershed studies in snow-dominated areas of Colorado and Wyoming indicates that removing the forest canopy from 100% of a watershed will increase mean annual water yields as follows: by a little over 1 inch or about 18% of the mean annual runoff when the mean annual precipitation is 21 inches (Bates and Henry, 1928); by 8 inches or roughly 90% when the mean annual precipitation is 30 inches (Troendle and King, 1985); and by over 12 inches or about 70% when the mean annual precipitation is 34 inches (Troendle et al., 2001). Nearly all of this increase in water yield will come on the rising limb of the snowmelt hydrograph in May-June. Complete removal of the forest canopy can be expected to increase the size of the mean annual peak daily flow by about 40% while having minimal effect on the timing of the annual peak flow (MacDonald and Stednick, 2003).

The hydrologic effects of insect outbreaks are similar in many respects to the effects of forest harvest, but there also are some important differences (MacDonald and Stednick, 2003; Uunila et al., 2006). One difference is that under natural conditions the insect-killed trees remain in place, and this residual canopy will still intercept a portion of the incoming rain and snow, especially while the needles and fine twigs are still in place. This means that the water yield increase due to bug-killed trees will be smaller than the water yield increase due to a comparable amount of forest harvest. A second important difference is that although the insects may kill most or all of the trees within small patches of a few acres, outbreaks never kill all of the trees across a large watershed or landscape; thus, the increases in water yield following insect outbreaks will be smaller than the values listed in the previous paragraph for complete tree harvest (Schmid et al., 1991). Finally, any increase in runoff will decay over time with forest re-growth, and the time to hydrologic recovery may be shorter for an insect outbreak as compared to forest harvest. Studies in Colorado indicate that the time needed for hydrologic recovery after a clearcut varies from about 60 years in the spruce-fir and lodgepole pine zones to around half this time in aspen stands (MacDonald and Stednick, 2003). Insect outbreaks usually kill a portion of the trees, and the surviving trees may grow two to four times faster than they did before the outbreak. Therefore, canopy basal area may return to pre-outbreak levels within a shorter period of time, and this will reduce the potential increase in water yields relative to timber harvest.

Several studies have attempted to evaluate or predict the hydrologic effects of insect outbreaks in Colorado and elsewhere, but most of these studies were been hampered by the lack of a well-controlled design and the available statistical tools. After the 1939-1946 spruce beetle epidemic in the White and Yampa River basins, Love (1955) claimed that annual streamflow in the White River increased by about 2.3 inches or 22%, but this was refuted by Bue et al. (1955). Bethlahmy (1974, 1975) conducted more extensive analyses using different techniques and claimed that the beetle epidemic increased annual water yields by up to 2.0 inches in the White River basin and 2.4 inches in the Yampa River basin, and that the water yield increases were still present after 25 years. A more recent modeling study predicted that water yields would increase in the North Platte River basin by 2.2 inches if 30-50% of the trees were killed by insects (Troendle and Nankervis, 2000). While none of these studies can be considered definitive, the general results are consistent with the principles and values outlined in this section.

In terms of water quality, forested areas typically have very high infiltration rates and rarely generate surface runoff. The death of trees by insects should not compact the soil or cause a loss of the protective litter layer. In the absence of any compaction or ground disturbance, there should be minimal change in soil infiltration rates or the soil moisture storage capacity. Hence an insect outbreak should not induce overland flow or increase erosion rates, even on steep slopes. On the other hand, the increased duration of high flows due to forest harvest or dieback can increase watershed-scale sediment yields by increasing the stream's sediment transport capacity (Troendle and Olsen, 1994). In practical terms this is of little significance because the sediment yields from forested areas are typically very low (MacDonald and Stednick, 2003). In many forested areas, unpaved roads are a primary source of sediment (Libohova, 2004), and the number, location, and design of forest roads is a key control on whether thinning or harvest activities will affect water quality and aquatic ecosystems (MacDonald and Stednick, 2003; Libohova, 2004). Forest harvest and bug kill can reduce slope stability as a result of the decay in root strength (Sidle et al., 1985), but the increased susceptibility to landslides and debris flows is rarely an issue in Colorado.

Although insect outbreaks usually produce little or no soil erosion, and may have minimal impact on runoff, other disturbances may have significant impacts on soils and runoff. The effects of wild and prescribed fires on runoff and erosion depend primarily on fire severity as well as the timing and cause of peak flows. Low severity fires have minimal effects on runoff and erosion rates because these do not remove the protective litter layer and generally do not kill the larger and more mature trees. In contrast, high severity fires consume all of the protective organic layer, kill most or all of the vegetation, and can induce a water repellent layer at or near the soil surface (Huffman et al., 2001; Benavides-Solorio and MacDonald, 2005; Pietraszek, 2006). In areas with summer convective storms, peak flows and erosion rates can increase by several orders of magnitude after a high-severity fire (Moody and Martin, 2001; Libohova, 2004; Benavides-Solorio and MacDonald, 2005), and the combination of ash and sediment can severely degrade water quality (Moody and Martin, 2001; Kunze and Stednick, 2006). A series of studies in the ponderosa pine zone in the Colorado Front Range suggests that long-term sediment delivery rates from unpaved roads may be similar in magnitude to rates from periodic high-severity fires, while forest thinning has no detectable effect on runoff or erosion rates (MacDonald and Larsen, in press). In snowmelt-dominated areas high-severity fires may have a much smaller effect because soils are not water repellent under wet conditions (MacDonald and Huffman, 2004), and the number and intensity of summer thunderstorms may be lower than in mid-elevation forests. Hence the hydrologic effects of fires in the higher-elevation forests may be more similar to the effects of forest harvest, but there are few data from these higher-elevation sites.

Potential Treatment Options

Even though the insect outbreaks now occurring in Colorado generally cannot be regarded as *ecological* emergencies, there is no denying that the extensive stands of dead and dying trees do affect the aesthetic and economic attributes of many forests. Moreover, forest fires may cause serious damage to property and may even threaten human lives – whether or not previous insect activity has caused those fires to be more severe than they would be otherwise. Therefore, efforts to reduce the impacts of insects and fires are warranted in many areas. The following sections describe and evaluate the likely effects of a range of treatments that have been used or proposed to ameliorate the effects of insect outbreaks and fires.

Option #1: Spraying with Insecticide

<u>Summary</u>: *This can be an effective means of saving high-value trees in localized areas, but is not feasible over large landscapes (Figure 10).*

Spraying trees with an appropriate insecticide can be an effective means of preventing bark beetle attack or reducing defoliator damage. County extension agents and personnel of the Colorado State Forest Service and USDA Forest Service can recommend the best products to use against a particular insect in a particular area.

This may be the best means available for protecting high-value trees around homes, in town parks, or other localized places. However, there are limits to what can be accomplished by spraying insecticides. Annual spraying, or even spraying several times in a single year, is required to prevent attacks by each successive

Figure 10. Spraying with insecticide can be an effective way to preserve high-value trees, such as around a home. However, spraying is not feasible or effective in stopping insect outbreaks over large landscapes. (photo by W. H. Romme)

generation of insects. Spraying is not feasible at the scale of an entire forest landscape because of cost and difficulty of hitting all of the places where insects may be present. In addition, insecticides are not entirely species-specific: a broad-scale spraying of insecticides will kill many harmless and beneficial insects, such as pollinators and butterflies, in addition to the target bark beetles and defoliators. In general, bark beetle preventive sprays have less impact on non-target insects than do insecticide sprays used to control defoliatiors, because the former sprays are targeted to the trunk of the tree whereas the latter sprays need to cover entire tree canopies.

Option #2: Preventing or controlling outbreaks through forest management

Summary: *Removing stressed or unhealthy trees, and thinning to prevent crowding and competition among trees, can effectively reduce the risk of an insect outbreak getting started in a forest stand. Forest management is unlikely to prevent all outbreaks, however, because (i) it will never be feasible to intensively manage all of the forests of Colorado, and (ii) drought and warm temperatures are also important causes of outbreaks. Once an outbreak has begun, management generally cannot stop it, because the insects are numerous enough to overcome even healthy trees (Figure 11).*

Because outbreaks may initiate in stressed or unhealthy trees, intensive forest management focused on regular removal of old or unhealthy trees may reduce the likelihood of an insect outbreak getting started in a stand. Thinning may reduce tree-to-tree competition, increase tree vigor, and thus provide an enhanced ability of trees to defend against an attack (Amman and Logan 1998, Schmid and Mata 2005). If periodic harvest removes large trees and maintains a preponderance of small-diameter trees, this too may help prevent the start of a bark beetle outbreak, since bark beetles (but not defoliators) prefer larger trees. Thus, careful forest management, including appropriate timber harvest, may help locally to prevent the onset of an outbreak (Cole et al. 1976).

By itself, however, forest management probably cannot prevent all insect outbreaks -- for two reasons. First, it is unlikely that all stands in Colorado landscapes will be managed intensively enough to remove all of the stressed trees in which an outbreak can get started; in fact, the public values “unmanaged” forests that contain large and old trees. Second, drought and warm temperatures are major causes of bark beetle outbreaks, and forest management by itself cannot entirely overcome these climatic effects. And it is important to recognize that once an extensive bark beetle outbreak has started, it is unlikely that timber management can stop it. Under outbreak conditions, the beetles can overwhelm even the healthiest trees, so selective removal of weak or stressed trees will

Figure 11. Removing stressed or unhealthy trees, and thinning to prevent crowding and competition among trees, can effectively reduce the risk of an insect outbreak getting started in a forest stand. (photo by W. H. Romme)

likely have little impact. Most entomological evidence indicates that once an outbreak has started, there is nothing that can be done to stop it. The outbreak ends when there are no more suitable trees for the beetles, or when unusually cold conditions kill beetle populations. Intensive even-aged management was applied to lodgepole pine forests in the Targhee National Forest, along the western boundary of Yellowstone National Park, from the 1960s through 1980s; yet a mountain pine beetle outbreak that swept through the region in the 1970s and early 1980s appeared to affect the managed Targhee stands as severely as the unmanaged stands in Yellowstone Park (Romme et al. 1986). Similarly, the lodgepole pine forests of British Columbia, Canada, are now being affected by a very extensive and severe mountain pine beetle outbreak, despite a long history of intensive forest management in this province.

Figure 12. Removing dead trees and other fuels can effectively reduce the risk of fire damage at a local scale, e.g., in the immediate vicinity of a home or community. However, the effectiveness of harvest in reducing fire risk to homes and communities over larger areas, e.g., a forest landscape, is less clear. (photo by W. H. Romme)

Option #3: Harvesting insect-killed trees to reduce wildfire risk

Summary: *Removing dead trees and other fuels can effectively reduce the risk of fire damage at a local scale, e.g., in the immediate vicinity of a home or community. However, the effectiveness of harvest in reducing fire risk over larger areas, e.g., a forest landscape, is less clear. Conventional timber harvest may do little to reduce fire risk at any scale if it removes primarily large trees, because smaller trees, brush, and dead fuels often are the major carriers of a spreading fire. Harvesting smaller trees and removing small fuels may more effectively reduce fire risk (Figure 12).*

As with the spraying and forest management options, the effectiveness of this option varies with the scale at which it is applied. Removing dead trees – plus other flammable material (including wood roofs and decks, woodpiles and burnable vegetation) from the immediate vicinity of a home or other vulnerable structure -- has been shown to be effective in protecting the structure from wildfire (Cohen 2000). The local characteristics of a home's external materials and adjacent fuels are the primary determinant of home ignitability -- not spatially extensive wildland fuel conditions. For example, the heat released even from intense crown fires will not ignite wooden walls at distances greater than 40 meters away (Cohen 2000). Fuel reduction around a home needs to focus not just on the dead fuels (e.g., the insect-killed trees), but often needs to include some of the live fuels (living trees and shrubs) which also carry fire under severe fire weather conditions. Specific guidelines for reducing fire risk around a home can be found at the Firewise website (Firewise.org) or from extension agents or the Colorado State Forest Service.

Moving up to a broader scale, however, the effectiveness of harvesting insect-killed trees to reduce fire risk across an entire forest landscape is far less certain than the effectiveness of Firewise techniques to protect an individual home. This is especially true in high-elevation forests such as lodgepole pine and spruce-fir. Commercial tree harvest typically involves the removal of large fuels (tree trunks) rather than smaller fuels (branches and needles) due to economic and logistical constraints. These smaller fuels contribute to ignition and spread of fire (e.g., to start a campfire one begins with tinder and kindling). Smaller surface and ladder fuels are important precursors to crown fire initiation (Agee and Skinner 2005). Hence, harvesting tree trunks has little effect on the risk of fire ignition or spread. It is true that if tree harvest also results in reduced canopy bulk density, this may make it more difficult for crown fires to spread. Nevertheless, it is the fine fuels (on the ground or in the canopy) that have the greatest influence on fire initiation and spread, not the large pieces of wood. Thus, management of fine surface or ladder fuels (which is usually time-consuming and expensive) would have the greatest impact on fire spread and potential high-severity crown fire.

It is important to acknowledge that traditional timber management usually is not designed or intended to reduce crown fire risk, but to produce wood fiber in an economically sustainable manner. Although anything that thins the canopy without greatly increasing the amount of fine fuels can reduce fire spread and intensity during moderate weather conditions (Graham et al. 2004), the most damaging wildfires typically occur under extreme conditions of wind and drought. Most traditional harvesting techniques (including overstory removal and individual tree selection) do not effectively reduce fire severity under extreme fire weather conditions (Stephens and Moghaddas 2005). In the 2002 Hayman fire, pre-fire harvesting where residual fuels (small, non-merchantable material) had not yet been removed, actually contributed to higher severity fire compared to unmodified areas (Omi and Martinson, 2002). If the goal is to reduce fire risk, removal of small trees either via mechanical thinning or prescribed fire (or a combination of both), plus retention of large, old-growth trees, can lower expected fire severity (Stephens and Moghaddas 2005, Agee and Skinner 2005). For example, portions of the 2002 Rodeo-Chediski fire in Arizona experienced lower fire severity where prescribed burning and other management activities during the previous decade had reduced fine fuels and small trees, but had left larger trees intact (Finney et al. 2005). Much of the research on thinning and underburning effects on subsequent wildfire severity has primarily been conducted in low-elevation, dry-forest types: similar effects cannot be assumed in high-elevation forests.

A single thinning treatment cannot maintain lowered wildfire risk over the long-term, because thinning typically stimulates rapid growth of the vegetation that is not taken (Graham et al. 2004). Research shows, for example, that past timber harvesting in ponderosa pine forests is responsible in part for the high densities we witness today (Kaufmann et al. 2000, Gruell et al. 1982, Baker et al. 2006). Although low-intensity prescribed burns reduce fine fuels in the short-term, they also contribute to subsequent dead fuels by killing understory trees, which can result in fuel levels that exceed pre-burn levels within a decade (Agee 2003). Therefore, repeated or staged prescribed fire or mechanical thinning treatments are essential for maintaining lower forest densities; otherwise, a one-time thinning may facilitate dense tree establishment.

Thus, it may be possible to reduce fire intensity and to obtain some control of fire spread patterns across a forest landscape by strategic placement of appropriate timber harvest activities, which may need to focus more on removal of small trees than of commercially valuable sawtimber (Finney 2001, Stratton 2004, Graham et al. 2004). Research is underway to develop specific prescriptions for effective use of vegetation management to alter wildfire intensity and spread at the scale of an entire forest landscape, e.g., at the U.S. Forest Service's fire laboratory in Missoula, MT (Mark Finney, personal communication). Another recently developed tool is the Fuel Treatment Evaluator, a web-based program that uses standard U.S. Forest Service inventory data to identify locations offering the greatest opportunities for hazardous fuel reduction activities (Wayne Shepperd, personal communication). However, this research is still in the early stages, and most has been conducted in only a few forest types (notably drier, lower-elevation forests like ponderosa pine). Thus, it is difficult at this time to make confident predictions of how a specific forest treatment will affect fire behavior under a range of forest types and fire weather conditions.

A major source of uncertainty about the effectiveness of landscape-level fuel treatments in altering fire behavior, is the fact that extreme fire weather can over-ride fuel effects (as seen, for example, in Hayman 2002, Routt National Forest 2002, and Yellowstone 1988). In the Hayman fire, most of the vegetation treatments that had been implemented prior to the fire had very little impact on the severity or direction of the fire during the extreme weather conditions of June 9th and 18th, which were the two days when the majority of the area burned (Finney et al. 2003). It should be noted that not all previous vegetation treatments in the Hayman area had been designed to mitigate fire behavior, but were implemented for other objectives such as timber stand improvement -- further illustrating the point that not all timber harvest activities can be assumed to reduce fire hazard. In the 1988 Yellowstone fires, once fuels reached critical moisture levels, the spatial pattern of burning was largely controlled by weather (wind direction and velocity), rather than by fuels (Minshall et al. 1989, Turner et al. 1994). A study of the 2002 fires in Routt National Forest in Colorado found that previous salvage logging had no detectable influence on fire extent or severity during the extreme drought conditions (Kulakowski and Veblen 2006).

In sum, there is no doubt that Firewise activities in the immediate vicinity of vulnerable structures can increase their survivability in a forest fire (though it must be recognized that the risk of fire damage can never be reduced to zero). However, it is far less certain how effective fuel reduction treatments at greater distances from homes will be in protecting those homes. We also note that timber harvest may be conducted for more purely ecological objectives rather than or in addition to protection of homes. In some types of forests, notably Southwestern ponderosa pine, thinning of overly dense small trees can reduce the risk of stand-replacing wildfire and also contributes to a larger goal of forest restoration (Friederici 2003, Schoennagel et al. 2004). But in other forest types, notably lodgepole pine and spruce-fir, thinning of small trees does not represent restoration of more natural conditions, because these kinds of forests are naturally dense and naturally burn at high intensities; fuel management also has less influence on fire behavior in these ecosystems where climate so strongly controls fire occurrence and severity (Schoennagel et al. 2004). We emphasize again the importance of distinguishing among forest types in evaluating the opportunities and impacts of forest management for wildfire mitigation and ecological restoration.

Option #4: Salvaging insect-killed trees to improve overall forest health

<u>Summary</u>: *From a purely ecological standpoint there usually is little or no need to remove insect-killed trees. However, many people do not like to see great numbers of dead trees surrounding their communities or places they like to visit. If the dead trees have a negative impact on aesthetic preferences or local economics, then it may be desirable to remove them (Figure 13).*

As discussed above, “forest health” is an ambiguous concept. From a purely ecological standpoint there usually is little or no need to remove insect-killed trees. In fact, standing snags and fallen logs actually contribute to a number of ecological and aesthetic values in forests, including maintenance of "natural" forest structures and processes, protection of soils and water quality, and preservation of species at risk from the effects of roads, exotic species, and habitat alteration. For example, the three-toed woodpecker feeds on bark beetles in dead and dying trees, and nests most successfully in areas of recent fire or beetle outbreak. Withdrawing all or most of the large dead trees after a fire or insect outbreak will reduce habitat quality for this and other species.

At the same time, there is a widespread public perception that a forest filled with dead or

Figure 13. From a purely ecological standpoint there usually is little or no need to salvage insect-killed trees in the interest of improving forest health. However, if the dead trees have a negative impact on aesthetic preferences or local economics, or if timber production is an important goal in an area, then it may be desirable to remove the dead trees. (photo by J. A. Hicke)

Figure 14. Salvage of insect-killed trees may be a preferred option in some areas because of the economic value of the timber product that can be obtained. In these situations, especially where lodgepole pine trees have been killed by mountain pine beetles, the dead trees must be harvested as soon as possible, because the wood quality deteriorates rapidly after the trees die. (photo by D. Binkley)

dying trees is “unhealthy,” and many people do not like to see great numbers of dead trees surrounding their communities or in places that they like to visit. Whether or not this perception is consistent with what we know about forest ecology, it nevertheless has an impact on aesthetic preferences and local economics. Visitors may choose not to come to a resort surrounded by dead trees; home buyers may avoid locations where the view is one of sick and dying trees. For these and other reasons, efforts to reduce tree mortality (options 1 and 2) and to remove the unsightly results of that mortality (this option), will be the preferred response to insect outbreaks in some locations.

Option #5: Salvaging insect-killed trees for economically valuable products

Summary: *Salvage of insect-killed trees may be a preferred option in some areas because of the economic value of the timber product that can be obtained. In these situations, the trees usually must be harvested as soon as possible, because the wood deteriorates rapidly after the trees die (Figure 14).*

Although salvage of insect-killed trees usually is not necessary for the normal development of the forest, it may be a preferred option in some areas because of the economic value of the timber product that can be obtained. Harvest of large trees for economic reasons can be done in ways that minimize adverse ecological impacts, e.g., by laying out harvest units in spatial patterns that mimic the patterns created by natural disturbances such as fire (e.g., Kohm and Franklin 1997, Friederici 2003, Romme et al. 2003, Perera et al. 2004). If ponderosa pine or lodgepole pine killed by mountain pine beetles are to be salvaged for their timber value, they must be harvested as soon as possible, because the wood deteriorates rapidly after the trees die. However, spruce trees killed by spruce beetles may remain merchantable for decades (Wayne Shepperd, personal communication).

Option #6 -- No treatment

Summary: *Natural ecological processes generally lead to the development of new forests after insect outbreaks, so a "no treatment" option can be a form of responsible forest management (Figure 15).*

Natural ecological processes generally lead to the development of new forests after insect outbreaks and fires, without salvage logging or other operations, so post-outbreak or post-fire treatment usually is unnecessary from a purely ecological perspective. Other choices may be made for other reasons, such as including a logging program to salvage economic value from dead trees or to create more desirable visual conditions (options 4 and 5 above).

Figure 15. Natural ecological processes generally lead to the development of new forests after insect outbreaks, as in this lodgepole pine forest 30 years after a bark beetle outbreak killed more than 50% of the canopy. Thus, a "no treatment" option can be a form of responsible forest management. (photo by W. H. Romme)

Nevertheless, a "no treatment" option can be a form of responsible forest management.

Acknowledgments

We thank the following scientists for critical reviews of an earlier version of this article: Mark Finney, Wayne Shepperd, and Chuck Troendle (retired) of the Rocky Mountain Research Station, U.S. Forest Service; Bob Cain and Claudia Regan of the U.S. Forest Service Region 2; Mike Babler of The Nature Conservancy; Bob Sturtevant of the Colorado State Forest Service and Colorado State University; Dan Binkley of the Colorado Forest Restoration Institute and Colorado State University; and Jim Meiman of Colorado State University. Their comments and suggestions greatly improved this article. We also thank Laurie Huckaby, Rocky Mountain Research Station, for drafting Figure 4.

forest policy

Implementing the 2012 Forest Planning Rule: Best Available Scientific Information in Forest Planning Assessments

C.M. Ryan, L.K. Cerveny, T.L. Robinson, and D.J. Blahna

National forests and grasslands in the United States are governed by land and resource management plans that should be updated every 15 years to reflect changing social, economic, and environmental conditions and to address new priorities. A new forest planning rule finalized in 2012 introduces new planning approaches and requirements, and several forests have completed the forest assessment phase of their planning process. Using document analysis and interview data, we analyzed four completed forest assessments to gain insights into early forest planning efforts under the 2012 rule. We found that forest assessments address the required topics, although the organization and depth of treatment varies across cases; government sources and academic publishers are relied on most often as sources of scientific information; and approaches to best available scientific information rely on peer-reviewed information, agency technical reports and syntheses, and personal expertise and judgement.

Keywords: early adopter, expertise, US Forest Service

Management of the 154 national forests and 20 grasslands in the United States is governed by land and resource management plans (also called forest plans), as required by the National Forest Management Act of 1976 (NFMA; 16 U.S.C. 1604). The forest plan functions as a guiding document that outlines goals, objectives, and strategies for management of the unit. Periodically, the rule related to forest planning is revised to reflect societal changes, new approaches and technologies, and scientific discoveries. For many years the US Forest Service (USFS), which manages the system of national forests and grasslands, has operated under a planning rule finalized in 1982 (47 FR 43026) despite several efforts (2000, 2005, and 2008) to revise and improve the rule (Schultz et al. 2013). A new planning rule issued in April 2012 (77 FR 21161) introduces several significant changes, including a renewed emphasis on collaboration, improved transparency, and a strengthened role for public involvement throughout the planning process. Of interest for our study is the requirement to use the best available scientific information (BASI) to inform the assessment, plan revision decisions, and monitoring program.

To date, little research has addressed implementation of the 2012 planning rule. Schultz et al. (2013) examined approaches to wildlife conservation planning under the new rule, raising concerns regarding potential extirpation of species. Another study analyzed public participation processes in 12 national forests (University of Montana 2015), and Schembra (2013) explored the role of standards and guidelines and how they are used in planning activities. Forest planning under the 2012 rule consists of three phases (assessment, plan development, and monitoring). The assessment phase is important, as it assembles relevant scientific information that planners will rely on to make decisions on forest management in the plan development phase. Our study contributes to this growing body of knowledge by examining the assessment phase of the forest planning process.

Eight "early adopter" national forests, along with several other forests, are currently developing their forest plans using the 2012

rule. These forests were designated as early adopters because they provide important benefits, had strong existing collaborative networks in place, and needed to revise their forest plans (USDA Forest Service 2012a). The eight early adopter forests are: Cibola (NM), Chugach (AK), El Yunque (PR), Nez Perce and Clearwater (ID), and three forests that are coordinating planning on a regional basis: Inyo, Sequoia, and Sierra (CA).

Although implementation is still in early stages, several of the early adopter forests have completed their forest assessments and draft forest plans, which presents an opportunity to study implementation of the planning process under the new rule. One forest (the Francis Marion in SC) has completed the full plan revision process as of this writing. We examined four forests that have completed their assessments, including three forests identified by the agency as early adopters and one forest that is keeping pace with this group. The study explored three questions: 1) What does the 2012 planning rule require regarding the structure, content, and process for forest assessments? 2) How have forests implemented the directives related to forest assessments under the 2012 planning rule? 3) How are forests approaching the requirement for the use of best available scientific information in their assessments?

Forest Planning under the 2012 Rule

The 2012 planning rule suggests an adaptive approach to forest planning, instructing managers to 1) *assess* forest conditions; 2) *revise or amend* plans if the assessment indicates a need for change; and 3) *monitor* plan implementation (36 CFR 219.5). The process is cyclical, with monitoring data feeding back into the assessment of conditions in the management unit (USDA Forest Service 2012b). During the assessment phase, planners are expected to "rapidly evaluate existing information about relevant ecological, economic, and social conditions, trends, and sustainability, and their relationship to the land management plan within the context of the broader landscape" (36 CFR 219.5(a)(1)). The second phase of the planning process is plan development, amendment, or revision, where planners use the results of the assessment to establish a need for change and generate planning alternatives (36 CFR 219.5(a)(2)), and the public has the greatest opportunity for input. The plan development phase includes environmental impact assessment, public input, and plan publication (36 CFR 219.5(a)(2)). The third phase (monitoring) is an opportunity to track and measure management effectiveness over time (36 CFR 219.5(a)(3)). The planning *process* under the 2012 rule is similar to the process specified under the 1982 rule, but differs in terms of the specific elements required for the *assessment* (2012 rule) and the *analysis of the management situation* (the assessment's counterpart in the 1982 rule).

We focused our study on the assessment phase of the planning process. The assessment phase is important because it requires the forest to assemble and synthesize the most recent, relevant, and highest-quality science on social, ecological, and economic conditions to inform the plan development. Not only does this provide planners an opportunity to evaluate changes in biophysical and socio-economic conditions based on the latest monitoring data, it also represents a chance to reflect on new concepts, models, and methods that result in new scientific information about the local forest environment. Under the 2012 planning rule, the assessment phase identifies existing conditions, trends, risks, uncertainties, and information gaps that are relevant to land and resource management issues in the unit (36 CFR 219.5–219.6). In the assessment phase, the planning unit is not required to generate new studies or information, but is expected to obtain pre-existing information that is publicly available or voluntarily provided (36 CFR 219.6). Information can come from government and nongovernment sources, and the rule instructs the Forest Supervisor to provide opportunities for stakeholders to provide information for the assessment (36 CFR 219.6). The primary product of the assessment phase is an assessment document that evaluates existing information for 15 specific topic areas (Figure 1). Although the general topic areas are mandated by the 2012 rule, the Forest Supervisor has discretion to determine the scope, scale, and timing of the assessment, assuming the other requirements in the planning rule are followed (36 CFR 219.6).

Role of Science in Natural Resource Management

Historically, natural resource management in the United States was guided by the idea of scientific management and Progressive-era approaches (Taylor 1896). In particular, Samuel Hays's "gospel of efficiency" relied on a rational and scientific method of making decisions through a single, central authority. The thought was to avoid conflict via a scientific approach to social and economic issues (Hays 1959, p. 267). The US Forest Service exemplifies the approach of technical rationality and empirical science as the basis for sound resource management practices (Wellman 1987; Kaufman 1960). Foresters and natural resource managers

Management and Policy Implications

Although implementation of the US Forest Service's 2012 planning rule is still in the early stages, several national forests have completed the assessment phase and moved on to the next phase of forest planning. Our analysis of forest assessments from several "early adopter" forests illustrates that forest planners are making serious efforts to address required topics and rely on the best available scientific information. Assessment reports were disproportionately heavy in science related to terrestrial and aquatic ecosystems, and more limited in treatment of infrastructure, land ownership and access patterns, cultural heritage, and areas of tribal importance. Ensuring that assessment teams include broad and diverse disciplinary experts will help address this challenge, recognizing that some forests may not have access to necessary disciplinary specialists. It is also possible that some of the topics (e.g., ecosystem services, tribal and cultural resources, land status and use patterns) simply do not have as much relevant and available information as other topics. Assessment teams may want to consider additional ways to interact with scientists and others to create functioning communities of practice related to science exchange for forest planning. In the same way, agency scientists may consider forging new and enduring relationships with planners and managers that could generate new science that is of immediate relevance. We found similarities across all forests in the most common approaches to identifying BASI in addition to other approaches such as data sharing meetings, a wiki review site, and requests for a science synthesis. Information from non-peer-reviewed sources was more difficult for planners to assess and evaluate. Sharing best practices, along with revised guidance for planning rule implementation, may help national forest planners improve the utility, efficiency, and quality of forest assessments.

- Terrestrial ecosystems, aquatic ecosystems, and watersheds
- Air, soil, and water resources and quality
- System drivers, including ecological processes, disturbance regimes, and stressors
- Baseline carbon stocks
- Threatened, endangered, proposed and candidate species; potential species of concern
- Social, cultural, and economic conditions
- Benefits people obtain from the planning area (ecosystem services)
- Multiple uses and their contributions to economies
- Recreation settings, opportunities, and access, and scenic character
- Renewable and nonrenewable energy and mineral resources
- Infrastructure (recreational facilities, transportation and utility corridors)
- Areas of tribal importance
- Cultural and historic resources and uses
- Land status, ownership, use, and access patterns
- Existing designated areas including wilderness and wild and scenic rivers; need and opportunity for new designations

Figure 1. Topics for forest plan assessments (36 CFR 219.6)

are expected to incorporate state-of-the-art scientific knowledge to manage public lands (Lachapelle et al. 2003). However, the role of science in natural resource decision-making has become much more complex (Mills and Clark 2001). Recent literature acknowledges that no important policy issue or decision is purely technical, that established practices are problematic, and that politics are unavoidable (Brunner et al. 2005). In spite of this, numerous policies reflect the scientific management paradigm in their calls for best available science.

In the United States, many policies and statutes contain references to best available science, including the Marine Mammal Protection Act of 1972, the Endangered Species Act of 1973, and the Safe Drinking Water Act of 1974. Despite references to the concept of best available science, these policies do not include specific definitions of its properties, standards, or practical application in the decision-making process (Doremus 2004; Smallwood et al. 1999), leading to different definitions of what it means. Ryder et al. (2010) identify attributes of best available science from published literature that span topics such as endangered species legislation, protection of conservation areas, forest management, water resource management, and ocean fisheries. The paper highlights the diversity of attributes assigned to best available science, and demonstrates that no single attribute is common to all studies, suggesting that best available science is context specific (Ryder et al. 2010). Moreover, as Lowell and Kelly (2016) observe, the ability to use best available science may be inhibited by institutional constraints within particular agencies limited by time or organizational capacity. Other literature has attempted to assign descriptors to the concept. For example, "best" often connotes scientific information with the greatest degree of excellence and authenticity based on sound logic (Moghissi et al. 2010), or that there is no better scientific information, and suggests the use of the most relevant and contemporary data and methods (National Research Council 2004). "Available" connotes scientific information that is accessible and attainable (Moghissi et al. 2010), or that decisions can be consistent with the scientific information that is available even though data gaps exist (National Research Council 2004). "Science or Scientific information" is defined as knowledge that emerges from a process of observation, identification, description, and testing of explanatory hypotheses about fundamental principles that govern cause-and-effect (National Research Council 2004). The National Research Council report includes guidelines for effectively using best available science, including concepts of relevance, inclusiveness, objectivity, transparency and openness, timeliness, and peer review. Finally, Charnley et al. (2017) analyzed a science synthesis for three national forests and suggest criteria for evaluating "best available *social* science," which may be different from the criteria used to evaluate best available biophysical science.

A key aspect of the 2012 planning rule is that it requires the planning process to draw on the best available scientific information (36 CFR 219.3). The preamble to the planning rule notes that there is a range of information that can be considered BASI, stating:

> In some circumstances, the BASI would be that which is developed using the scientific method, which includes clearly stated questions, well-designed investigations and logically analyzed results, documented clearly and subjected to peer review. However, in other circumstances the BASI for the matter under consideration may be information from analyses of data obtained from a local area, or studies to address a specific question in one area. In other circumstances, the BASI also could be the result of expert opinion, panel consensus, or observations, as long as the responsible official has a reasonable basis for relying on that scientific information as the best available. (77 FR 21192 [April 9, 2012])

Planning Directives are agency guidance documents that direct implementation of rules such as the 2012 planning rule, and directives for assessments are in Chapter 10 of the Land Management Planning Handbook (USDA Forest Service 2015a). The definition of BASI is contained in the "zero code" chapter of the handbook and specifies three primary criteria for determining BASI: accuracy, reliability, and relevance (FSH 1909.12.07.12), in addition to referencing the Data Quality Act (PL 106–554) for guidance on evaluating available information (Figure 2). Available is defined as information that currently exists in a form useful for the planning process without further data collection, modification, or validation (FSH 1909.07.01).

The directives also provide guidance regarding sources of scientific information. The sources mentioned in the guidance include peer-reviewed articles, scientific assessments, other scientific information (expert opinion, panel consensus, inventories, or observational data), data prepared and managed by the Forest Service

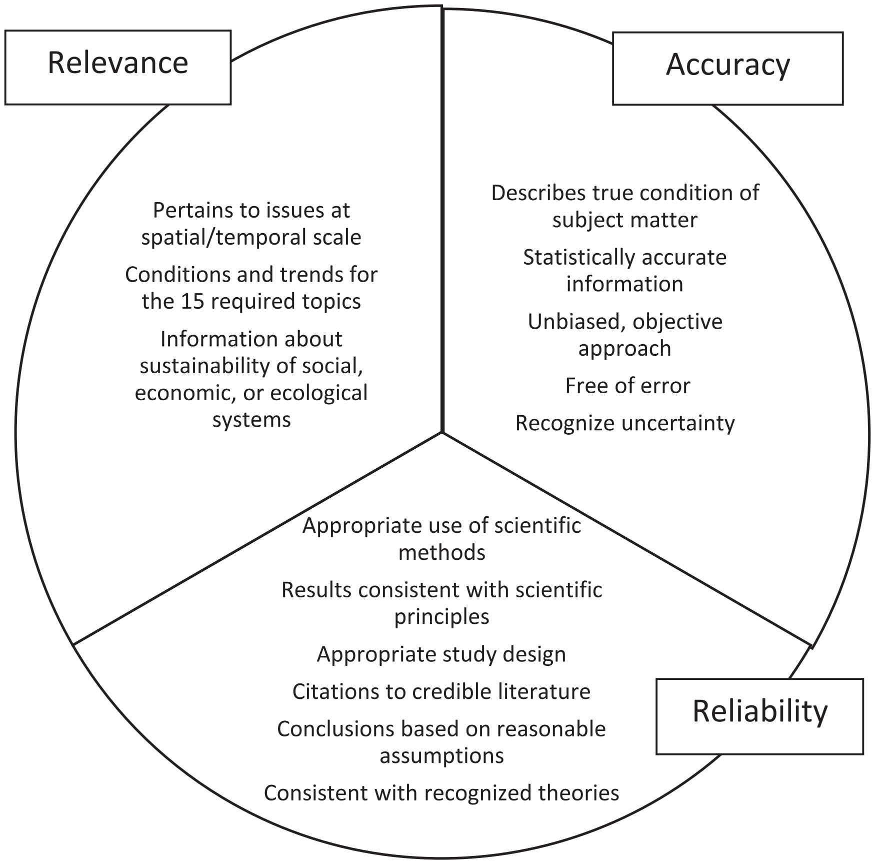

Figure 2. Criteria for determining best available scientific information (BASI). Source: Forest Service Handbook 1909.12.07.12

or other federal agencies, information prepared by universities, national research networks, and other reputable scientific organizations, and data or information from public and governmental participation (FSH 1909.12.07.13).

At the US Forest Service, two regional science synthesis efforts were initiated to assist forest planners in identifying BASI for their assessments. The first synthesis included the Sierra Nevada, southern Cascades, and Modoc plateau areas of California, and informed plan revisions on three national forests (Long et al. 2014). The second synthesis is currently underway as part of the Northwest Forest Plan area planning process, which covers 17 national forests and five Bureau of Land Management units across parts of the Cascade and coastal ranges of Washington, Oregon, and northern California. Once drafted, the synthesis report underwent independent third-party peer review, in addition to public review, and is currently under revision (Spies et al. 2017). Science synthesis efforts represent a noteworthy approach to developing BASI for use in forest assessments, creating a role for public engagement, and for employing a bioregional approach to assembling the latest science for use by multiple forests.

Methods

We used an exploratory case study approach to examine four national forest planning units that were revising their forest plans under the 2012 rule. Information on the USFS website helped us determine the planning status of each national forest as of spring 2015. The primary selection criterion was completion of the assessment process by spring 2015. We also strove to select national forests from different regions. Based on these criteria, we selected the Chugach National Forest (Alaska), Cibola National Forest (New Mexico), Inyo National Forest (California), and the Nantahala and Pisgah National Forests (North Carolina). Table 1 displays characteristics of each national forest planning unit in our sample.

Our research approach relied on content analysis of documents and interview data. We began by conducting a chapter-by-chapter analysis of each forest's assessment report to identify and characterize the information presented. We recorded page counts for each of the 15 assessment topics specified in the 2012 rule. In some cases, the chapters directly aligned with the required topics (Figure 1). In other cases, we had to make a more subjective characterization of the chapter contents. We also noted and analyzed any references to the use of best available science.

Second, as part of the document review, we analyzed data sources used in the assessment. For each assessment report, we identified all of the items cited in the reference section. We then coded each cited item according to the type of publishing entity and the type of document. Every cited item was placed in one category for each coding exercise. For each cited item, we determined the appropriate categories by examining the information in the citation entry and (when necessary) directly reviewing the item or gathering information on the publishing entity. We grouped publishing entities into five types: government; non-government; scientific, scholarly, or peer-reviewed; universities; and unknown or other (Table 2). This categorization approximates the rigor of scientific review, but there is overlap in categories. Most scholarly journals require a double-blind peer-review process, where reviewers and authors are

Table 1. Characteristics of national forests in the study.

Management unit(s)	Geography	Total acreage* (millions of acres)	Notes on use and resources	Designated early adopter?	Most recent previous plan revision	Notes on current plan revision
Chugach National Forest Alaska Region (R10)	Southcentral Alaska: major geographic areas are Cooper River, Prince William Sound, and eastern Kenai Peninsula	6.26	Subsistence, timber, recreation, mining. Human use concentrated in Kenai area. Very limited road coverage and use in other areas. Habitat for all 5 Pacific salmon species	Yes	2002	Managed by a planning team housed within unit
Cibola National Forest Southwest Region (R3)	West-Central New Mexico: Eight noncontiguous parcels organized around distinct mountainous areas known as "sky islands"	2.11	Recreation, timber, cultural heritage, range. Surrounding region experiencing population growth and demographic changes. Pinyon-juniper & ponderosa pine are predominate vegetation types	Yes	1985	Managed by a planning team housed within unit. Does not include 4 associated national grasslands
Inyo National Forest Pacific Southwest Region (R5)	Eastern California & West Nevada: Two noncontiguous parcels at intersection of Sierra Nevada, Great Basin, and Mojave Desert areas	2.07	Water supply, hydroelectricity, recreation, timber, range. Nearly 47% of total area is wilderness. Focus on wildland fire management. Substantial variation in vegetation type, habitat, and elevation	Yes	1988	One of three early adopters in R5. Coordination through a regional planning team, with separate planning teams for each unit. Each unit releases its own assessment & forest plan. Joint EIS for 3 units
Nantahala & Pisgah National Forests Southern Region (R8)	Western North Carolina: Blue Ridge region of Appalachian Mountains	2.48	Timber, recreation, cultural/historical heritage, water development. Located in Blue Ridge National Heritage Area. Hardwood forest with high species diversity	No	1987	Both units will use same revised plan. Managed by planning team housed at NF in NC headquarters

*Total acreage includes NFS-owned land and acreage under other ownership within each unit. Source: USDA Forest Service 2015b.

Table 2. Categories for coding type of publishing entity.

Publishing entity	Description of coding criteria
Government	Federal, tribal, state, or local governments in the United States; foreign governments; international intergovernmental groups such as the United Nations and affiliates. Includes peer-reviewed and non-peer-reviewed materials
Non-government	Materials not published by a government agency, university, or peer-reviewed entity. Includes businesses, consulting firms, and advocacy groups
Scientific scholarly or peer reviewed	Associations, societies, journal publishers, university presses, or other entities that produce peer-reviewed scientific or scholarly material
Universities	Materials from universities that may or may not be subject to rigorous academic peer review. Includes university or college departments, programs, laboratories, and centers, and theses and dissertations from universities
Unknown or other	News organizations or other undefined groups; disposition of publisher could not be determined

unknown to each other. University and government agency scientific documents often require peer review, but the level of rigor of the review may be variable. It was not possible to discern the level or type of peer review or scientific rigor for each category.

For the type of document, we sorted the references into 12 categories: academic book; non-academic book; conference proceeding; correspondence; database; scientific journal; news; technical report; statute or regulation; thesis or dissertation; website; and unknown (Table 3).

Our final data collection activity was qualitative interviewing with members of the planning teams at three of the forests in our study. We conducted nine semi-structured interviews (nine people in total; three interviews each from three forests). Unfortunately, we were not able to recruit interview participants from the Cibola planning effort. Potential interview participants were identified through the list of preparers included in each assessment document. Interviewees were subject matter experts who had contributed material to the assessment reports, along with planning staff officers or coordinators. Interview questions explored the overall structure of the assessment process, the role of the planning directives, the overall organization of the forests' plan revision efforts, and approaches to identification and use of best available science. Interviews were audio-recorded, transcribed, and analyzed using content analysis with a coding framework developed by the study team. Content analysis is a method that uses codes, or labels that assign meaning to descriptive or inferential data collected during a study (Miles et al. 2014). The codes are used to retrieve and organize similar data and aid the researcher in relating data to research questions, theoretical concepts, and themes (Araujo 1995; Miles et al. 2014).

Results

We present results of our analysis in three sections: 1) required topics; 2) sources and types of information; and 3) identifying and using BASI.

Required topics in the forest assessment

The number and percent of pages devoted to each required topic is presented in Table 4. We did not include introductory front matter in the page counts. A 0* entry means that the assessment report did not

Table 3. Categories for coding type of document.

Document type	Description of coding criteria
Academic book	An item printed, bound, distributed as a book, or released as an e-book by a peer-reviewed/scholarly entity
Non-academic book	An item printed, bound, distributed as a book, or released as an e-book by an entity whose primary orientation is not peer reviewed/scholarly
Conference proceeding	Papers, abstracts, and talks presented at a conference and published in a conference proceeding collection
Correspondence	Letters or emails written by individuals of any affiliation
Database	Raw data or data analysis tools/software; online databases
Scientific journal	A peer-reviewed article in a scholarly journal
News	Articles in newspapers (print or online) and news magazines
Technical report	Technical and research reports, white papers, policy papers, fact sheets, briefings
Statute, regulation, and planning documents	Federal, state, or local laws and rules; EISs; management plans; strategic plans
Thesis or dissertation	Advanced degree projects and papers
Website	One or more webpages on a non-database website, including encyclopedias with narrative entries
Unknown	The type of document could not be discerned

Table 4. Page counts and percentages of total pages for 15 required assessment topics.

		Number of pages (pct. of total pages in report)				Pct.
Topic #	Assessment topics (per 36 CFR 219.6)	Chugach	Cibola	Inyo	N&P	Avg.
1	Terrestrial ecosystems, aquatic ecosystems, and watersheds	66 (22.9%)	51.5 (11.2%)	38.5 (21.0%)	29 (15.7%)	**17.7**
2	Air, soil and water resources and quality	17 (5.9%)	88 (19.2%)	9 (4.9%)	19 (10.3%)	**10.1**
3	System drivers (processes, disturbance regimes, and stressors)	40 (13.9%)	21 (4.6%)	15 (8.2%)	7 (3.8%)	**7.6**
4	Baseline carbon stocks	7 (2.4%)	6 (1.3%)	4 (2.2%)	7 (3.8%)	**2.4**
5	Threatened, endangered, candidate species; potential species of conservation concern	12 (4.2%)	36 (7.9%)	24 (13.1%)	4 (2.2%)	**6.8**
6	Social, cultural, and economic conditions	21 (7.3%)	71 (15.5%)	14 (7.7%)	8 (4.3%)	**8.7**
7	Benefits obtained by people (ecosystem services)	49 (17.0%)	0* (0.0%)	2.5 (1.4%)	4 (2.2%)	**5.1**
8	Multiple uses and their contributions to economies	0* (0.0%)	26 (5.7%)	15 (8.2%)	17 (9.2%)	**5.8**
9	Recreation settings, opportunities, and access, and scenic character	29 (10.0%)	39 (8.5%)	15.5 (8.5%)	21 (11.4%)	**9.6**
10	Renewable and nonrenewable energy and mineral resources	17 (5.9%)	18 (3.9%)	3.5 (1.9%)	8 (4.3%)	**4.0**
11	Infrastructure	2 (0.7%)	12 (2.6%)	9.5 (5.2%)	10 (5.4%)	**3.5**
12	Areas of tribal importance	2 (0.7%)	13 (2.8%)	4.5 (2.5%)	3 (1.6%)	**1.9**
13	Cultural and historical resources and uses	3.5 (1.2%)	40 (8.7%)	7 (3.8%)	23 (12.4%)	**6.6**
14	Land status and ownership, use, and access patterns	8 (2.8%)	17 (3.7%)	7 (3.8%)	9 (4.9%)	**3.8**
15	Designated areas, potential/need for new designations	15 (5.2%)	20 (4.4%)	14 (7.7%)	16 (8.7%)	**6.5**
	TOTAL	**288.5**	**458.5**	**183**	**185**	**100**

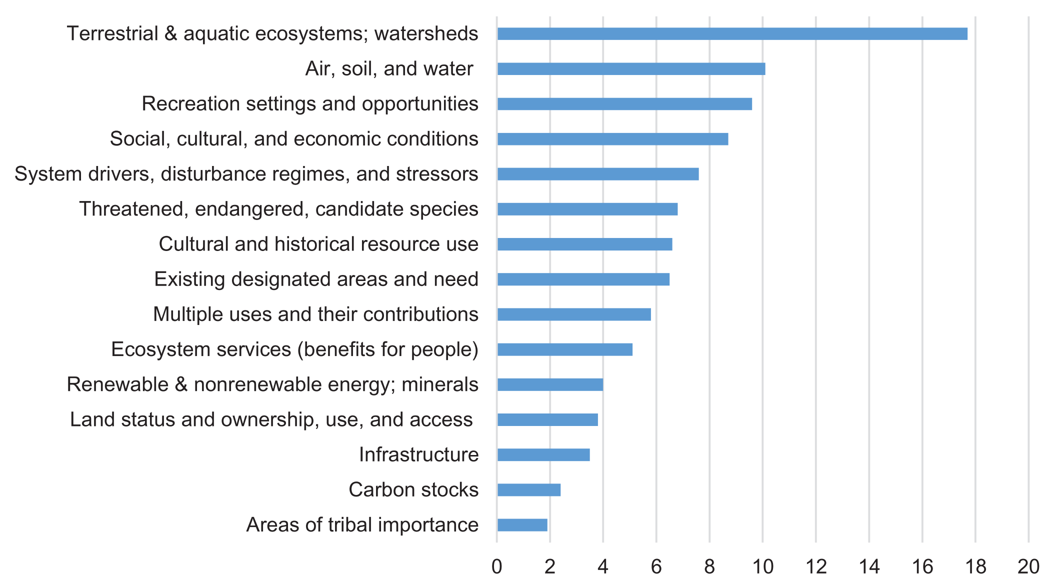

Figure 3. Average percentage of pages devoted to each topic in each forest assessment for all forests combined

have any pages that were specifically devoted to the topic, but references to the topic were instead interspersed throughout the report and it was too difficult to separate them from other topic page counts.

Two of the national forests (Inyo and Nantahala-Pisgah) published assessment reports that consisted of 15 chapters that directly reflected each of the required topics. Meanwhile, the Chugach and Cibola took a different approach; some of the chapter topics aligned with the topic requirements in the 2012 rule, but other required topics were broken up and distributed among multiple chapters. For example, the Chugach had one chapter for areas of tribal importance and one chapter for land status and ownership, but divided the terrestrial and aquatic ecosystems and watersheds

Table 5. Percent allocation of predominant topics among four forest assessments.

Rank	Chugach topics	Pct.	Cibola topics	Pct.	Inyo topics	Pct.	N&P topics	Pct.
1	Terrestrial and aquatic ecosystems	23%	Air, soil, and water	19%	Terrestrial and aquatic ecosystems	21%	Terrestrial and aquatic ecosystems	16%
2	Benefits obtained by people (ecosystem services)	17%	Social, cultural, and economic conditions	16%	Threatened and endangered species	13%	Cultural and historic resources	12%
3	System drivers, disturbance regimes, and stressors	14%	Terrestrial and aquatic ecosystems	11%	Recreation settings and opportunities	9%	Recreation settings and opportunities	11%
4	Recreation settings and opportunities	10%	Cultural and historic resources	9%	System drivers, disturbance regimes, and stressors	8%	Air, soil and water	10%
5	Social, cultural, and economic conditions	7%	Recreation settings and opportunities	9%	Multiple uses	8%	Multiple uses	9%
Total		71%		63%		59%		59%

into five chapters, one each for watersheds, fish, wetlands, vegetation, and wildlife, and these chapters were integrated with material discussing soils and carbon stocks. Two forests did not have any pages specifically devoted to one required topic each (benefits obtained by people for the Cibola, and multiple uses for the Chugach), but these subjects were still referenced in the context of the other topics.

For all four assessments combined, the required topic with the largest average percentage of pages was terrestrial and aquatic ecosystems and watersheds (17.7%), followed by air, soil, and water resources (10.1%) and recreation opportunities (9.6%) (Figure 3).

Terrestrial and aquatic ecosystems and watersheds comprised the largest section of the assessment for three of the four forests. Air, soil, and water was especially prominent for the Cibola National Forest, and all of the forest assessments covered recreation evenly. In contrast, the three required topics with the smallest page counts, on average, were areas of tribal importance (1.9%), carbon stocks (2.4%), and infrastructure (3.4%). Benefits obtained by people (ecosystem services) had the most variable coverage, with one of the shortest sections for three of the four forest assessments, but the second longest topic for the Chugach National Forest. In all four assessment documents, benefits obtained by people were mentioned throughout the document in sentences or paragraphs at too fine a scale for this analysis to count.

We found some variation among the forest assessments in terms of the extent to which a forest focused on a particular topic (Table 5).

For the Chugach National Forest, the top five topics comprised more than 70% of the assessment, with the bulk emphasizing terrestrial and aquatic ecosystems, which reflects the importance of salmon habitat. The Chugach was the only forest to emphasize ecosystem services as a predominant framework to capture benefits obtained by people. However, other forests may have captured this topic under the category of multiple uses. Disturbance regimes (fire and invasive species) were also important for the Chugach. The Cibola National Forest was unique in their emphasis on air, soil, and water as well as social, cultural, and economic conditions and cultural and historic sites. Because water access is very important in the southwest, the predominance of this topic is not surprising. For the Inyo National Forest, the topic of threatened and endangered species was prominent, while topics related to recreation and disturbance regimes (fire, invasive species, and other ecosystem stressors) were also important. Meanwhile, cultural and historical resources were prominent in the Nantahala and Pisgah National Forests, along with recreation.

Although the 2012 rule provides a list of 15 distinct required topics, these topics overlap and are not discussed in complete isolation from one another. As we found in our analysis, it is difficult to discuss multiple uses without also discussing benefits obtained by people; air, soil, and water resources; recreation; and terrestrial and aquatic ecosystems and watersheds. In our analysis, we often found that an assessment chapter devoted to a required topic also contained information that closely resembled material discussed elsewhere. In particular, we found the chapters on multiple uses and benefits obtained by people to be largely redundant, given the other topics that were also included in the report.

Sources and types of information in the forest assessment

To understand the sources and types of information used in the assessments, we conducted a systematic examination and tally of citations by publication source and type. Overall, government sources were the most commonly cited information source (51.8%), followed by scientific scholarly publications (30.7%) (Table 6).

Table 6. Citations based on information source for forest assessments.

	Count (Percent)				
Publishing entity	Chugach	Cibola	Inyo	Nantahala & Pisgah	TOTAL (Mean)
Government	239 (53.6%)	159 (49.8%)	131 (49.8%)	109 (54.0%)	**638 (51.8%)**
Scientific scholarly or peer reviewed	155 (34.8%)	82 (25.7%)	82 (31.2%)	63 (31.2%)	**382 (30.7%)**
Non-government	21 (4.7%)	39 (12.2%)	24 (9.1%)	18 (8.9%)	**102 (8.7%)**
Universities	30 (6.7%)	39 (12.2%)	19 (7.2%)	11 (5.5%)	**99 (7.9%)**
Unknown or other	1 (0.2%)	0 (0%)	7 (2.7%)	1 (0.5%)	**9 (0.9%)**
TOTAL	446	319	263	202	**1230**

Table 7. Citations based on document type for forest assessments.

Document type	Count (Percent)				
	Chugach	Cibola	Inyo	Nantahala & Pisgah	**TOTAL**

News	0 (0.0%)	1 (0.3%)	3 (1.1%)	0 (0.0%)	**4 (0.4%)**
Unknown	0 (0.0%)	0 (0.0%)	3 (1.1%)	0 (0.0%)	**3 (0.3%)**
TOTAL	446 (100.0%)	319 (100.0%)	263 (100.0%)	202 (100.0%)	**1230 (100.0%)**

A large portion of the government sources included US Forest Service publications (average of 28%), which were more commonly cited than other federal government sources (average of 12%) or state and local governments (average of 11%). Some variation exists among the forests in our sample, but the trends were consistent in terms of reliance on government sources and scholarly peer-reviewed publishers for the majority of citations (82.5% combined average for both categories). The Chugach relied to a greater degree on scholarly publications than other forests. The Cibola had the highest proportion from non-governmental organizations and trade groups (12.2%). The Inyo and the Nantahala and Pisgah mirrored the group average.

Next, we explored citations by the type of document referenced. We found that technical reports were the most common type of document cited in the assessments, with an average of 38.5% (Table 7).

The technical report classification is broad and includes technical and scientific reports, policy briefings, white papers, and other types of information (sometimes referred to as gray literature). All four forests were consistent in the ratio of technical reports cited. The second most common document type was the scientific journal article, with an average of 23%, although the Cibola assessment featured far fewer than the other forests. All of the forests cited a wide variety of regulations, statutes, and planning documents, (e.g., water quality regulations, county comprehensive plans, environmental impact statements, state resource management plans, and forest plans). The Cibola assessment featured the greatest variety of document types, relying on websites and academic books more than the other forests. The Nantahala and Pisgah assessment relied more heavily on conference proceedings. The least commonly cited document types, on average, were news articles (0.4%), theses or dissertations (0.9%), and correspondence (1.5%). Although there is a separate category for websites, documents in many of the other categories were readily available online.

Table 8. Approaches to identifying and using BASI from interview data.

BASI approach	Chugach	Nantahala/ Pisgah	Inyo
Literature review (e.g. Google Scholar for scholarly literature)	x	x	x
Forest Service reports, monitoring data	x	x	x

Gray ("non-peer-reviewed") literature, traditional knowledge			x

Identifying and using best available scientific information in the forest assessment

In interviews, respondents were asked how they identified and obtained BASI for their assessment. Table 8 displays the different approaches used by three of the four forests.

Literature reviews and searches, Forest Service reports and datasets, and personal scientific expertise were mentioned by all nine respondents as primary ways that they identified and obtained BASI. Literature reviews focused on identifying peer-reviewed journals, conference proceedings, or agency reports. Existing datasets and nearby Forest Service research stations and universities were also relied upon. The Sierra Nevada science synthesis effort, which informed the Inyo National Forest assessment, took nearly 18 months to complete (Long et al. 2014). The Inyo also posted draft documents on a wiki site for public review and editing. All nine interviewees stated that their assessment team used the Draft Planning Directives, but also mentioned that the directives were not clear, save for the focus on organizing around the 15 topics. No respondent mentioned specific guidance beyond the draft directives on how to identify BASI. The final directives do specifically address the definition of BASI, as discussed above (Figure 2). Gray literature and traditional knowledge presented challenges, as it at times conflicted with peer-reviewed information. Two respondents mentioned that they wanted to incorporate this type of information, but were unsure how to do so.

Assessments must document what information was determined to be BASI, explain the basis for that determination, and explain how the information was applied to the issues considered (36 CFR

219.3). Our analysis of the assessment documents reveals that all documents discuss the use of high-quality and valid scientific information, citing criteria such as clearly defined and well-developed methodology; standardized methodology; logical conclusions; and reasonable inferences (Chugach National Forest 2014; Inyo National Forest 2014; Nantahala and Pisgah National Forests 2014; Cibola National Forest and National Grasslands 2015). The assessments for all forests mention their reliance on information relevant to their specific forests and issues. Only the Nantahala-Pisgah assessment presented a hierarchy of information sources, with peer-reviewed journal articles the highest, followed by government documents and reports, monitoring datasets, theses and dissertations from universities, and expert opinion where facts were not known through the other sources.

Discussion

The 2012 forest planning rule requires that each national forest or grassland conduct a scientific assessment to guide plan development. We found that assessment reports were disproportionately heavy in science related to terrestrial and aquatic ecosystems, and more limited in treatment of infrastructure, land ownership and access patterns, cultural heritage, and areas of tribal importance. Recreation was the only topic to receive consistent attention across all four forests, although the topic was overshadowed by terrestrial and aquatic ecosystems. We may only speculate about why terrestrial and aquatic ecosystem information was the most prevalent in all four forests, but it is consistent with agency administrative hiring practices since the 1980s that have emphasized recruitment of ecologists, biologists, and other biophysical scientists, compared to social scientists, for example (Thomas and Mohai 1995). The abundance of agency specialists in these topic areas may reinforce the relative importance of terrestrial and aquatic ecosystems compared to other topic areas, such as recreation, social science, or cultural resource management. This has been confirmed by a national assessment of interdisciplinary planning team composition (Cerveny et al. 2011). Ensuring that assessment teams include broad and diverse disciplinary experts will help address this challenge, recognizing that some forests may not have access to necessary disciplinary specialists. It is also possible that some of the topics (e.g., ecosystem services, tribal and cultural resources, land status and use patterns) simply do not have as much relevant and available information as other topics.

The benefits obtained by people (ecosystem services) topic received little or no explicit coverage in all but one assessment. The limited coverage of ecosystem services may make sense because it was not even considered an area of research until the late 1990s, so there would be less existing information on certain important ecosystem service topics (e.g., pollination, stormwater attenuation, medicinal resources, and spiritual and historical significance) compared to recreation, threatened and endangered species, and other traditional assessment topics (Blahna et al. 2017). Previously, "forest benefits to people" were considered elements of "multiple use" and planners might have addressed these benefits under the "multiple use" topic. Ecosystem services (ES) are often categorized into four classes: provisioning, regulating, cultural, and supporting. Timber, recreation, wildlife, and other traditional forest planning topics all fall into one of these four classes. Another reason for lack of coverage of ecosystem services may be that planners could not differentiate the normal assessment topics from the ecosystem service classes. Efforts to help planning team members understand ecosystem services approaches and how they can be used to inform the planning process may be warranted, and the rule's current requirement for only using existing data in assessments may need to be revisited (Blahna et al. 2017). For example, implementation teams working on ecosystem services may consider the benefits of providing specific tools, frameworks, and guidelines for integrating ecosystem services models into the forest planning process. In addition, critical issues and topics (e.g., newly listed threatened or endangered species, or changing recreation behaviors) that forest plans need to address may change from one planning cycle to the next.

The specific required topics may not be universally appropriate for every planning unit. Planners felt obligated to address all 15 topics, but the lack of coverage for some topics suggests that the topic was not deemed relevant or meaningful for their plan, there was no available data on the topic, or it was unclear how the topics could be covered. Variability in application of the directives, and acknowledgment of local context and conditions, is consistent with the overall Forest Service approach toward decentralized decision-making (Kaufman 1960; Tipple and Wellman 1991; Koontz 2007) and localized interpretation by planning teams, similar to "street-level" bureaucrats who create de facto policy through everyday practice (Sabatier et al. 1995; Lipsky 2010; Trusty and Cerveny 2012). Kaufman (1960) observes the traditional Forest Service practice of maintaining control of heterogeneous and geographically dispersed management units by issuing centralized directives that provide parameters (or "side boards") within which line officers have some leeway to make decisions. This tendency toward uniformity and "pre-formed" decisions may result in some inefficiencies and omissions. The implied obligation to cover all 15 topics may have resulted in some assessments that distract from the most important management issues for the unit. This will be especially important during the next stage of planning—revision or amendment—where the assessment data will be used to analyze different management scenarios. Approaches for identifying and analyzing the most relevant assessment data that address the key environmental problems or social conflicts that confront each planning unit will be needed (Blahna et al. 2017). This is especially important for topics like human benefits (ecosystem services) and multiple uses, which cut across all of the other topical areas and are not as easily categorized in assessments. Recent efforts to engage the public in science synthesis efforts in support of forest planning suggest that there may be an important role for the public to help prioritize forest assessment topics.

The most common sources of information were government sources, followed by scholarly academic sources. Many of the agency sources were peer-reviewed scientific studies, which appear to be especially useful because of the topical specificity or geographic focus (relevance). Although not all technical reports are peer reviewed, they may be more accessible and usable compared to scholarly journal articles, which may require planning team members to interpret the findings and make inferences for relevance to local conditions. This finding is consistent with previous research examining the information needs and sources of Forest Service fire managers (Ryan and Cerveny 2011) and recreation managers (Ryan and Cerveny 2010). Fire managers relied heavily on agency information sources. Although managers in the study noted the availability of high-quality, relevant information, they faced significant barriers in terms of time, funding,

and personnel to access and use that information. Similarly, recreation managers also relied on agency information sources, but indicated strong preferences for enhanced interactions with agency scientists, including collaborative research, conferences, and a desire for agency researchers to reach out more directly to managers to ensure their research was relevant and useful. With regard to forest assessments, engagement with scientists is particularly important for topics where little research is available. Assessment teams may want to consider additional ways to interact with scientists and others to create functioning communities of practice related to science exchange for forest planning. In the same way, agency scientists may consider forging new and enduring relationships with planners and managers that could generate new science that is of immediate relevance.

The 2012 planning rule and its directives provide criteria for BASI, and we found similarities across all forests in the most common approaches to identifying BASI, in addition to other approaches, such as data sharing meetings, a wiki review site, and requests for a science synthesis. Information from non-peer-reviewed sources was more difficult for planners to assess and evaluate, and it is not clear how this information was incorporated into each assessment. Teams may not have the capacity to separately evaluate and assess the many different types and sources of information, and so they rely on hierarchical ranking approaches (peer-reviewed sources being highest rank) to streamline the evaluation. Planning teams clearly value peer-reviewed and agency-generated information, and it may be that they are simply identifying information that is "available" and using the "best" of that based on their judgments. This may result in situations where the science expertise on each team could influence BASI decisions. As discussed above, consideration of the makeup and membership of the assessment team is important here, as well as increased transparency regarding the process for determining science relevance and quality.

Conclusion

Implementation of the US Forest Service 2012 planning rule is still in its early stages. Our study illustrates that forest planners use a variety of approaches to address required topics, and do rely on BASI as they develop their forest assessments. While each national forest assessment included the 15 required topics, we found considerable variation in coverage, which suggests that planners may emphasize topics most relevant to their forest, or that variation exists in terms of what science or planning team expertise is available or deemed desirable. The predominance of science related to terrestrial and aquatic ecosystems in the assessments compared to other topics warrants further inquiry in order to learn whether this asymmetry is based on policy, availability of information, existing expertise, or other factors. Efforts to include the public in the process of prioritizing topics for the assessments could also be evaluated. The reliance on government sources for scientific information suggests that agency-supported science is either more accessible or more relevant to the planning team. It also suggests that there may be benefits to bolstering "communities of practice" for key topical areas covered by forest assessments that bring together university and agency scientists with managers.

The appearance of science in an assessment report is important, but the actual *use* of science in planning may be more important. Although our findings are not generalizable to all national forests, they do provide an understanding of plan assessment activities for those in the early phases of forest planning, whose efforts are likely to inform and influence other national forests. Our goal was to provide an early glimpse of plan revision efforts in order to highlight important lessons learned and create a foundation for future research. For example, do planners find that the required topics provide useful guidance for developing their assessments? How can planners become more confident in knowing what BASI is, and how to identify and use it? Is additional guidance needed for incorporation of traditional knowledge and other information? Of particular interest is whether the "science synthesis" information is useful to forest planners in addressing their forest assessment needs, given the significant agency resources devoted to developing science syntheses. Finally, how is information from the assessment used in forest plan revision (development and selection of management options) and monitoring efforts? While draft environmental impact assessment (EIS) reports are available in various stages, as of this writing only one final Record of Decision (ROD) has been issued for a forest plan undergoing revision under the 2012 rule. Thus, it remains to be seen how scientific information will be incorporated in development of alternatives, impact statements, and final management decisions.

The Interaction of Fire, Fuels, and Climate across Rocky Mountain Forests

TANIA SCHOENNAGEL, THOMAS T. VEBLEN, AND WILLIAM H. ROMME

Understanding the relative influence of fuels and climate on wildfires across the Rocky Mountains is necessary to predict how fires may respond to a changing climate and to define effective fuel management approaches to controlling wildfire in this increasingly populated region. The idea that decades of fire suppression have promoted unnatural fuel accumulation and subsequent unprecedentedly large, severe wildfires across western forests has been developed primarily from studies of dry ponderosa pine forests. However, this model is being applied uncritically across Rocky Mountain forests (e.g., in the Healthy Forests Restoration Act). We synthesize current research and summarize lessons learned from recent large wildfires (the Yellowstone, Rodeo-Chediski, and Hayman fires), which represent case studies of the potential effectiveness of fuel reduction across a range of major forest types. A "one size fits all" approach to reducing wildfire hazards in the Rocky Mountain region is unlikely to be effective and may produce collateral damage in some places.

Keywords: fire ecology, forest management, forest health, Rocky Mountain forests, climate

The interaction between climate, fuels, and the frequency and severity of wildfires across Rocky Mountain forests is complex. A comprehensive understanding of the relative influence of fuels and climate on wildfires across this heterogeneous region is necessary to predict how fires may respond to a changing climate (Dale et al. 2001) and to define effective fuel management for controlling wildfires in this increasingly populated region (USDA 2002). The annual area burned by wildfires has apparently increased during the last few decades across North America, and in the southern Rocky Mountain region in particular, possibly in response to recent climate change and the gradual accumulation of fuels following decades of effective fire suppression (figure 1; Grissino-Mayer and Swetnam 2000). However, more complete modern records, and an increase in land under federal protection since the 1960s, may also have contributed to this apparent trend over the last half-century. Nonetheless, the United States recently experienced a series of big fire years: According to the National Interagency Fire Center (*www.nifc.gov*), wildfires in 1988, 2000, and 2002 burned 3.0 million, 3.4 million, and 2.8 million hectares (ha), respectively, Most of these fires took place in the western United States, which is characterized by fire-prone ecosystems.

In an effort to mitigate the risk to life and property from wildfires and the high cost of fighting fire throughout the western United States, fuel reduction has become an important forest and fire management tool. In 2002, thinning and prescribed-fire projects were carried out across 1 million ha of federal land as part of the US National Fire Plan (*www.fireplan.gov*) to reduce the fire hazard and to restore historical species composition and stand structures. The goals of fire-hazard reduction and ecological restoration may converge in some ecosystems, yet they may be incompatible in others (Veblen 2003).

The idea that decades of fire suppression have promoted unnatural fuel accumulation and subsequent unprecedentedly large, severe wildfires across western forests was developed primarily from experience in dry ponderosa pine (*Pinus ponderosa*) forests in the US Southwest, the interior West, and the Sierra Nevada (Covington and Moore 1994, Caprio and Swetnam 1995, Moore et al. 1999). Historically, short-interval, low-severity surface fires maintained sparse, open stands in most dry ponderosa pine forests (Swetnam and

Tania Schoennagel (e-mail: tschoe@colorado.edu) is a postdoctoral research associate, and Thomas T. Veblen is a professor, in the Department of Geography, University of Colorado, Boulder, CO 80309. William H. Romme is an associate professor in the Department of Forest, Rangeland, and Watershed Stewardship, Colorado State University, Fort Collins, CO 80523.

Baisan 1996). With fire suppression, young fire-intolerant trees can establish during lengthened fire intervals. Denser stands provide "ladder" fuels at intermediate heights that carry fire up into continuous canopy fuels, promoting unprecedentedly large, catastrophic fires. This system has presented a strong case for thinning to reduce the fire hazard and to restore historical stand structure.

Ecological restoration and fire mitigation are urgently needed in dry ponderosa pine forests, where previous research supports this management action. However, we are concerned that the model of historical fire effects and 20th-century fire suppression in dry ponderosa pine forests is being applied uncritically across all Rocky Mountain forests, including places where it is inappropriate (e.g., USDA 2002, White House 2002). Of particular concern is President Bush's Healthy Forests Initiative, which identifies unnatural fuel buildup as a widespread risk across the West: "Today, the forests and rangelands of the West have become unnaturally dense, and ecosystem health has suffered significantly. When coupled with seasonal droughts, these unhealthy forests, overloaded with fuels, are vulnerable to unnaturally severe wildfires. Currently, 190 million acres [77 million ha] of public land are at increased risk of catastrophic wildfires" (White House 2002, executive summary). This initiative was recently enacted as HR 1904, the Healthy Forests Restoration Act of 2003.

The relative contribution of fuels and climate to recent fire activity across forest types throughout the western United States is hotly debated (e.g., see *Conservation Biology,* vol. 15 [2001]). It is easy to identify either local situations in which fire suppression has allowed unusual fuel accumulations or, by contrast, those in which fuel conditions remain within the historical range and the effects and frequency of fire are controlled primarily by weather conditions, not by fuels. What is lacking is a broad synthesis of the geographical patterns in historical fire regimes, and of 20th-century changes in these regimes, addressing these key questions:

- Where, in what ecosystem types, and to what degree have fuels increased with fire suppression across the Rocky Mountain region (Arizona, New Mexico, Colorado, Utah, Wyoming, Montana, and Idaho)?
- Where are forest restoration treatments appropriate, and how will fire respond to fuel-reduction treatments in different forest types?
- Where and when is the influence of short-term (i.e., seasonal and annual) climatic variation expected to override the effectiveness of fuel treatments?

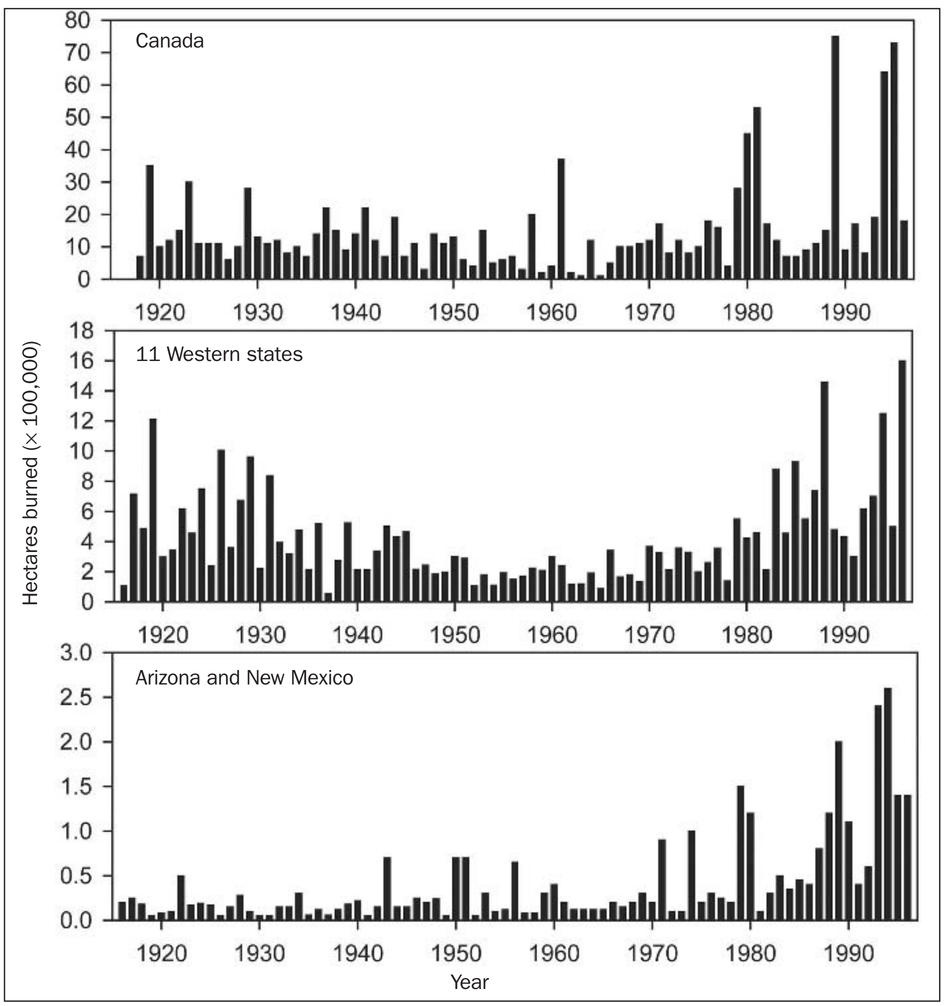

***Figure 1. Area burned by wildfires in different regions under federal protection across North America. The apparent increase in the extent of fires over the last century is most pronounced in the southwestern United States (Arizona and New Mexico), although we urge caution in interpreting these trends. Source: Grissino-Mayer and Swetnam (2000); reprinted with permission from* The Holocene.**

To address these questions, we synthesize current understanding of the different types of fire regimes (defined by the historical range of variability in fire size, severity, and frequency) that occur across the Rocky Mountain region. The fire regime is a central concept in fire ecology and is essential for understanding the character, effect, and variability of disturbance patterns across regions. Our analysis of different fire regimes is based on the classic fire triangle of weather, fuels, and ignition, which identifies the factors controlling combustion. All three factors must be present in a form conducive to combustion, or fire will not occur. However, the inherent variability, and therefore the limiting role, of these three ingredients is dramatically different among forest types and geographic regions. For example, we argue below that fuel types and amounts are less limiting to fire spread in subalpine forests than in low-elevation forests, but suitably dry weather conditions for fire spread in subalpine forests occur infrequently. Hence, variability in seasonal and annual climate is more limiting and has a greater influence on fire extent and severity in these generally cool, moist ecosystems.

In contrast, periods of several months of warm, dry weather occur almost annually in most southwestern ponderosa pine forests, leaving fuels sufficiently desiccated for extensive fires to occur annually. Given the higher frequency of weather conditions that desiccate fuels in this ecosystem, factors that affect fuel type, quantity, and configuration are more limiting than climate in controlling this fire regime. Variations in local site productivity, and in the time elapsed since the last fire event, affect fuel accumulation in the dry, low-elevation ponderosa pine forests. Annual climatic variation affects fuels indirectly in these forests both through short periods of above-average moisture availability, which enhance the production of fine fuels (e.g., leaves, grasses, forest litter), and through fuel-desiccating drought. But overall, climate is more limiting in subalpine forests, where short-term (i.e., months to a few years) variability in climate primarily affects fire severity and spread through fuel desiccation and wind, not fuel abundance. In contrast, the fire regime in dry ponderosa pine woodlands is more limited by annual variability in fine fuel amounts and by ladder-fuels related to the time elapsed since the last fire. Ignition sources also may be important, at least locally, but in this study we do not identify spatial patterns in this component of the fire regime. Assuming instead that ignition sources are always available, we evaluate the relative importance of variability in short-term climatic variation and in fuel quantity and configuration.

We identify three major types of historical fire regimes (Agee 1998): (1) high severity, (2) low severity, and (3) mixed severity. In addition to developing a general theoretical framework for assessing controls on local fire regimes, we summarize the lessons learned from three recent large wildfires (the 1988 Yellowstone fires and the 2002 Rodeo-Chediski and Hayman fires). These case studies reveal the potential effectiveness of fuel reduction under varying climate conditions across a range of major forest types and historical fire regimes. Finally, we develop coarse estimates of the spatial extent of the three major historical fire regimes to broadly quantify heterogeneity in fire regimes and responses to fire suppression across the Rocky Mountain region.

To develop coarse estimates of the proportion and extent of historical fire regimes across the Rockies, we rely on research reported in the peer-reviewed literature to group major forest types that historically experienced each of the three major fire regimes we discuss. Because it is relatively difficult to define the spatial extents of different fire regimes at this scale, we rely on two independent maps of forest cover to highlight general trends and degrees of uncertainty in the relative proportion of major fire types across the Rocky Mountain region. In the first analysis, forest types are based on a map of Küchler's potential natural vegetation (PNV) groups (climax vegetation types that are expected, given the occurrence of natural disturbances such as fire, based on site characteristics such as soils, climate, and topography), modified by Schmidt and colleagues (2002). In our reclassification of these data, we combine eight PNV groups into three main forest types: (1) ponderosa pine (pine forest and Great Basin pine), (2) mixed ponderosa pine (pine–Douglas fir, Douglas fir, grand fir–Douglas fir, and Southwest mixed conifer [Arizona, New Mexico]), and (3) spruce–fir (spruce–fir and spruce–fir–Douglas fir). In the second analysis, forest types are based on a map of current cover types, which Schmidt and colleagues (2002) developed by combining the Forest and Range Resource Planning Act map of US forest type groups with AVHRR (Advanced Very High Resolution Radiometer) satellite imagery. In our reclassification of these data, we combine the current cover types into three main forest types, similar to those obtained by combining the PNV groups: (1) ponderosa pine, (2) Douglas fir, and (3) spruce–fir–lodgepole pine.

In this summary, we assume a one-to-one correspondence between forest types and fire regimes; however, as we emphasize throughout the text, this is a considerable oversimplification. Nonetheless, this summary reveals coarse levels of heterogeneity in fire regimes across the Rocky Mountain region, unaccounted for in current forest policy debates. Other endeavors to define fire regimes at this scale include the work of Schmidt and colleagues (2002), who developed a map of historical fire regimes and departures from historical conditions throughout the continental United States for strategic fire-planning purposes, but who relied primarily on managers' expert knowledge rather than on peer-reviewed empirical studies in defining fire regimes. In addition, McKenzie and colleagues (2000) developed a regional model of fire frequency within the interior Columbia River basin, based on a large fire-history database from the western United States.

Overall, our analysis highlights the heterogeneity of forest types and fire regimes across the Rocky Mountain region. Further, it provides insight into pressing management questions of when and where various fuel treatments are consistent with the goal of ecological restoration, and where such treatments are likely to be successful in reducing the size and severity of wildfires. We focus on the Rocky Mountain region; however, the spatial and geographic heterogeneity in fire regimes across this region is also evident throughout the West (e.g., Agee 1998).

High-severity fire regimes

High-severity or stand-replacing fires are defined by the death of canopy trees, in contrast to low-severity fires, which do not kill overstory trees. High-severity fires typically burn the treetops (crown fires) but may also kill trees through very hot surface fires, which primarily burn the forest floor.

High-elevation subalpine forests in the Rocky Mountains typify ecosystems that experience infrequent, high-severity crown fires (Peet 2000, Veblen 2000). The forest types that occur in the subalpine zone range from mesic spruce–fir forests to drier, dense lodgepole pine stands; and xeric, open woodlands of limber and bristlecone pine. The most extensive subalpine forest types are composed of Engelmann spruce (*Picea engelmannii*), subalpine fir (*Abies lasiocarpa*), and lodgepole pine (*Pinus contorta*), all thin-barked trees easily killed by fire.

Extensive stand-replacing fires occurred historically at long intervals (i.e., one to many centuries) in subalpine forests (Romme 1982, Kipfmueller and Baker 2000, Veblen 2000, Schoennagel et al. 2003), typically in association with infrequent high-pressure blocking systems that promote extremely dry regional climate patterns (Romme and Despain 1989, Renkin and Despain 1992, Bessie and Johnson 1995, Nash and Johnson 1996). Persistent high-pressure blocking systems affect regional temperature and precipitation patterns throughout the Rockies and may respond to global climate anomalies (Baker 2003). Regional synchrony of large, high-severity fires across subalpine forests corroborates the idea that high-elevation forest fires respond to broad scale synoptic climate (Nash and Johnson 1996, Kipfmueller and Baker 2000, Veblen 2000, Baker 2003). In moist high-elevation forests, successive seasons of drought can initiate large, stand-replacing fires (Balling et al. 1992, Kipfmueller and Swetnam 2000). In these generally cool subalpine environments, significant drought events are infrequent, which prevents the frequent occurrence of large, high-severity fires. Although they occur infrequently, drought-induced large fire events account for the greatest percentage of the area burned in subalpine forests (figure 2; Bessie and Johnson 1995).

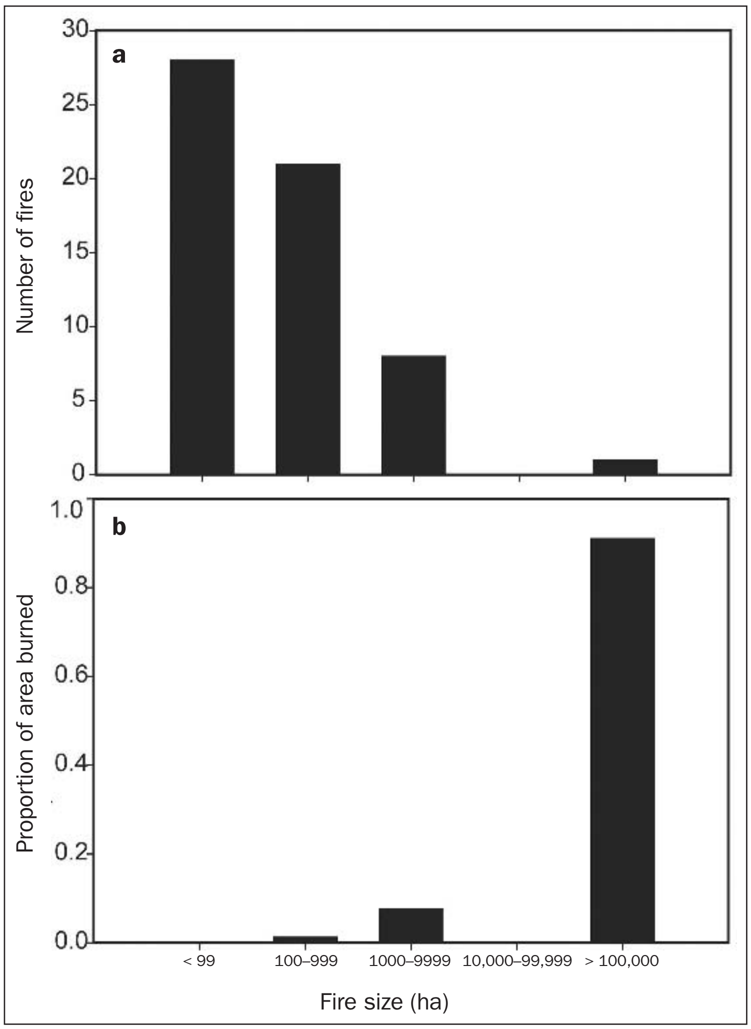

Figure 2. (a) Histogram of the occurrence of different size classes of stand-replacing fires in Yellowstone National Park (1895–1991). (b) Proportion of the total area burned in each size class for the same period (1.0 = 100% of total area). Although large stand-replacing fires (i.e., fires that burn more than 1000 hectares) are infrequent, they are the dominant influence on subalpine forests. Data are from Balling and colleagues (1992).

Subalpine forests typically experience stand-replacing crown fires, rather than low-severity surface fires, because they lack fine fuels on the forest floor but have abundant ladder fuels that carry fire into the treetops. These dense, closed-canopy forests typically support sparse understory vegetation, and the short, stout needles of subalpine trees compact tightly on the forest floor, creating a poor substrate for fire spread (Swetnam and Baisan 1996). This is in stark contrast to the warmer, open-canopied, productive forests at lower elevations, which support abundant, well-aerated fine fuels on the forest floor (Swetnam and Baisan 1996). Although fine surface fuels are sparse in subalpine forests, ladder fuels are abundant. Shade-tolerant fir and spruce trees have abundant lateral branches, which easily carry fire up into the canopy. By contrast, shade-intolerant lodgepole pines have few lateral branches, but these trees tend to grow in very dense stands that thin over time, contributing to abundant dead ladder fuels (figure 3). The abundance of ladder fuels, the proximity of crowns, and the lack of abundant, spatially continuous fine surface fuels all promote high-severity crown fires that dominate subalpine forests.

The low abundance of small fuels, and the relatively high abundance of large dead and live fuels, explains why fires are infrequent but typically large in subalpine forests. Fuel moisture levels respond to ambient environmental conditions and are critical in determining fire potential. Small-diameter dead fuels dry quickly; for example, 1-hour fuels (particles less than 0.6 centimeters [cm] in diameter) approach equilibrium with ambient relative humidity within an hour. By contrast, dead branches, logs, or other large, slow-drying materials (7.6 to 20.3 cm in diameter) are known as 1000-hour fuels because they require 1000 hours to equilibrate (figure 4). Live fuels dry even more slowly than dead fuels and are influenced most strongly by sustained periods of drought. Because of the paucity of small dead fuels such as needles and grasses in subalpine forests, short-duration drying episodes generally do not create sufficiently dry conditions to sustain a fire. However, prolonged dry weather conditions (about 40 days without precipitation) can sufficiently dry live fuels and larger dead fuels to carry large, intense fires once they are ignited (figure 5). Conditions necessary for large fires are infrequent and often coupled with the occurrence of lightning. This suggests that Native Americans probably did not have a major influence on fires in the subalpine forest types, except in some localized areas.

The recent period of consistent, effective fire suppression in remote high-elevation sites, which has lasted 50 years at most, represents only a small portion of typical fire-free intervals in subalpine forests. Studies of fire history show that long fire-free periods (as long as, or longer than, the fire exclusion period during the 20th century) characterized the fire regimes of these forests before Euro-American settlement (Romme 1982, Romme and Despain 1989, Kipfmueller and Baker 2000, Veblen 2000, Schoennagel et al. 2003). Therefore, it is unlikely that the short period of fire exclusion has significantly altered the long fire intervals in subalpine forests (Romme and Despain 1989, Johnson et al. 2001, Veblen 2003). Furthermore, large, intense fires burning under dry conditions are very difficult, if not impossible, to suppress (Wakimoto 1989), and such fires account for the majority of area burned in subalpine forests (figure 2; Romme and Despain 1989, Bessie and Johnson 1995). At lower elevations within its range, lodgepole pine may also experience occasional small surface fires (Kipfmueller and Baker 2000), but their spatial extent and frequency are not well quantified. Suppression of smaller, less intense fires under moderate climate conditions probably has had little influence on the dominant fire regime in subalpine forests (Johnson et al. 2001, Veblen 2003). Our understanding of the dominant fire regime in these high-elevation, cool forests leads us to conclude that any recent increases in area burned in subalpine forests are probably not attributable to fire suppression. Evidence from the subalpine forests of Yellowstone indicates that fires of comparable size to the 1988 fires occurred in the early 1700s (Romme and Despain 1989).

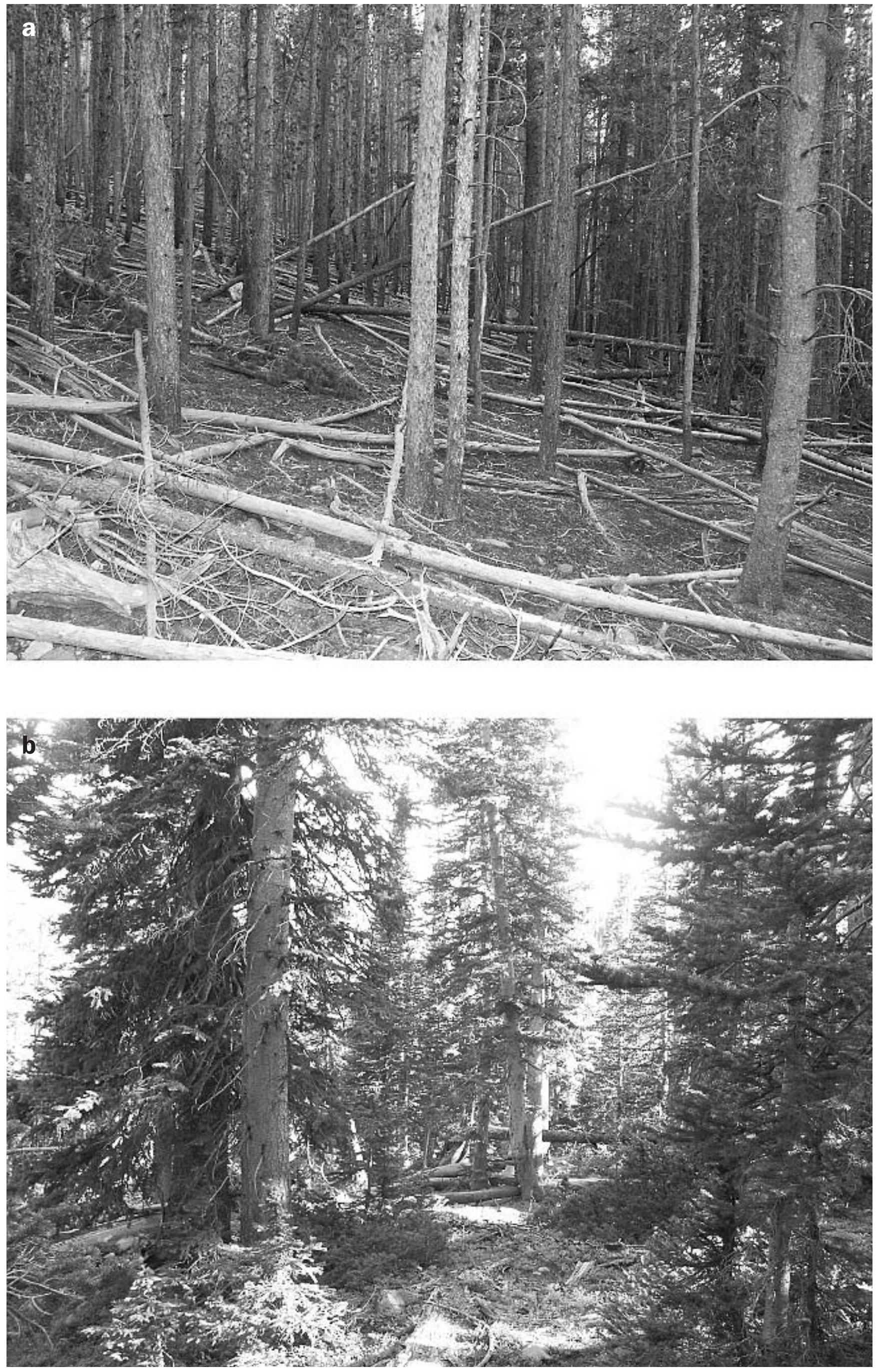

Figure 3. Typical subalpine forest stand structure, which easily carries fire into the canopy, promoting high-severity crown fires. (a) Lodgepole pine stand with sparse understory fuels and high tree densities. (b) Spruce–fir stand with abundant live ladder fuels throughout the vertical profile. Photographs: Tania Schoennagel.

Moreover, there is no consistent relationship between time elapsed since the last fire and fuel abundance in subalpine forests (Brown and Bevins 1986), further undermining the idea that years of fire suppression have caused unnatural fuel buildup in this forest zone. For example, lodgepole pine stands experience high rates of self-thinning that contribute large dead fuels as stands mature (Kashian 2003). However,

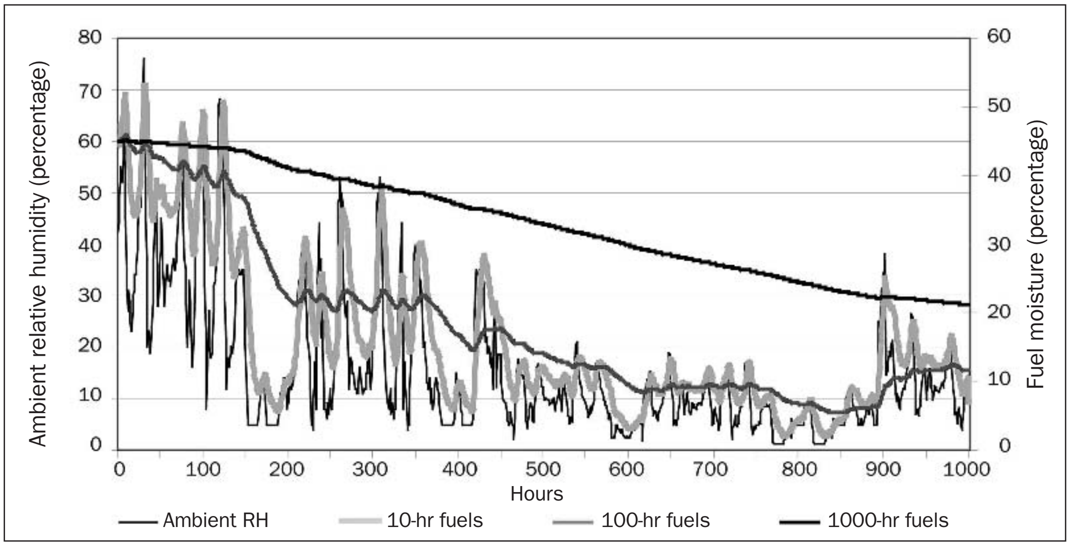

Figure 4. A theoretical example illustrating differences in fuel-moisture time lags for small (10-hour), intermediate (100-hour), and large (1000-hour) fuels. Small fuels dry out rapidly and respond more quickly to short-term variability in ambient relative humidity, while large fuels exhibit a more lagged response, requiring much longer dry periods to reach similar dryness.

the legacy of wood from the prefire stand contributes abundant loads of large fuel to young postfire stands (Romme 1982). Bessie and Johnson (1995) report little variation in total fuel loads, relative to variation in weather, in subalpine forests of different ages. No evidence suggests that spruce–fir or lodgepole pine forests have experienced substantial shifts in stand structure over recent decades as a result of fire suppression. Overall, variation in climate rather than in fuels appears to exert the largest influence on the size, timing, and severity of fires in subalpine forests (Romme and Despain 1989, Bessie and Johnson 1995, Nash and Johnson 1996, Rollins et al. 2002). We conclude that large, infrequent stand-replacing fires are "business as usual" in this forest type, not an artifact of fire suppression.

Case study: The 1988 Yellowstone fires. In 1988, according to the National Interagency Fire Center, more than 700,000 ha burned in mostly high-elevation subalpine forests throughout Wyoming, Montana, and Idaho. Yellowstone National Park was the focus of public attention during these fires. Some 40% of the park burned, much of it at high severity (Turner et al. 1994). Drought, which had started years earlier, extended beyond its immediate region during the summer of 1988. From 1977 to 1989, a strong Pacific North America pattern developed, creating a blocking ridge over the northwestern United States that reduced winter snowpack across Montana and Wyoming (Baker 2003). Low winter snowpack in 1988, followed by an unusually dry, hot, and windy summer, contributed to extreme burning conditions in the park (Balling et al. 1992). Precipitation in July and August was only 20% of normal levels; relative humidity fell to 6%; and strong, dry, gusty winds (60 to100 kilometers [km] per hour) spread multiple fires ignited by humans and lightning.

Variation in daily area burned was highly correlated with the moisture content of 100-hour (2.5- to 7.6-cm diameter) and 1000-hour dead fuels (Turner et al. 1994). Once fuels reached critical moisture levels later in the season, the spatial pattern of the large, severe stand-replacing fires was controlled by weather (wind direction and velocity), not by fuels, stand age, or fire-fighting activities (Minshall et al. 1989, Wakimoto 1989, Turner et al. 1994). Variation in fuel abundance and topography (including formidable barriers such as the Grand Canyon) had little influence on the severity or direction of the fire when fuel moistures were critically low (Turner et al. 1994). Stand-replacing fire affected stands of all ages, including some as young as 7 years old (Schoennagel et al. 2003).

Contrary to popular opinion, previous fire suppression, which was consistently effective from about 1950 through 1972, had only a minimal effect on the large fire event in 1988 (Turner et al. 1994). Reconstruction of historical fires indicates that similar large, high-severity fires also occurred in the early 1700s (Romme and Despain 1989). Given the historical range of variability of fire regimes in high-elevation subalpine forests, fire behavior in Yellowstone during 1988, although severe, was neither unusual nor surprising.

Summary: High-severity fire regimes in subalpine forests. Subalpine forests that experience infrequent, high-severity fires cover approximately 32% to 46% of the forested area in the Rocky Mountain region, which encompasses the three major forest types discussed in this article (table 1). The following insights are drawn from analyses of historical fire regimes and contemporary fire behavior in subalpine forests.

- Infrequent, high-severity, stand-replacing fires dominate the historical and contemporary fire regime in these forests.
- Climatic variation, through its effects on the moisture content of live fuels and larger dead fuels, is the predominant influence on fire frequency and severity.
- Dense trees and abundant ladder fuels are natural in subalpine forests and do not represent abnormal fuel accumulations.

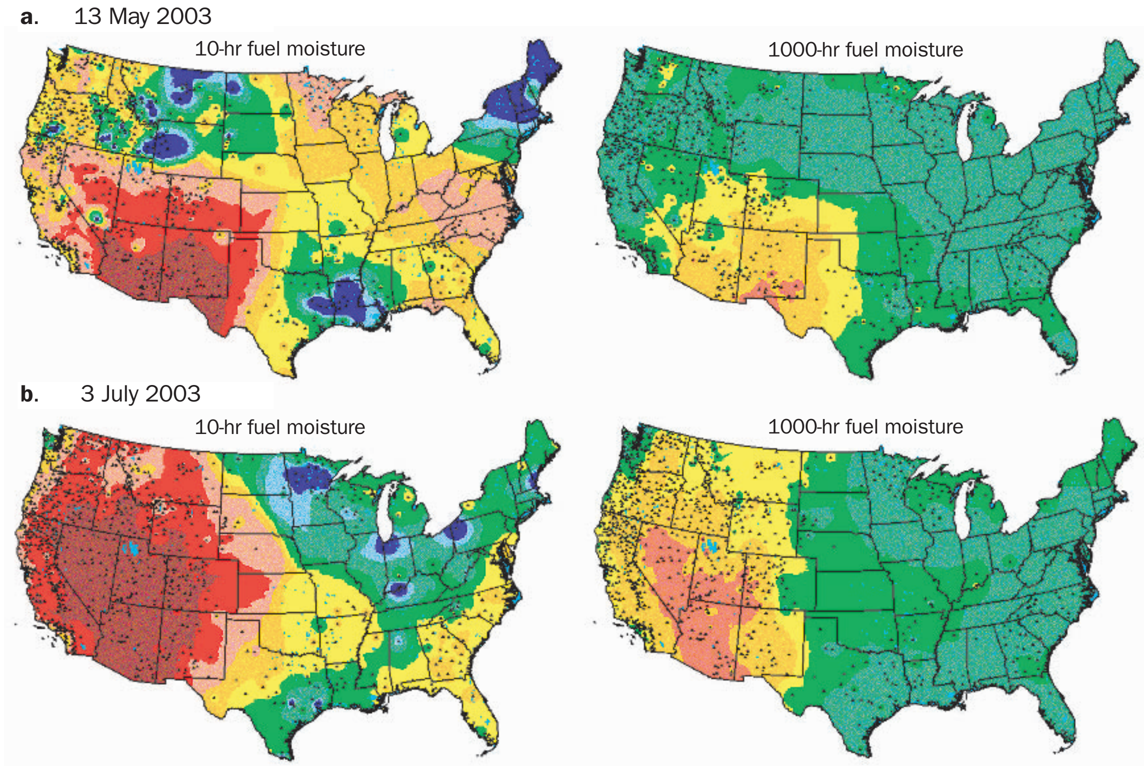

Figure 5. Maps of fuel moisture for small (10-hour) and large (1000-hour) fuels, showing responses to (a) short-term (1- to 2-day) and (b) longer-term (1- to 2-month) drying conditions in the southwestern United States. Large fuels dry sufficiently to carry fire only under longer drying conditions, while smaller fuels may dry sufficiently to carry fire under short-term or moderate drying conditions. The maps were developed by the National Interagency Fire Center (17 June 2004; **www.fs.fed.us/land/wfas/wfas10.html**).

- Fire suppression has had minimal influence on the size, severity, and frequency of high-elevation fires.
- Mechanical fuel reduction in subalpine forests would not represent a restoration treatment but rather a departure from the natural range of variability in stand structure.
- Given the behavior of fire in Yellowstone in 1988, fuel reduction projects probably will not substantially reduce the frequency, size, or severity of wildfires under extreme weather conditions.

Low-severity fire regimes

In marked contrast to the infrequent, high-severity fire regimes characteristic of subalpine forests, many low-elevation ponderosa pine forests historically experienced frequent, low-severity fires. A meta-analysis of 63 fire histories from similar-size southwestern ponderosa pine sites (10 to 100 ha) indicates that surface fires returned at mean intervals of 4 to 36 years (based on fire dates recorded for more than 10% of the sampled trees; Swetnam and Baisan 1996), an order of magnitude shorter than the intervals for subalpine forest stands. Some low-elevation ponderosa pine stands in Colorado, near the Plains grasslands, show evidence of 8- to 10-year intervals for fire returning to the same small stand or tree before the 1900s (Veblen et al. 2000). In the Black Hills of South Dakota, the mean fire interval was 20 to 23 years at each of four low-elevation ponderosa pine sites (about 100 ha each) for the period from 1388 to 1900 (Brown and Sieg 1996). Although detailed comparison of fire-interval statistics across study sites is problematic because of differences in the extent of the study area and the intensity of sampling, these studies clearly indicate a significant difference in fire interval and severity between low-elevation, dry ponderosa pine forests and high-elevation, moist subalpine forests.

Frequent, low-severity fire regimes occurred predominantly in dry, low-elevation ponderosa pine forests that were formerly open woodlands with abundant, contiguous fine fuels in the understory. This surface fuel layer, dominated by grasses and long cast needles, dries easily and thus promotes the spread of frequent surface fires. Historically, climate, fine-fuel abundance, and fire were highly interrelated in dry, low-elevation ponderosa pine forests. El Niño–Southern Oscillation (ENSO) patterns correlate tightly with the incidence of synchronous, low-severity fires in dry, low-elevation forests of the Southwest (Swetnam and Baisan 1996, Grissino-Mayer and Swetnam 2000, Kitzberger et al. 2001). The ENSO cycle alternates between El Niño and La Niña conditions at

Table 1. Two coarse estimates of the extent and proportion of three major forest types across the Rocky Mountain region (Arizona, New Mexico, Colorado, Utah, Wyoming, Montana, and Idaho). The first estimate is based on a map of Küchler's potential natural vegetation groups, modified by Schmidt and colleagues (2002). The second estimate is based on a map of current cover type developed by Schmidt and colleagues (2002). A different historical fire regime is associated with each of the three forest types, although the correspondence is not exact.

Forest type	Area (hectares)	Percentage of total	Associated severity of historical fire regime
Based on PNV groups			
Ponderosa pine (pine forest, Great Basin pine)	8,201,600	17.7	Low
Mixed ponderosa pine (pine–Douglas fir, Douglas fir, grand fir–Douglas fir, Southwest mixed conifer)	23,176,200	49.9	Mixed
Spruce–fir (spruce–fir, spruce–fir–Douglas fir)	15,056,000	32.4	High
Total	46,433,800	100.0	
Based on current cover types			
Ponderosa pine	13,009,100	36.7	Low
Douglas fir	6,176,000	17.4	Mixed
Spruce–fir–lodgepole pine (lodgepole pine, fir–spruce)	16,287,200	45.9	High
Total	35,472,300	100.0	

PNV, potential natural vegetation.

Note: Total is the forested area in the Rocky Mountain region defined by the three major forest types listed. Some other forest types, such as piñon-juniper woodlands, are not included.

2- to 6-year frequencies. In the southern Rockies, El Niño years are characterized by wetter-than-average winter and spring conditions, which enhance the growth of fine fuels (especially grasses). Drier-than-average La Niña years typically follow, desiccating abundant fine surface fuels. Time-lag analysis shows that dry, low-elevation ponderosa pine forests commonly experience more extensive fires when wetter conditions 1 to 3 years before a fire are followed by dry conditions during the year of the fire. Infrequent or anomalous prolonged drought conditions are not the primary factor promoting fires in dry, low-elevation pine forests, as they are in subalpine forests. Summers in the low-elevation forests are typically dry enough to promote low fuel moisture levels that would permit ignition, although the abundance and continuity of fine surface fuel historically were the primary limiting factors (Swetnam and Baisan 1996, Rollins et al. 2002).

Unlike the historical fire regime in subalpine forests, the fire regime in dry, low-elevation ponderosa pine forests has been significantly altered as a result of fire suppression and its effects on historical fuel structure (Arno and Gruell 1983, Swetnam and Baisan 1996, Veblen et al. 2000). Before fire suppression, the frequent, low-severity surface fires in these forests kept dry ponderosa pine stands sparse and open by killing young, newly established trees. With fire suppression and livestock grazing (which reduces the amount of grass fuel), fire intervals have lengthened, and dense stands have developed in which fine grass fuels are less abundant and dense ladder fuels are capable of carrying fire up into the canopy (figure 6). Consequently, high-severity fires potentially can occur in dry ponderosa pine forests, where historically they were rare because of the sparse ladder fuels and the lack of contiguous tree crowns. This pattern has been well documented on the basis of fire scars, repeat photography, and stand age structures, especially for forests in Arizona and New Mexico (Covington and Moore 1994, Allen et al. 1998, Mast et al. 1999, Moore et al. 1999), for some sites in the Colorado Front Range (Veblen and Lorenz 1991, Brown et al. 1999, Kaufmann et al. 2000), and for portions of the Bitterroot Range in Montana (Gruell 1983, Arno et al. 1995). As a consequence of fire suppression, the size and occurrence of high-severity fires has increased in this forest type. Reduction of ladder fuels through mechanical thinning and prescribed fire can effectively reduce the unprecedented occurrence of extensive crown fires and restore the historical surface fire regime in dry, low-elevation ponderosa pine forests (Covington et al. 1997, Allen et al. 2002, Fule et al. 2002).

Case study: The 2002 Rodeo-Chediski fire complex. The Rodeo-Chediski fire, which burned 189,095 ha in northern Arizona from 18 June through 7 July 2002, was the largest Arizona fire in recorded history. The area burned was dominated by ponderosa pine, with isolated pockets of mixed conifers at higher elevations along the Mogollon Rim, where the northern half of the fire burned. Fire-history studies conducted before the fire, in nearby ponderosa pine stands, record frequent surface fires with mean fire intervals of 7 to 10 years (based on fires recorded by more than 10% of sampled trees in 10- to 100-ha study areas; Swetnam and Baisan 1996). In 2002, high-severity crown fire affected 48% of the Rodeo-Chediski fire area, an extent of severe burning that is unprecedented in the low-elevation, dry ponderosa pine forests of this area.

The summer of 2002 marked the fourth year of drought in the Southwest. That May had been the second driest on record across Arizona and New Mexico in 108 years. Levels of fuel moisture before the fire were unusually low: 7% in 1000-hour fuels, as low as 2% in 10-hour (0.6- to 2.4-cm diameter) and 100-hour fuels, and below critical thresholds in live pine and brush fuels (Wilmes et al. 2002). The Haines index is a measure of lower-atmosphere stability and dryness correlated with wildfire growth. Low values (2 or 3) indicate moist, stable conditions; the highest values (5 or 6) represent dry, unstable conditions that favor moderate to high fire activity. The Haines index was 6 on many days during the Rodeo-Chediski fire.

Prescribed fire, salvage logging in previously burned stands, and fuel-reduction treatments (including the removal of slash, or woody debris, from branches and treetops) were effective in reducing fire severity and spread in the Rodeo-Chediski fire, even under extreme weather conditions (figure 7; Wilmes et al. 2002), as predicted by restoration research in Arizona (Fule et al. 2002). High-severity crown fires affected 35% of the stands that had been treated within the last 15 years, compared with 55% of the untreated stands. The average stand density of treated and untreated stands was 387 and 1108 trees per hectare, respectively. All prefire fuel treatments appeared to lower burn severity except for precommercial treatments, which increased it. In precommercial treatments, slash (branches and tree tops) was lopped and scattered throughout the stand, which contributed to higher fuel loads than those in untreated stands. Areas that had high forage production and low tree density experienced less severe burning during the Rodeo-Chediski fire, suggesting that open stands with abundant fine surface fuels were more resistant to high-severity canopy fire (figure 8). Overall, burn severity was positively correlated with overstory tree density (Wilmes et al. 2002). This outcome, in clear contrast with the findings from Yellowstone (where weather rather than fuel type and arrangement influenced fire behavior), highlights the heterogeneity of forest types and fire effects across the Rocky Mountain region.

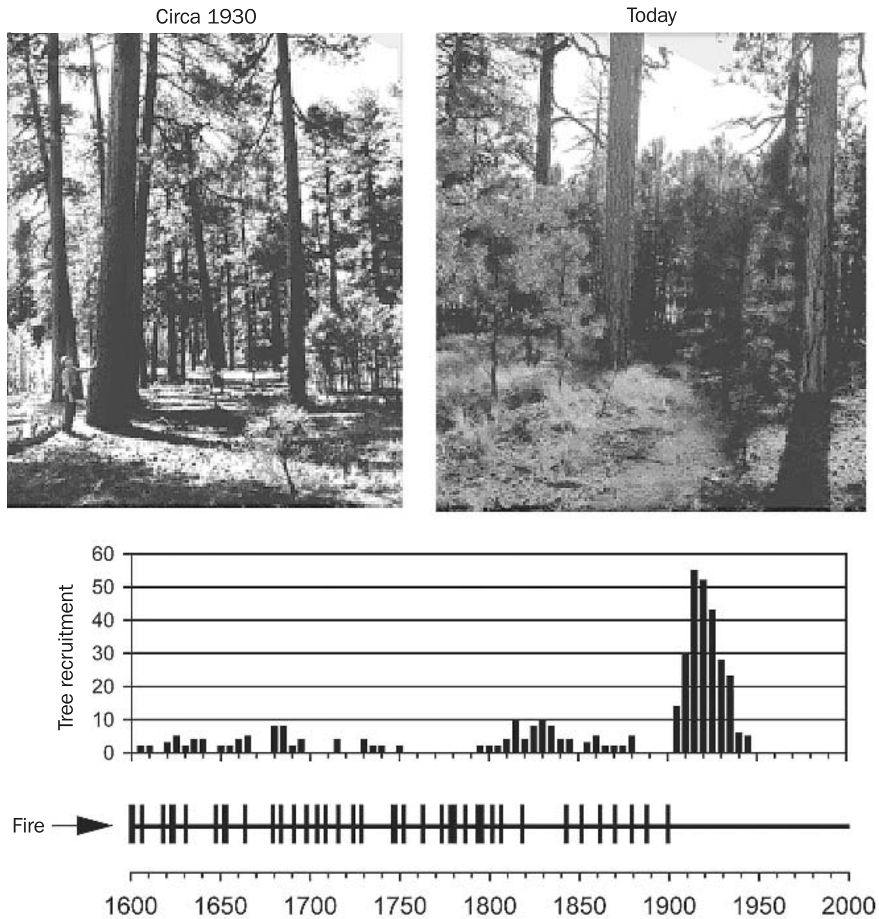

Figure 6. A comparison of historical and contemporary stand structure of dry ponderosa pine stands from the Jemez Mountains of New Mexico, and the relationship of this change to the frequency of low-severity surface fires. Source: Modified from Allen et al. 1998.

Summary: Low-severity fire regimes in low-elevation ponderosa pine forests. Dry, low-elevation ponderosa pine forests in the Rocky Mountain region, which were historically characterized by frequent low-severity fire regimes, make up an estimated 19% to 37% of the forested area that encompasses the three forest types discussed in this article (table 1). Such historically sparse forests, subject to high-frequency fires, comprise much of the ponderosa pine forest in Arizona and New Mexico but only a small fraction of the ponderosa pine forest in the central and northern Rockies. Regional modeling of fire regimes, based on a large fire-history database from the western United States, similarly predicts decreasing fire frequency from southern to northern latitudes (McKenzie et al. 2000). Important lessons about fire regimes in dry, low-elevation ponderosa pine forests are listed below.

- The historical fire regime in these forests was characterized by frequent, low-severity surface fires.
- Historically, the frequency, size, and severity of fires were largely controlled by spatial and temporal variation in fine fuels.
- Fire suppression has significantly increased tree densities and ladder fuels in low-elevation ponderosa pine forests.
- As a consequence of this change in stand structure, unprecedented high-severity fires now occur.

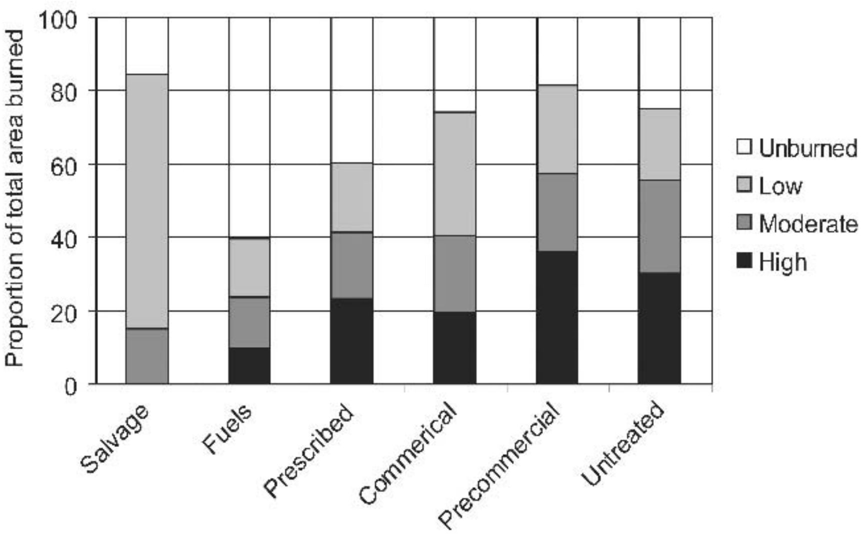

Figure 7. Proportion of different prefire fuel treatments burned at different severities during the Rodeo-Chediski fire in the Apache-Sitgreaves National Forests, Arizona, 2002. Burn severity, defined by the Burned Area Emergency Rehabilitation team **(www.fs.fed.us/r3/asnf/salvage/publications/proj_record/001_rodeo_baer_report_7-29-02.pdf),** ***ranges from unburned (surface fire with little or no canopy damage, tree foliage unscorched) through low severity (some tree crowns scorched but most trees not killed) and moderate severity (variable tree mortality, foliage scorched but not consumed) to high severity (complete tree mortality, foliage completely consumed). Fuel treatments are defined as salvage (removal of trees after a fire), fuels (thinning, chipping, and pile burning), prescribed fire (broadcast burning), commercial (removal, seed cut, regeneration, harvest, partial removal, final cut, or thinning), or precommercial (thinning with chipping, lopping, or both; no slash removal). Data are from Wilmes and colleagues (2002).***

- Fuel-reduction treatments involving mechanical thinning and prescribed fire are likely to be effective in mitigating extreme fire behavior and restoring this forest type to the historical fire regime.

Mixed-severity fire regimes

Mixed-severity fire regimes are intermediate between the infrequent, high-severity fire regimes of high-elevation subalpine forests and the frequent, low-severity fire regimes of dry, low-elevation ponderosa pine forests. Both high- and low-severity fires can occur at varying frequencies in mixed-severity fire regimes. This fire regime occurs predominantly at mid elevations, where topographic variation creates a complex moisture gradient resulting in a mosaic of tree species and densities that is sometimes referred to as mixed conifer forest. There is also evidence of mixed-severity fire regimes that predate fire suppression in some forests dominated by ponderosa pine, and even in pure or nearly pure ponderosa pine stands at low to mid elevation (Veblen and Lorenz 1986, Mast et al. 1998, Kaufmann et al. 2000, Ehle and Baker 2003).

Historically, forests that experienced mixed-severity fire regimes had variable densities of ponderosa pine, Douglas fir (*Pseudotsuga menziesii*), grand fir (*Abies grandis*), and western larch (*Larix occidentalis*), depending on their location. These forests constituted a mosaic of even-aged stands resulting from stand-replacing fire, interspersed with uneven-aged stands that experienced low-severity surface fires and episodic tree regeneration (Arno 1980, Brown et al. 1999, Kaufmann et al. 2000). Pre-1900 stand-replacing fires in these forest types have been documented by historic photographs and by the occurrence of even-age stand structures whose age corresponds to that of fire scars on adjacent trees (Gruell 1983, Veblen and Lorenz 1986, 1991, Arno et al. 1995, Swetnam and Baisan 1996, Shinneman and Baker 1997, Mast et al. 1998, Brown et al. 1999, Kaufmann et al. 2000, Ehle and Baker 2003). Low-severity fires are also well documented by historic photographs, fire scars, and all-age stands that include centuries-old trees, although these surface fires usually occurred less frequently than in the lower-elevation dry ponderosa pine forests described above (Arno 1980, Veblen and Lorenz 1991, Swetnam and Baisan 1996, Brown et al. 1999, Moore et al. 1999, Kaufmann et al. 2000, Veblen et al. 2000). The relative importance of surface versus crown fires and the size of these post-disturbance patches in shaping forests of mixed-severity fire regimes remain uncertain and have probably varied spatially and temporally.

Since the late 19th century, the densities of relatively fire-intolerant and shade-tolerant species, such as Douglas fir and grand fir, have increased in response to the suppression of low-severity fires in areas that historically experienced mixed-severity fire regimes (Arno et al. 1995, Kaufmann et al. 2000). Increases in density probably have occurred more commonly at lower elevations, on drier aspects, and adjacent to grasslands where frequent, low-severity fires were more dominant historically. Sites that previously supported denser stands because of favorable topographic and edaphic conditions have probably changed less as a result of fire suppression; those sites historically experienced stand-replacing fires, and high stand densities are a normal part of the postfire recovery process (Veblen and Lorenz 1986, Arno et al. 1995, Mast et al. 1998, Kaufmann et al. 2000, Ehle and Baker 2003). With fire suppression, forests that historically experienced mixed-severity fire regimes have developed a more homogenous forest structure across the landscape, resulting in larger areas of continuously dense forest and perhaps in larger patches of crown fire than were witnessed historically. In some areas, tree regeneration following logging of these forests in the late

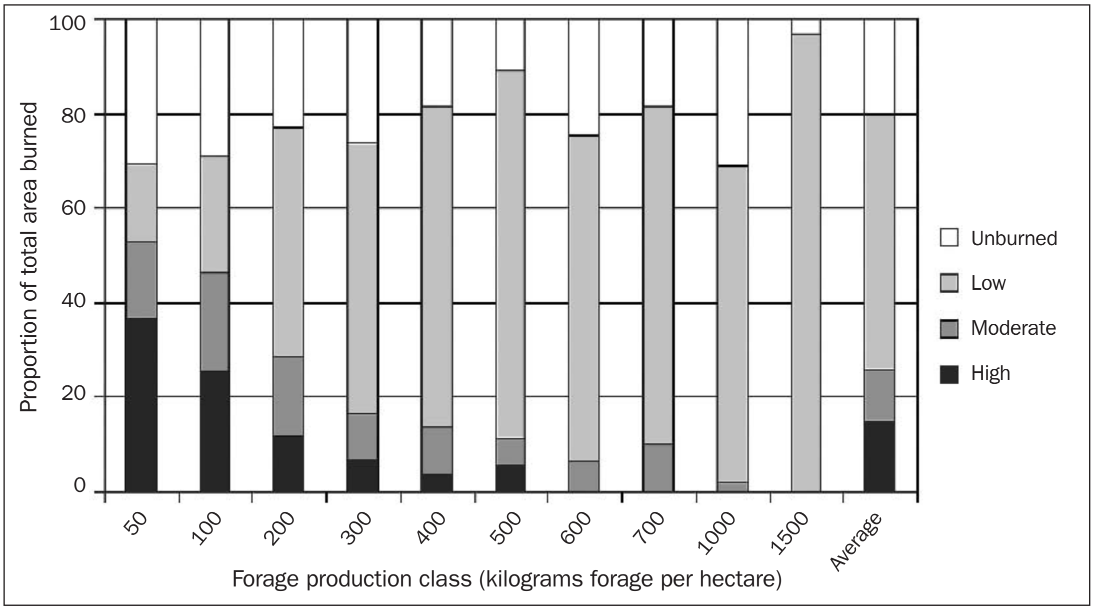

Figure 8. Proportion of different forage production classes burned at different severities during the Rodeo-Chedeski fire in relation to forage production classes for Carlisle and Town Tank allotments on the Lakeside Ranger District, Apache-Sitgreaves National Forest. Data are from Wilmes and colleagues (2002).

19th and early 20th centuries has contributed to high stand densities (Veblen and Lorenz 1986, Kaufmann et al. 2000). Overall, fire suppression has probably significantly affected only sites within the mixed conifer zone at lower elevations, on drier aspects, and adjacent to grasslands where fires historically were more frequent. Therefore, current fire regimes and stand densities in mixed conifer forests are likely to be within the historical range of variability, or at least are not likely to be as far outside this range as those in the dry ponderosa pine forests discussed above (Veblen 2003). However, additional research is needed on the causes of variability in mixed-severity fire regimes and the attendant effects of fire suppression.

In mixed-severity fire regimes, climate and fuels interact in a complex manner to control the frequency and severity of fires. Arno (1980) describes this interaction in mixed-severity fire regimes: "Under severe burning conditions, especially with strong winds, fires sometimes crowned and covered sizeable areas. When conditions moderated, fire would creep along the ground, with occasional flare-ups. Often the major fires burned at several intensities in reaction to changes in stand structure, fuel loadings, topography, and weather. The result was a mosaic of fire effects on the landscape" (p. 463). In mixed-severity regimes, in contrast to the previous two types of fire regime discussed, both climate and fuels (surface and ladder fuels) vary considerably and are important drivers of fire frequency and severity. We look to the example of the Hayman fire to tease apart these interactions in more detail.

Case study: The 2002 Hayman fire. The Hayman fire burned a 55,915-ha area southwest of Denver, Colorado, where previous fire history and forest structure studies (Brown et al. 1999, Kaufmann et al. 2000), mechanical fuel treatments, and burns (wild and prescribed) had occurred. Making use of this unplanned experiment, researchers assessed the relative effect of fuels and climate on fire behavior in the area, which had a historical mixed-severity fire regime (Finney et al. 2003).

Short-term drought during the 5 years before the fire created important antecedent conditions. In particular, below-normal precipitation and unseasonably dry air masses had persisted since 1998, when drier-than-average La Niña conditions began to develop. These conditions persisted intermittently through the spring of 2002. As a consequence, the Colorado Front Range received low snow during the winters of 2001 and 2002, with snowpack recorded in May 2002 at less than 50% of normal levels. By spring 2002, measurements of large-fuel moisture (moisture in 100-hour and 1000-hour fuels) in mid- to low-elevation forests of the southern Rockies were among the driest in the previous few decades, dipping as low as 3% when typically they exceed 12% (Graham 2003).

The size and severity of the Hayman fire can largely be explained by the extreme fire activity during two separate periods associated with sustained, exceptionally dry, forceful winds. First, on 9 June, the fire grew from 485 to 24,700 ha (43% of the total fire size); later, on 18 June, it traveled 5 miles along its southeastern flank (figure 9). During these two periods, mean relative humidity dipped below 8%, maxi-

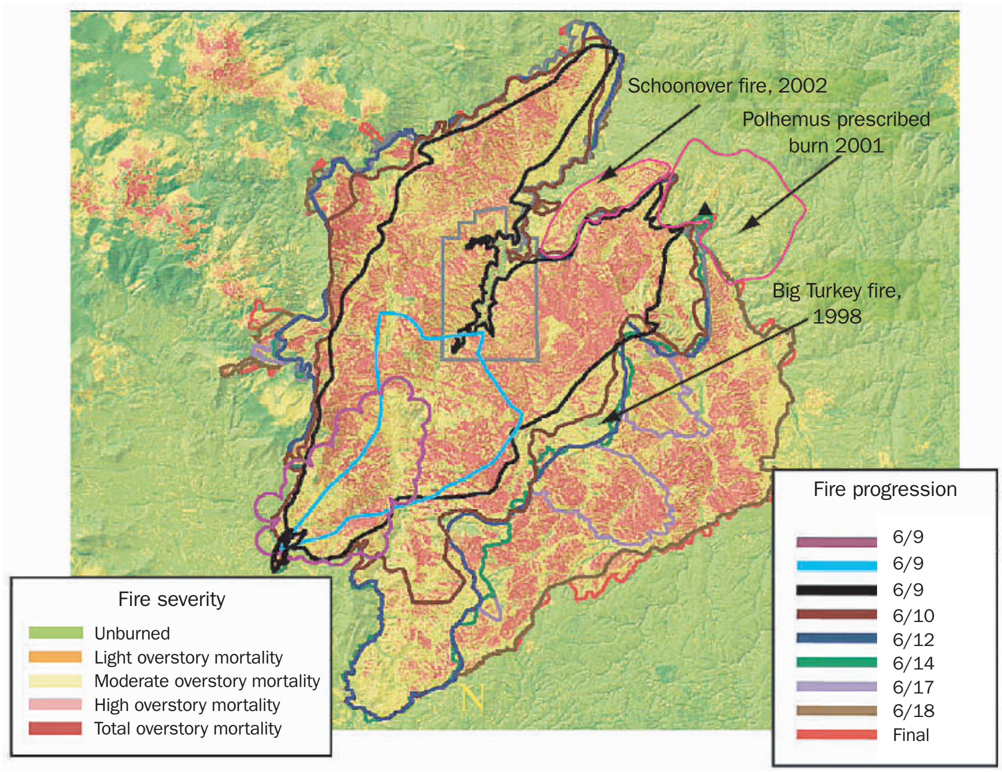

Figure 9. Map of the Hayman fire progression during the period 9–18 June 2002. Note the significant progress of the fire on 9 June (black line) and 18 June (brown line). Not all days are shown, because fire perimeters on slow-growth days overlapped previous days. Burn severity classes are based on the difference-normalized burn ratio from the US Geological Survey's National Burn Severity Mapping Project. Gray line represents the Cheesman Reservoir boundary, pink lines represent the perimeter of recent burns. Source: Modified from Finney and colleagues (2003).

mum wind gusts reached 84 miles (135 km) per hour, and the Haines index was 6, marking very dry, unstable conditions conducive to high fire spread. Both periods produced extensive torching, crown fire, and spotting (firebrands thrown in advance of the fire). These high-activity periods terminated with the passage of fronts followed by upslope winds that substantially increased ambient relative humidity (Finney et al. 2003).

During the substantial fire-progression days of 9 and 18 June, most fuel treatments had very little impact on the severity or direction of the fire (Finney et al. 2003). On 9 June, for example, the burned area included more than 2400 ha that had experienced previous prescribed fires or other fuel-reduction treatments. These treatments, which included previous wildfires (in 1963 and 1998), prescribed fires (in 1990, 1992, 1995, and 1998), and numerous stand modifications with and without subsequent slash removal (table 2), had virtually no effect on the Hayman fire. This is in marked contrast to the behavior of the Rodeo-Chediski fire, whose severity was affected by previous fuel-reduction treatments even under extreme climate and weather conditions. In the Hayman fire, extreme weather conditions overwhelmed the effectiveness of most fuel treatments. However, the fire stopped abruptly at the edge of the area that had been burned by two fires months to weeks before, in fall 2001 (Schoonover fire) and May 2002 (Polhemus prescribed burn), where very little fuel had accumulated during a spring of extreme drought (figure 9; Finney et al. 2003). Overall, the direction, severity, and size of the fire on extreme days were mostly explained by high wind and low relative humidity (table 3), with little effect of past fire or thinning activity. The Hayman review team concluded that "fuel modifications generally had little influence on the severity of the Hayman Fire during its most significant run on June 9th" (Finney et al. 2003) but acknowledged that the small size of these treatments contributed to their lack of effectiveness. On days of moderate fire growth, however, fuel modifications did influence fire spread and severity; of these modifications, recent wild or prescribed fires and thinning with slash removal were most effective. In an example of the interactions between fuels and climate, on 17 June the Hayman fire split into two runs on either side of the area burned by the Big Turkey fire in 1998 (figure 9); however, when the weather became more extreme the following day, this effect on fire shape and extent was obliterated (figure 9; compare 17 June and 18 June perimeters).

Table 2. Distribution of fire severity classes among fuel-modified areas on moderate slopes (defined as slopes of less than 30%) that burned in the Hayman fire on 9 June 2002.

Level of prefire fuel modification	Area (ha)	Fire severity class (percentage) Unburned	Low	Moderate	High
Unmodified	9128	4	18	8	70

Summary: Mixed-severity fire regimes in the Rocky Mountain region. Mixed-severity fire regimes account for an estimated 17% to 50% of the forested area in the Rocky Mountain region that encompasses the three major forest types discussed in this article (table 1). These forests experience the most complex type of fire regime and the least understood. Nonetheless, we have learned several important lessons about mixed-severity fire regimes in Rocky Mountain forests.

- The historical fire regime in these forests is complex, including both low-severity surface fires and infrequent high-severity crown fires.
- Both fuels and climate have major influences on the frequency, severity, and size of fires.
- Fire suppression has had variable effects on fuel densities in mixed-severity fire regimes, with the greatest impacts on sites that formerly supported open woodlands.
- The occurrence of high-severity crown fires is not outside the historical range of variability, although their size and frequency may be increasing.
- Extreme climate and weather conditions can override the influence of stand structure and fuels on fire behavior.
- Fuel-reduction treatments (mechanical thinning and prescribed burning) may effectively reduce fire severity under moderate weather conditions, but these treatments may not effectively mitigate fire behavior under extreme weather conditions and may not restore the natural complexity of historical stand and landscape structure.

Implications for fire mitigation and restoration

What does an understanding of the spatial variation in dominant controls on wildfire frequency and severity mean for ecological restoration and for effective fuel treatments to reduce the threat of large, severe wildfires? The Yellowstone fires in 1988 revealed that variation in fuel conditions, as measured by stand age and density, had only minimal influence on fire behavior. Therefore, we expect fuel-reduction treatments in high-elevation forests to be generally unsuccessful in reducing fire frequency, severity, and size, given the overriding importance of extreme climate in controlling fire regimes in this zone. Thinning also will not restore subalpine forests, because they were dense historically and have not changed significantly in response to fire suppression. Thus, fuel-reduction efforts in most Rocky Mountain subalpine forests probably would not effectively mitigate the fire hazard, and these efforts may create new ecological problems by moving the forest structure outside the historic range of variability (Veblen 2003, Romme et al. 2004).

In contrast, for many low-elevation, dry ponderosa pine forests, it is both ecologically appropriate and operationally possible to restore a low-severity fire regime through thinning and prescribed burning (Covington et al. 1997, Allen et al. 1998, 2002). Fuels rather than climate appear to be the most significant factor affecting fire spread and severity in these forests. Fire suppression in dry ponderosa pine forests appears

Table 3. Comparison of the mean and range of weather indices associated with the type (high, moderate, or low) of fire-growth days during the Hayman fire, 9 June to 18 June 2002.

		Mean (range)			
Fire-growth days	*n*	Relative humidity (percentage)	10-minute average wind (kph)	Maximum wind gust (kph)	Haines index
Low	4	36.6 (8–68)	11.2 (0–30.4)	22.4 (3.2–57.6)	3.7 (2–6)
Moderate	4	27.6 (5–76)	11.2 (0–28.8)	24 (1.6–54.4)	4.2 (2–6)
High	2	7.8 (5–15)	16 (1.6–48)	38.4 (3.2–134.4)	5.7 (5–6)

kph, kilometers per hour.

Note: The Haines index, ranging from 2 to 6, measures the moisture and stability of the lower atmosphere; low values indicate moist, stable conditions, and high values indicate dry, unstable conditions conducive to fire. The two high fire-growth days occurred on 9 and 18 June. High- and moderate fire-growth days are identified on the Hayman fire progression map (figure 9); low fire-growth days are those omitted from the map because fire perimeters were not significantly different from previous days. Data are summarized from Finney and colleagues (2003).

to have contributed to an unprecedented buildup of fuels and to the occurrence of high-severity fires. Indeed, the objectives of fire mitigation and forest restoration generally converge in forests of this type.

Perhaps the most difficult forests to assess are the mid-elevation forests that historically were characterized by mixed-severity fire regimes. Because mixed-severity fire regimes are most complex and least well understood, we must exert caution in developing simple prescriptions for wildfire mitigation that may not bring predictable results under extreme climate conditions. Our analysis reveals that fire regimes, climate, fuel type and abundance, and stand structure vary significantly across the Rocky Mountain region. As a consequence, the heterogeneous forests in this region require very different approaches to restoration and wildfire management (Gutsell et al. 2001). Clearly, policymakers need to incorporate ecological heterogeneity into their decisions in order to implement sound forest management policy.

In addition to the fuel-management operations described above, we need new research to clarify the geographic variation in fire regimes across different forest types in this large, heterogeneous region. There is great geographical variation in the distribution of the three broad fire regimes defined here. In Montana, for example, subalpine forests cover roughly 40% of the forested area, while in Arizona the extent of these forests is significantly smaller and they are more isolated on scattered mountaintops. At a regionwide scale, it is difficult to define the precise extent of these different fire regimes and their spatial location (and especially to distinguish between the low-severity and mixed-severity fire regimes), as illustrated by the variation between the estimates based on PNV groups and those based on current cover type (table 1). There is also significant variation in fire regimes within each of the three broad fire-regime classes in response to local topography and landscape position, and there are other important vegetation types not covered in this brief article (e.g., piñon-juniper woodlands; Romme et al. 2003).

A "one size fits all" approach to reducing wildfire hazards in the Rocky Mountain region is unlikely to be effective and may even produce collateral damage in some places. We do not advocate delaying action until all of the ecological questions have been answered; in many places, there is an urgent need and a solid ecological basis for restoration and fire-mitigation efforts. In other areas, however, where the ecological basis for aggressive fuel reduction is inadequate or lacking, uncritical extrapolation of models from other systems may cause more harm than good.

Acknowledgments

We would like to thank numerous researchers who have added to our understanding of fire regimes throughout the Rocky Mountain region. In particular, we thank Tom Swetnam and three anonymous reviewers for helpful comments and perspectives on an earlier draft. This work was funded in part by a National Science Foundation Postdoctoral Fellowship in Biological informatics, by the US Geological Survey's Biological Resources Division, by an award from the National Science Foundation (DEB-0314305), and by research grants from the National Science Foundation and the US Forest Service that supported fire ecology research in Yellowstone National Park and the southern Rocky Mountains.

PERSPECTIVE

Adapt to more wildfire in western North American forests as climate changes

Tania Schoennagel[a,1], Jennifer K. Balch[a,b], Hannah Brenkert-Smith[c], Philip E. Dennison[d], Brian J. Harvey[e], Meg A. Krawchuk[f], Nathan Mietkiewicz[b], Penelope Morgan[g], Max A. Moritz[h], Ray Rasker[i], Monica G. Turner[j], and Cathy Whitlock[k,l]

Edited by F. Stuart Chapin III, University of Alaska, Fairbanks, AK, and approved February 24, 2017 (received for review October 25, 2016)

Wildfires across western North America have increased in number and size over the past three decades, and this trend will continue in response to further warming. As a consequence, the wildland–urban interface is projected to experience substantially higher risk of climate-driven fires in the coming decades. Although many plants, animals, and ecosystem services benefit from fire, it is unknown how ecosystems will respond to increased burning and warming. Policy and management have focused primarily on specified resilience approaches aimed at resistance to wildfire and restoration of areas burned by wildfire through fire suppression and fuels management. These strategies are inadequate to address a new era of western wildfires. In contrast, policies that promote adaptive resilience to wildfire, by which people and ecosystems adjust and reorganize in response to changing fire regimes to reduce future vulnerability, are needed. Key aspects of an adaptive resilience approach are (*i*) recognizing that fuels reduction cannot alter regional wildfire trends; (*ii*) targeting fuels reduction to increase adaptation by some ecosystems and residential communities to more frequent fire; (*iii*) actively managing more wild and prescribed fires with a range of severities; and (*iv*) incentivizing and planning residential development to withstand inevitable wildfire. These strategies represent a shift in policy and management from restoring ecosystems based on historical baselines to adapting to changing fire regimes and from unsustainable defense of the wildland–urban interface to developing fire-adapted communities. We propose an approach that accepts wildfire as an inevitable catalyst of change and that promotes adaptive responses by ecosystems and residential communities to more warming and wildfire.

wildfire | resilience | forests | wildland–urban interface | policy

Wildfire is a key driver of ecosystem change that increasingly poses a significant threat and cost to society. In western North America (hereafter, the West), warming, frequent droughts, and legacies of past management combined with expansion of residential development have made social–ecological systems (SESs) more vulnerable to wildfire. As the annual area burned has increased over the past three decades, we are confronting longer fire seasons (1, 2), more large fires (3, 4), a tripling of homes burned (5), and more frequent large evacuations. In 2016, the Fort McMurray Fire in Alberta, Canada and the Blue Cut Fire in southern California prompted evacuation orders for a combined total of more than 160,000 people. The costs of wildfire have also risen substantially since the 1990s. The US Congress appropriated $13 billion for fire suppression and $5 billion for fuels management in fiscal years 2006–2015 (6). Other societal costs, including real estate devaluation, emergency services, and postfire rehabilitation, total up to 30 times the direct cost of firefighting (7).

Notwithstanding these costs, many plants, animals, and ecosystem services benefit from fire, and those dependent on frequent fire have been negatively affected by the significantly reduced burning resulting from fire suppression, as compared with the period before European settlement

(8). However the response of ecosystems to increases in wildfire activity and warming in the coming decades is not well understood. Broad heterogeneity among western forest landscapes in terms of biophysical environment, past management, human footprint, and the role of fire and future warming creates a complicated playing field. Managing ecosystems, people, and wildfire in a changing climate is a complex but critical challenge that requires effective and innovative policy strategies (9, 10).

Our key message is that wildfire policy and management require a new paradigm that hinges on the critical need to adapt to inevitably more fire in the West in the coming decades. Policy and management approaches to wildfire have focused primarily on resisting wildfire through fire suppression and on protecting forests through fuels reduction on federal lands. However, these approaches alone are inadequate to rectify past management practices or to address a new era of heightened wildfire activity in the West (11–14).

In delivering this message, we focus specifically on the distinction between specified, adaptive, and transformative resilience (15, 16). Rigorous definition and critical assessment of resilience to wildfire are needed to develop effective policy and management approaches in the context of climate change. We suggest an approach based on the concept of adaptive resilience, or adjusting to changing fire regimes (e.g., shifts in prevailing fire frequency, severity, and size) to reduce vulnerability and build resilience into SESs. Adaptive resilience to wildfire means recognizing the limited impact of past fuels management, acknowledging the important role of wildfire in maintaining many ecosystems and ecosystem services, and embracing new strategies to help human communities live with fire. Our discussion focuses on western North American forests but is relevant to fire-influenced ecosystems across the globe. We emphasize that long-term solutions must integrate relevant natural and social science into policies that successfully foster adaptation to future wildfire.

Why Has Coping with Wildfire Become Such a Challenge?

Three primary factors have produced gradual but significant change across western North American landscapes in recent decades: the warming and drying climate, the build-up of fuels, and the expansion of the wildland–urban interface (WUI; the zone where houses meet or intermingle with undeveloped wildland vegetation).

In terms of climate, wildfire activity is closely tied to temperature and drought over time scales of years to millennia (2, 17–19). Globally, the length of the fire season increased by 19% from 1979 to 2013, with significantly longer seasons in the western United States (1). Since 1985, more than 50% of the increase in the area burned by wildfire in the forests of the western United States has been attributed to anthropogenic climate change (20). Increases in the number of wildfires and area burned in most forested ecoregions of the West are a result of rising temperatures, increased drought, longer fire seasons, and earlier snowmelt (1–4, 21). Specifically, since the 1970s the frequency of large fires has increased most dramatically in the forests of the Northwest (1,000%) and Northern Rocky Mountains (889%), followed by forests in the Southwest (462%), Southern Rockies (274%), and Sierra Nevada (256%), in response to earlier snowmelt and a longer fire season (21). Based on spatial overlays in western United States forests of large wildfires since 1984 (Monitoring Trends in Burn Severity, available at www.mtbs.gov/dataaccess.html and Existing Vegetation Types, available at https://www.landfire.gov/vegetation.php), we found that in northern regions with dramatic increases in fire activity (the Canadian Rockies, Middle Rockies, and Idaho Batholith ecoregions) cold/wet subalpine forests predominantly burned. These forests characteristically burn at high severity and have not experienced a significant build-up of fuels. Overall, cold/wet forests account for about a quarter of total forest burning in the US West since 1984.

Fire suppression, in addition to past logging and grazing and invasive species, has led to a build-up of fuels in some ecosystems, increasing their vulnerability to wildfire. For example, drier, historically open coniferous forests in the West ("dry forests") have experienced gradual fuels build-up in response to decades of fire suppression and other land-use practices (8, 22, 23). Historically, predominantly frequent, low-severity fires killed smaller, less fire-resistant trees and maintained low-density dry forests of larger, fire-resistant trees. Large, high-severity fires now threaten to convert denser, more structurally homogeneous dry forests to nonforest ecosystems, with attendant loss of ecosystem services (24). However, only forests in the Southwest show a clear trend of increasing fire severity over the last three decades, and only a quarter to a third of the area burned in the western United States experienced high severity during that time (25, 26). Although fuels build-up in dry forests can increase the area burned because of higher contagion, the 462% increase in the frequency of large fires in southwestern forests since the 1970s is also a result of an extension of the fire season by 3.6 mo [the average for the western United States is 2.8 mo (21)]. Overall, dry forests account for about half of the total forest burning in the western United States since 1984.

Alongside these increases in warming and fuels, the WUI has expanded tremendously in the past few decades, augmenting wildfire threats to people, homes, and infrastructure. Between 1990 and 2010, almost 2 million homes were added in the 11 states of the western United States, increasing the WUI area by 24% (27). Currently, most homes in the WUI are in California (4.5 million), Arizona (1.4 million), and Washington (1 million) (27). Since 1990, the average annual number of structures lost to wildfire has increased by 300%, with a significant step-up since 2000 (28). About 15% of the area burned in the western United States since 2000 was within the WUI, including a 2.4-km community protection zone, with the largest proportion of wildfires burning in the WUI zone in California (35%), Colorado (30%), and Washington (24%) (Fig. 1) (27). Additionally, almost 900,000 residential properties in the western United States, representing a total property value more than $237 billion, are currently at high risk of wildfire damage (29). Because of the people and property values at risk, WUI fires fundamentally change the tactics and cost of fire suppression as compared with fighting remote fires and account for as much as 95% of suppression costs (28). Together, these gradually changing variables—climate change, fuels build-up, and residential development—interact with rapid combustion to increase wildfire risks and costs to society and some ecosystems substantially.

Potential Consequences of Future Wildfire

Wildfire activity is predicted to increase in the West over the next century (20, 30, 31). This anticipated ramp-up in burning and possible directional changes in fire regimes (e.g., increases in fire frequency, severity, and/or size) could transform the composition, structure, and function of many forest (8, 32, 33), shrubland, and grassland ecosystems (34). Changes in temperature and precipitation in semiarid shrublands and grasslands may reduce fuel availability subsequently, to the extent that fire occurrence, size, and severity in such areas will eventually decline (35). Thus, although fire activity is projected to increase in the West in the near term (i.e., in the next few decades), longer regional trends will depend on feedbacks between vegetation and fire as well as on anthropogenic alterations in vegetation and land use (36, 37).

Increased exposure of communities to wildfire is also expected with additional warming. More than 3.6 million ha, or almost 40% of the current WUI in the western United States, is predicted to experience moderate to large increases in the probability of wildfire in the next 20 y (Fig. 2). This increase is in addition to the growing wildfire risk to developed nonurban areas (e.g., energy production) and infrastructure (e.g., power lines, pipelines) that define a broader wildland–development

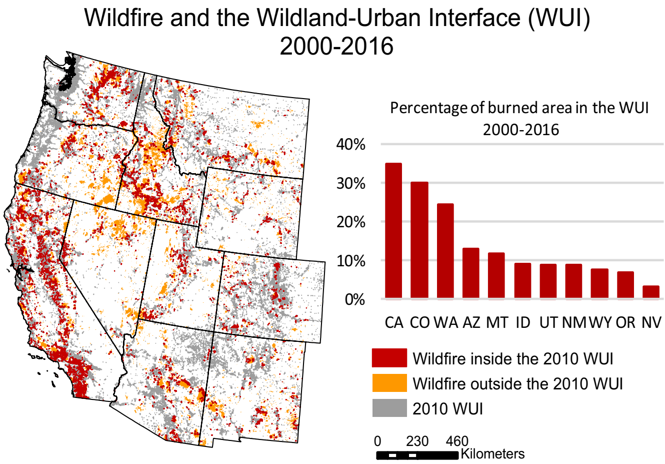

Fig. 1. (*Left*) **Area burned by wildfires between 2000 and 2016 across the western United States inside and outside the 2010 WUI including a 2.5-km community protection zone (27). (*Right*) About 15% of the WUI burned during this period, with largest proportions of the WUI burning in California, Colorado, and Washington.**

interface. Continued WUI growth will further increase human exposure to wildfires (38) and anthropogenic ignitions (37, 39). By midcentury, 82 million people in the western United States are likely to experience more and longer "smoke waves," defined as consecutive days of high, unhealthy particulate levels from wildfires (40). Climate change and increasing exposure of existing and future development to wildfire and smoke present a dangerous and vexing problem for residents, local officials, fire fighters, and managers.

Gradual but significant changes in climate, fuels, and the WUI affect wildfire impacts on ecosystems and society but are difficult to recognize and are challenging to alter meaningfully. There often is a lack of political will to implement policies that incur short-term costs despite their long-term value or to change long-standing policies that are ineffective. For example, few jurisdictions have the will or means to restrict further residential development in the WUI, although modifying and curtailing residential growth in fire-prone lands now would reduce the costs and risks from wildfire in the long term. Furthermore, although the impacts of fire suppression on fuels build-up are now well understood, fire-suppression policies still dominate current fire management (13). Projected global warming of at least 1.1–3.1 °C in the coming century offers a unique opportunity to change policy and the course of our response to wildfires (41). A paradigm shift now in approaches to WUI development and management of fire and fuels can yield tremendous benefits to society later.

Specified, Adaptive, and Transformative Resilience to Wildfire

Resilience is increasingly invoked as a guiding principle in strategies that address the social and ecological dimensions of wildfire. The US Forest Service's National Cohesive Wildland Fire Management Strategy (42) specifically addresses the need to bolster social and ecological resilience to increasing wildfires. Although often invoked in wildfire management and policy, resilience is defined inconsistently or neglects social or ecological contexts, despite the need for uniformity and specification in setting goals and evaluating progress (43, 44).

Defining resilience to wildfire in an SES is especially challenging in the WUI, where people, ecosystems, and wildfire interact over multiple spatial and temporal scales (12). An SES is the intersection and interdependence of biophysical units and associated people and institutions. Resilience in an SES generally has been defined as the capacity to absorb disturbance so as to retain essential structures, processes, and feedbacks and to adapt to and reorganize following disturbance (45). These perspectives of resilience, absorbing versus adapting to disturbance, offer different guiding principles for policy and management in responding to wildfire and measuring success over different planning timelines (44). Here we outline a consistent framework that defines resilience to wildfire in coupled SESs based on the concepts of specified resilience and general resilience, the latter of which includes adaptive and transformative approaches (Table S1) (15, 16, 44).

When climate trends or disturbance regimes are relatively stable and well-characterized and planning horizons are short (years), specified resilience or restoration is an appropriate guiding principle. "Specified resilience" refers to the buffer capacity of a system to retain its identity after a well-specified disturbance (16). Specified resilience reflects the concept of ecological resilience, which refers to the capacity of a system to absorb or tolerate disturbance without shifting to a qualitatively different state controlled by a different set of processes (46). In terms of wildfire, specified resilience applies when fire characteristics are within the bounds of historical range of variability (HRV) of disturbance regimes and a burned forest recovers without converting to another state, e.g., to a nonforest state such as a persistent grassland. In a social context, specified resilience is evident when a community recovers economically and rebuilds similar structures in similar locations following a wildfire (44, 47). Management guided by specified resilience often values recent ecological and social dynamics, particularly when the goal is the conservation of particular species or landscapes. Such management is often informed by short temporal windows of HRV, or "recent HRV" (rHRV) (Fig. 3). This approach can be useful for responding to fires in the short term. However, when social and environmental conditions change rapidly, this approach may foster management goals that are unrealistic or unsustainable in the long run (48, 49).

When climate and wildfire trends are changing and planning horizons are intermediate (decades), general resilience is a more appropriate and desirable guiding principle. "General resilience" refers to the capacity of an SES to adapt or transform in response to unknown shocks or disturbances outside the rHRV (16). Adaptive resilience incorporates aspects of change, reorganization, learning, and adaptability in response to changing climate and disturbance regimes and is an on-going process achieved by harnessing adaptive capacity. In an ecological context, adaptive resilience refers to actively or passively supporting species compositions and fuel structures that are better adapted to a warming, drying climate with more wildfire. Management of specified resilience maintains ecosystems within the rHRV,

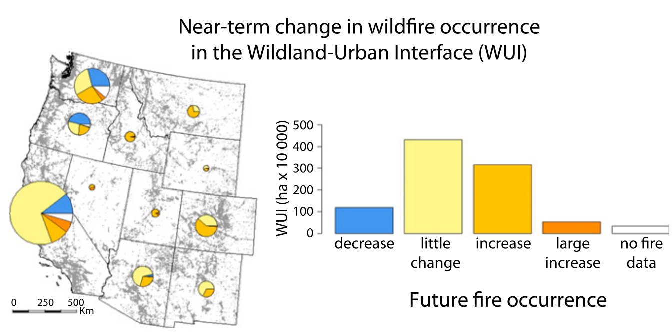

Fig. 2. (*Left*) **Area of the WUI in the conterminous western United States, classified according to projected near-term changes in fire occurrence. The size of each pie is scaled relative to the area of the WUI (both intermix and interface) in each state, based on data from Martinuzzi, et al. (27). Within each pie, slices represent the proportion of WUI area overlapping the five categories of projected fire occurrence for the period 2010–2039, based on data from Moritz, et al. (30). (*Right*) The bar chart summarizes the area of the WUI projected to experience each level of change in fire occurrence in the western United States.**

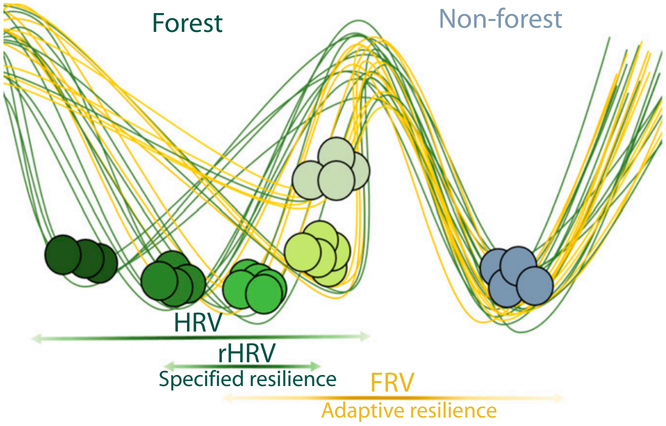

Fig. 3. **Conceptual ball-and-basin representation of specified and adaptive resilience across a forested landscape. Lines defining basins depict the ranges of variation in fire regimes across forest types. Sets of green balls reflect the variation in abundance and composition within different forest types, and the set of blue balls represents nonforest ecosystems. Specified resilience of forests to wildfire is maintained within basins that fall within an rHRV of fire regimes over recent decades to centuries, typically derived from historical documents, remotely sensed data, and tree-ring data. Longer definitions of HRV reflect variation in fire regimes over the last 4,000–5,000 y, when present-day forest types were established in most regions; these data are derived from paleoecological reconstructions. Adaptive resilience to changing fire regimes is reflected within basins that fall within the FRV (yellow). Under the FRV, shifts to nonforest ecosystems remain unlikely in some cases (lower green balls) and more likely in other cases with easier transition to nonforest basin (higher green balls). Changes in the severity, frequency, and size of fire regimes and long-term regeneration following fire events reflect adaptive responses to changing fire regimes and climate conditions across broad scales.**

whereas managing for adaptive resilience considers how changing disturbance regimes may favor suites of traits that are better adapted to a future range of variability (FRV) (Fig. 3) (22). Alignment of fire regimes with adaptive regeneration traits of native vegetation defines a safe operating space (50). The HRV can still play a role by providing insight into how adaptive traits align with changing disturbance regimes to confer adaptive resilience, but under the FRV the safe operating space is shifting (Fig. 3) (50, 51, 52). In a social context, communities exhibiting adaptive resilience engage in ecological, psychological, social, and policy processes that set the community on a trajectory of change to reduce future vulnerability (Fig. 4) (53). Strategies may include changing building codes to make structures more fire-resistant, planning communities to avoid or withstand future wildfire, or providing incentives, education, and resources to reduce vulnerability to future wildfire (47). Adaptive resilience also involves institutional learning, where past management approaches to wildfire evolve.

When climate and wildfire trends are significantly altered from historical trends and/or variability, and planning horizons are long (century), transformative resilience may be necessary. "Transformative resilience" refers to planned fundamental change in response to drastically altered disturbances that have the potential to create broad-scale, systemic shifts in ecological states or radical shifts in values, beliefs, social behavior, and multilevel governance. Examples might include significant regional changes in ecosystem states and associated loss of ecosystem services and/or the relocation of communities of people away from wildfire-prone areas (44, 54). Rapid, planned social–ecological transformation is rare and difficult to implement because of uncertainties about future risk, inflexible institutions and behaviors, and the high cost of transformative action (55).

Although distinct, these approaches to resilience may be nested. Promoting specified resilience may make some forests better poised for adaptive resilience as climate changes, but in some forests or conditions specified resilience may not be effective as climate changes (e.g., refs. 56, 57). Allowing postfire shifts from forest to grassland or shrubland may increase adaptive resilience to changing wildfire and climate conditions. Approaches to adaptive resilience could reduce the need for transformation if efforts keep pace with climate and wildfire trends or may help pave the way toward inevitable social–ecological change. Embracing specified resilience may be the easiest, most familiar path with the least uncertainty, but this approach is short-sighted and could come at the cost of adaptation to future wildfire as climate change continues.

Taking an adaptive resilience approach now is critical, because specified resilience, although useful in some contexts, will become a less useful guiding principle as we exceed HRVs. Adaptive resilience means adjusting to changing fire regimes and climate—in both social and ecological systems—by taking advantage of opportunities to moderate potential impacts and cope better with the consequences. Adapting to wildfire sooner rather than later provides the widest benefits to society at the least cost. If we do not adapt to wildfire now, disruptive and unintended transformations of SESs in the West may ensue.

How Policy and Management Can Promote Adaptive Resilience to Wildfire

Current approaches to managing wildfire focus primarily on controlling fire through suppression and secondarily focusing on managing fuels build-up in forests. Within the context of current and future trends in wildfire, we evaluate the following three approaches in terms of their promise for fostering adaptive resilience in ecosystems and residential communities living with more wildfire: (*i*) managing fire, (*ii*), managing fuels, and (*iii*) promoting adaptive capacity (Fig. 5).

Fig. 4. **Wildfires are catalysts of change that promote adaptive resilience by communities and ecosystems to future wildfires. (*A* and *B*) Example of adaptation in communities. (*A*) A home burned in the 2010 Fourmile fire, Boulder County, CO, which at the time was the most destructive fire in Colorado history in terms of home loss. (*B*) A home that survived the 2016 Cold Springs fire, where many residents managed structural and vegetative fuels around their home to reduce fire hazard after the Fourmile fire through Boulder County's Wildfire Partners program. (*C* and *D*) Heterogeneity in wildfire severity promotes diversity in postfire regeneration and fuels in the 2002 Rodeo-Chediski fire, Coconino and Navajo counties, AZ (*C*) and the 2016 Canyon Creek fire, Grant County, OR (*D*). Managing Wildfire

Suppressing Fewer Fires and Prescribing More Burning. Increasing the use of prescribed fires and managing rather than aggressively suppressing wildland fires can promote adaptive resilience as the climate continues to warm. Many dry forests currently experience significantly less burning than in the period just before European settlement (8, 35, 58). In recognition of the fire-dependence of many ecosystems, the 1995 Federal Wildland Fire Management policy ushered in the first federal policy aimed at reintroducing more wildfire on public lands; that policy remains in effect today. US federal agencies actively managed an average of 75,000 ha of lightning-caused fires per year under the Wildland Fire Use policy from 1998–2008 and currently burn about 1 million hectares per year with prescribed fires (58). However, prescribed fires still constitute only about 10% of the treatments implemented by the US Forest Service in the West and burn about one-third of the area burned by wildfires (National Interagency Fire Center, https://www.nifc.gov/). In the United States and Canada, suppression remains the primary approach to wildfire, with more than 95% of all wildfires suppressed (28). Continued aggressive fire suppression is counterproductive to building adaptive resilience to increasing wildfire in the long term (13, 14).

Using Fire to Foster Adaptive Resilience to Climate Change. In some systems, fire today attenuates future fire effects, because flames that burn dead and live fuel limit where and how severely subsequent fires burn, at least for a time (59–61). Fires often create complex patterns of burn severity that create variation in postfire regeneration and fuels (62–67). As fire regimes shift over time, individual fire events filter for species adapted to changing fire and climate conditions (68). Strategic planning for more managed and uncontrolled wild fires on the landscape today (69) may help decrease the proportion of large and severe wildfires in the coming decades and may enhance adaptive resilience to changing climate. Prescribed fires, ignited under cooler and moister conditions than are typical of most wildfires, can reduce fuels and minimize the risk of uncontrolled forest wildfire near communities. In contrast to wildfires, prescribed fire risks are relatively low, and more than 99% of prescribed fires are held within planned perimeters successfully (58).

Challenges to increasing use of managed and prescribed fires vary from the public's limited experience with smoke and wildfire to significant direct health impacts of smoke on vulnerable populations, including children, the elderly, and low-income communities (40, 70, 71). Some smoke hazards can be reduced through careful planning and management of fire, public health monitoring, and provisioning of health services for vulnerable populations. Public perceptions of fire are also an important hurdle, given the success of Smokey Bear's fire-prevention campaign and because most urban and suburban residents have very limited experience with wildfire compared with rural residents of the early 20th century. Therefore, public education programs that demonstrate the inevitability of wildfire will be a key aspect of living with increasing fire in the West. We need to develop a new fire culture. Despite these and various legal and operational challenges (58), the benefits of prescribed fire and managed wildfires to ecosystems and communities are high (72). Promoting more wildfire away from people and prescribed fires near people and the WUI are important steps toward augmenting the adaptive resilience of ecosystems and society to increasing wildfire.

Managing Fuels

Limiting Reliance on Fuels Treatments to Alter Regional Fire Trends. Managing forest fuels is often invoked in policy discussions as a means of minimizing the growing threat of wildfire to ecosystems and WUI communities across the West. However, the effectiveness of this approach at broad scales is limited. Mechanical fuels treatments on US federal lands over the last 15 y (2001–2015) totaled almost 7 million ha (Forests and Rangelands, https://www.forestsandrangelands.gov/), but the annual area burned has continued to set records. Regionally, the area treated has little relationship to trends in the area burned, which is influenced primarily by patterns of drought and warming (2, 3, 20). Forested areas considerably exceed the area treated, so it is relatively rare that treatments encounter wildfire (73). For example, in agreement with other analyses (74), 10% of the total number of US Forest Service forest fuels treatments completed 2004–2013 in the western United States subsequently burned in the 2005–2014 period (Fig. 6). Therefore, roughly 1% of US Forest Service forest treatments experience wildfire each year, on average. The effectiveness of forest treatments lasts about 10–20 y (75), suggesting that most treatments have little influence on wildfire. Implementing fuels treatments is challenging and costly (7, 13, 76, 77); funding for US Forest Service hazardous fuels treatments totaled \$3.2 billion over the 2006–2015 period (6). Furthermore, forests account for only 40% of the area burned since 1984, with the majority of burning in grasslands and shrublands. As a consequence of these factors, the prospects for forest fuels treatments to promote adaptive resilience to wildfire at broad scales, by regionally reducing trends in area burned or burn severity, are fairly limited.

Targeting Fuels Treatments in Ecosystems with Fuel Build-Up and on Private Lands. Strategically targeting treatments in areas where fuels build-up has increased the expected burn severity may augment the adaptive resilience of those ecosystems to increasing wildfire. For example, treating drier forests, where the likelihood of fire is

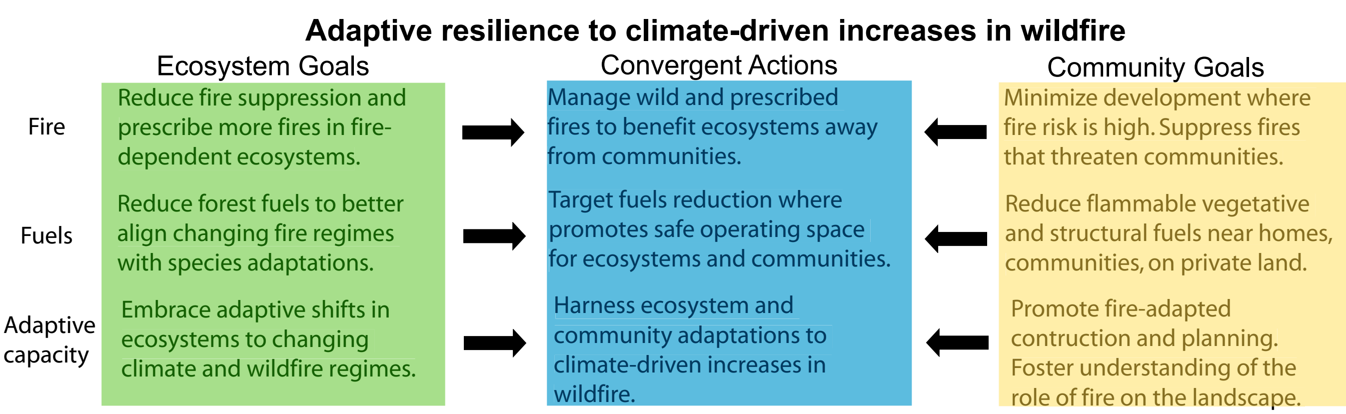

Fig. 5. Convergent actions that promote adaptive resilience to climate-driven increases in wildfire in the West by ecosystems and communities, based on goals related to management of fire, fuels, and adaptive capacity.

high, may also increase opportunities to modify wildfire behavior and postfire recovery. Burn severity has increased because of past fire suppression and fuels build-up in low-elevation dry forests adapted to predominantly frequent, low-severity surface fires (8, 11, 22, 25, 78, 79). In these forests, fuels treatments that remove midstory and understory fuels through thinning and prescribed fire can reduce fire intensity, severity, and rate of spread and may promote adaptive resilience to more frequent fire. Such forests were preferentially treated under the National Fire Plan in 2004–2008 (80). Thinning may effectively restore more frequent, low-severity fire in some dry forests, but when thinning is combined with the expected warming, unintended consequences may ensue, whereby regeneration is compromised and forested areas convert to nonforest (56, 57, 81). Strategic placement of treatments to promote low-severity fire at ecotones between dry and mesic forest distributions may help facilitate postfire migration of species better adapted to warmer, drier conditions.

Midelevation mixed conifer forests, or mesic forests, which typically experienced broad variance in fire frequency and severity, may also benefit from fuels treatments that reduce the likelihood of large patches of high-severity fire and facilitate the migration of species adapted to drier, warmer conditions (77). In contrast, cold/wet forests, such as high-elevation subalpine forests, are adapted to high-severity fire that historically recurred at relatively long (∼100–300 y) intervals (19, 82, 83) and have not experienced unprecedented fuels build-up in recent decades. Severe wildfires have occurred for millennia across a broad range of forests and shrublands, and in many ecosystems species are adapted to severe fire (17, 19, 84, 85), although postfire regeneration may be comprised by drier, warmer conditions (86).

Fuel-reduction treatments also hold promise for locally reducing wildfire hazard around WUI communities if treatments are strategically located to protect homes and the surrounding vegetation. Fuel reduction on federal lands and in municipal watersheds is a primary management tool that has limited application in the WUI, where the majority of land is privately owned (87). Home loss to wildfire is a local event, dependent on structural fuels (e.g., building material) and nearby vegetative fuels (88, 89). Therefore, fuels management for home and community protection will be most effective closest to homes, which usually are on private land in the WUI where ignition probabilities are likely to be high (37). Programs that facilitate the targeted removal of fuels from private land, such as community chipping programs, have been highly successful in some areas, at relatively low cost. The Wyden and Good Neighbor authorities and federal programs, such as the US Forest Service Collaborative Forest Landscape Restoration Program, take an "all-lands" approach to forest management through collaboration with landowners and communities. These policies and programs are roadmaps for augmenting fuel-management efforts across land ownerships. These and other more ambitious policies that facilitate significant fuels management on private land, on a par with fuel-reduction efforts on federal lands, are needed. New policies that facilitate private-land fuels management are critical to augment significantly the adaptive resilience of communities to increasing wildfire.

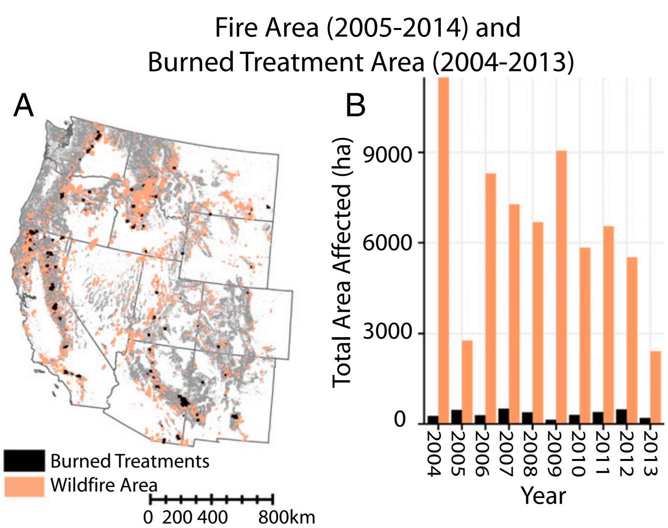

Fig. 6. (*A*) Spatial distribution and area of US Forest Service fuels treatments from 2004–2013 and wildfire from 2005–2014 across forests and woodlands in the western United States. About 3% of the total treated area and 10% of the total number of treatments burned in the period 2005–2014. (*B*) Annual total wildfire area and total burned treatment area. Data are from the following: (1) US Forest Service fuels treatments: Hazardous Fuel Treatment Reduction Polygon (https://data.fs.usda.gov/geodata/edw/datasets.php), (2) Wildfires >1000 ac: Monitoring Trends in Burn Severity Burned Areas Boundaries (www.mtbs.gov/dataaccess.html), (3) Wildfires ≤1000 ac: GeoMAC Historic Fire Perimeters (https://rmgsc.cr.usgs.gov/outgoing/GeoMAC/historic_fire_data/).

Promoting Adaptive Capacity

Fostering and Embracing Adaptive Shifts in Ecosystems. Management of fire and fuels will help some ecosystems withstand more frequent fires and possibly may reduce the risk of larger, more severe fires that may compromise forest recovery. Such efforts will be significant in high-value ecosystems or locations, in helping slow the pace of change and providing a chance for ecosystems and species to adapt to changing fire regimes. The HRV concept can guide management in identifying ecological vulnerabilities and adaptation strategies to changing disturbance regimes (Fig. 3) (50, 51, 52). However, quantifying ecological objectives outside the HRV will be increasingly important in guiding management as fire regimes and climate continue to change (90, 91). Given such uncertainties, management must be adaptive and iterative, and monitoring will be critical to assessing progress. Given the vast area of fire-prone forests in the West, management can directly affect only a small portion of forests. In the majority of forested ecosystems beyond our effective reach, we will have to accept and even embrace changing ecological conditions. While some forests may be entering decades of significant change with high tree mortality in response to drought, wildfire, insect outbreaks, and legacies of past management (86, 92), they also are in the process of adjusting to new conditions to which they will be better adapted and that may challenge our existing philosophies of and approaches to conservation.

Creating Fire-Adapted Communities. The majority of home building on fire-prone lands occurs in large part because incentives are misaligned, where risks are taken by homeowners and communities but others bear much of the cost if things go wrong. Therefore, getting incentives right is essential, with negative financial consequences for land-management decisions that increase risk and positive financial rewards for decisions that reduce risk. For example, shifting more of the wildfire protection cost and responsibility from federal to state, local, and private jurisdictions would better align wildfire risk with responsibility and provide meaningful incentives to reduce fire hazards and vulnerability before wildfires occur. Currently, much of the responsibility and financial burden for community protection from wildfire falls on public land-management agencies. This arrangement developed at a time when few residential communities were embedded in fire-prone areas. Land-management agencies cannot continue to protect vulnerable residential communities in a densifying and expanding WUI that faces more wildfire (12). The US Government Accountability Office questioned the US Forest Service's prioritizing protection of WUI communities that lie under private and state jurisdictions and has argued for increased financial responsibility for WUI wildfire risk by state and local governments (93). This shift in obligation would enhance adaptive governance and could increase the motivation to pursue adaptive resilience of WUI communities to increasing wildfire (94).

Another promising approach for increasing adaptive resilience of WUI residents to wildfire is the promotion of fire-adapted planning in communities. Providing incentives for counties, communities, and homeowners to plan fire-safe residential development for both existing and new homes and discouraging new development on fire-prone lands will make communities safer (89, 94–96). Communities can use land-use and development codes that encourage developers to set aside open space and recreational trails as fuel breaks and require ignition-resistant construction materials in fire-prone settings. For example, San Diego, California enforces strict brush management regulations; the Flagstaff, Arizona fire department uses a WUI development code to protect properties; and Santa Fe, New Mexico applies stringent fire-safe regulations on new developments to protect its watershed (97). Programs such as the Community Planning Assistance for Wildfire (CPAW; planningforwildfire.org), funded by the US Forest Service and private foundations, offer assistance to communities in the form of advice on land-use planning and detailed mapping of wildfire risk. Another example is California, which employs a statewide Fire Hazard Severity Zone map to guide development plans and building codes that reduce wildfire risk. With 84% of potential WUI lands in the West still undeveloped (98), land-use planning now has high potential to reduce the vulnerability of communities to future wildfire. Furthermore, fire-adapted planning may increase management options in terms of how, where, and when fire can be used as a tool for reducing the spread of wildfires into communities and rejuvenating fire-dependent ecosystems, thus increasing the adaptive resilience of communities and ecosystems to more wildfire.

Strengthening and expanding programs such as Fire Adapted Communities, Fire Adapted Communities Learning Network, Firewise Communities USA, and FireSmart Canada will also help communities become more fire-adapted. Capacities to assume these responsibilities will vary significantly among homeowners, communities, and local jurisdictions with markedly different risks and resources (99–101). For example, home hazard mitigation programs and community planning tools are more successful in communities at the fringe of urban areas that have more financial resources and often have a greater trust in government than in more isolated, resource-dependent WUI communities, immigrant non–English-speaking communities, or tribal and First Nations communities (101). Although some tax incentives and rebates are available for wildfire risk mitigation on and around homes, more comprehensive programs that include broader incentives and support are needed for meaningful and widespread impacts. Efforts that combine wildfire-specific efforts with other community capacity-building efforts may leverage the networks that enable communities to act on shared notions of risk (102).

Overall, a shift in resources from the defense of the WUI from wildfire to the mitigation of wildfire hazards and risks in advance of events will build a safe operating space for fire-prone communities that increases adaptive resilience to wildfire. Encouraging development away from fire-prone areas, reducing fuels on private lands in and near communities, and retrofitting and building homes to withstand ignition will increase the adaptive capacity for managing more wildfire (89), similar to adaptive approaches for other natural hazards such as flooding and earthquakes (12). Communities and institutions are long-lived, and disruptive events such as wildfires create windows of opportunity that can shift rules, norms, and expectations to increase adaptive resilience to future wildfires.

Conclusions

Policies that foster adaptive resilience enable WUI communities and fire-prone ecosystems to adjust to increased wildfire risk and reduce future vulnerability. Adaptive resilience provides a realistic framework as the climate warms and wildfires increase, but how will we know if we are achieving adaptive resilience to future fires? On the societal front, minimizing the costs of suppression in the WUI, the number of homes lost to wildfire, the area burned in the WUI, and the number of smoke-related health problems are some metrics. Developing state- or county-wide maps of fire hazard, home survivability rating, and the adaptive capacity of communities would be useful tools in developing this framework.

Some ecosystems will survive and thrive as they adapt to novel future conditions, but not all will. Embracing rather than resisting ecological change will require a significant paradigm shift by individuals, communities, and institutions and will challenge our conservation philosophies. Wildfire is an important catalyst of responses to climate change by communities and ecosystems. Patterns of wildfire are changing with rising global temperatures, and will accelerate in the future. What we can do now is focus management efforts on the places where intervention is needed to slow the pace of change and thereby give particular species and ecosystems a chance to adapt. We also can change how we build, live, and work in fire-prone landscapes to keep our communities safe, healthy, and vibrant.

Acknowledgments

This work emerged from a wildfire science communication workshop organized by COMPASS and the Wilburforce Foundation in 2014. We thank all fire and social scientists who participated and two anonymous reviewers who helped improve the paper.

ABSTRACT In 2012, the United States Forest Service (USFS) promulgated new planning regulations in accordance with the National Forest Management Act (NFMA). These regulations represent the most significant change in federal forest policy in decades and have sweeping implications for wildlife populations. We provide a brief overview of the history of the NFMA planning regulations and their wildlife provisions and review the current science on planning for effective wildlife conservation at the landscape scale. We then discuss the approach to wildlife conservation planning in the 2012 rule and compare it to alternatives that were not selected and previous iterations of the planning rule. The new planning rule is of concern because of its highly discretionary nature and the inconsistency between its intent on the one hand and operational requirements on the other. Therefore, we recommend that the USFS include in the Directives for implementing the rule commitments to directly monitor populations of selected species of conservation concern and focal species and to maintain the viability of both categories of species. Additional guidance must be included to ensure the effective selection of species of conservation concern and focal species, and these categories should overlap when possible. If the USFS determines that the planning unit is not inherently capable of maintaining viable populations of a species, this finding should be made available for scientific review and public comment, and in such cases the USFS should commit to doing nothing that would further impair the viability of such species. In cases where extrinsic factors decrease the viability of species, the USFS has an increased, not lessened, responsibility to protect those species. Monitoring plans must include trigger points that will initiate a review of management actions, and plans must include provisions to ensure monitoring takes place as planned. If wildlife provisions in forest plans are implemented so that they are enforceable and ensure consistency between intent and operational requirements, this will help to prevent the need for additional listings under the Endangered Species Act and facilitate delisting. Although the discretionary nature of the wildlife provisions in the planning rule gives cause for concern, forward-thinking USFS officials have the opportunity under the 2012 rule to create a robust and effective framework for wildlife conservation planning.

KEY WORDS at-risk species, coarse-filter, fine-filter, focal species, forest planning, monitoring, viability.

In April 2012, the United States Forest Service (USFS) issued its final planning rule in accordance with requirements of the National Forest Management Act of 1976 (NFMA; 77 FR 21162). The 2012 rule took over 2 years to complete and included extensive public involvement, consultation through forums with scientists and policy experts, and environmental analysis conducted in accordance with the National Environmental Policy Act of 1969 (NEPA; USFS 2012). The new rule represents the most substantive change in federal forest policy in 30 years, with sweeping implications for wildlife. We review the administrative history of the planning rule, explore the provisions that affect the conservation of wildlife and biodiversity, and discuss how careful implementation could lead to more efficient and effective wildlife management. To provide a context for interpreting the changes that will come with implementation of the new rule, we begin with a short administrative history, and then provide a conceptual framework for interpreting the management implications of the rule. We also consider the intersection of the NFMA and the Endangered Species Act (ESA) and look at the implications of this rule change for ESA decision making. We conclude with a series of observations and recommendations for how the wildlife profession might help ensure that sound science and practical policy are effectively wed as the planning rule is implemented across the nation's public forest lands over the years to come.

A BRIEF HISTORY OF THE 2012 PLANNING RULE

The NFMA created a 3-tiered, regulatory approach to planning. At the highest tier, national-level regulations govern the development and revision of second-tier forest plans. Site-specific plans for projects and other activities make up the third tier, and they must be consistent with both sets of higher-level regulations. Forest plans typically make zoning and suitability decisions and regulate various activities within a forest area, therefore acting as a gateway through which subsequent project-level proposals must pass. They do not, however, authorize or mandate site-specific projects. Instead, plans address issues such as the prioritization of various multiple-use goals, requirements for managing resources such as wildlife, watersheds, or soils, and the determination of which land is suitable for timber cutting, along with allowable volume and the choice of harvesting and regeneration methods.

Efforts to revise the rules governing Forest Service planning have been many, and debate has been intense, resulting in considerable confusion regarding the requirements, process, and legal provisions underlying recent forest planning and management. During development of the 2012 rule, the USFS operated under the 1982 planning rule (47 FR 43026), despite the issuance of more recent rules in 2000 (65 FR 67514), 2005 (70 FR 1023), and 2008 (73 FR 21468). The 2000 rule, developed by the Clinton administration with guidance from a Committee of Scientists (Committee of Scientists 1999), was deemed by the subsequent administration too "costly, complex, and procedurally burdensome" (77 FR 21162: 21164) to implement, and the USFS reverted to planning under the terms of the 1982 rule. Both the 2005 and the 2008 rules were enjoined by the courts because of a failure to meet legal requirements. The agency had argued that planning regulations did not have environmental impacts and thus did not require analysis under the NEPA and the ESA, but this argument failed to survive judicial review (*Citizens for Better Forestry v. USDA* 2007, 2009). A desire to address these persistent weaknesses and to avoid a similar judicial outcome is evident in the language of and justification for the 2012 rule.

One of the most controversial and highly litigated aspects of previous USFS planning rules has been the regulations written in accordance with the NFMA's requirement to "provide for a diversity of plant and animal communities based on the suitability and capability of the specific land area in order to meet overall multiple-use objectives" (16 USC 1604[g][3][B]). To interpret the diversity provision and other requirements of the NFMA, a Committee of Scientists was convened in 1977, in accordance with requirements of the NFMA, to assist with the development of the first planning rule (issued in 1979 and revised in 1982). The diversity regulations in the 1982 rule required that "fish and wildlife habitat shall be managed to maintain viable populations of existing native and desired non-native vertebrate species in the planning area" (36 CFR 219.19). The reference to "viable populations," drawn directly from fundamental principles of population biology, embedded specific, scientific intent into the Forest Service's planning and management responsibilities.

Subsequently, this provision caused significant controversy and drove change in forest management (Corbin 1999, Duncan and Thompson 2006). For example, compliance with the viability provision initiated litigation over the northern spotted owl (*Strix occidentalis caurina*), and led the courts to reject forest plans in the Pacific Northwest for failure to protect the viability, not only of the owl, but also of other species associated with late-successional forests (Duncan and Thompson 2006). Implementation of the 1982 rule relied primarily on the selection of management indicator species, like the northern spotted owl, meant to serve as surrogates to indicate management impacts on a broader suite of unmeasured species. Most forests indirectly assessed the status and trends of management indicator species by measuring habitat amount, a controversial practice that has been the subject of numerous court cases (Corbin 1999). Nonetheless, the use of habitat as a proxy for population status was established in court as not necessarily prohibited by the 1982 regulations (*Inland Empire Public Lands Council v. USFS* 1996).

In the 1990s, the USFS made several attempts to revise the planning rule, and in 1997 a second Committee of Scientists was convened. Its recommendations served as the basis for the 2000 rule, which maintained the viability requirement and extended it to all plant and animal species. The Committee of Scientists suggested a combination of coarse-filter approaches, which focus on the maintenance of ecosystems defined in terms of dominant vegetation types and their successional stages (see Hunter 1990), and fine-filter approaches, which involve direct species-specific measurements of population status and trends (Haufler et al. 1996, Committee of Scientists 1999). Specifically, the 2000 rule required that focal (see below) and at-risk species be monitored using fine-filter approaches. Diversity provisions of the 2000 rule were never implemented, because in 2001 the USFS reverted to the 1982 rule, using a transitional provision in the 2000 rule, while the Bush administration initiated revisions to the planning rule. Both the 2005 and 2008 rules relied entirely upon a coarse-filter approach to wildlife conservation. Contrary to assertions from the scientific community (Noon et al. 2003, 2005), the USFS argued that maintenance of broad ecosystem diversity (as represented by coarse-filter approaches) would adequately protect species and address their diversity obligations under the NFMA. These rules did not require any fine-filter, species-specific planning or monitoring. When the 2005 and 2008 rules were enjoined, the court gave the USFS the option of using the 2000 or the 1982 rule. The USFS chose to use the provisions of the 1982 rule, including the viability provision, through the transitional language in the 2000 rule. In its justification of the most recent planning effort, the USFS claims that the 1982 rule is out-of-date in its scientific foundations, planning procedures, and social values, and is too complex, expensive, and procedurally burdensome to implement (77 FR 21162).

CONCEPTUAL BASIS FOR WILDLIFE CONSERVATION PLANNING

In addressing asserted shortcomings of the 1982 rule, the Forest Service adopts an approach to wildlife conservation that hinges primarily on the assessment, analysis, management, and monitoring of habitat. The 2012 Programmatic Environmental Impact Statement for the planning rule states, "The best opportunity for maintaining species and ecological integrity is to maintain or restore the composition, structure, ecological functions, and habitat connectivity characteristics of the ecosystem. These ecosystem components, in essence, define the coarse-filter approach to conserving biological diversity" (USFS 2012:126). This contrasts with the 1982 and 2000 rules that emphasized population viability.

A Combined Coarse-Filter/Fine-Filter Approach

Most wildlife ecologists believe that effective biodiversity conservation planning requires an appropriate balance between habitat-based, coarse-filter approaches and insights from fine-filter, species-level assessment and monitoring (Noon et al. 2009). The 2012 Programmatic Environmental Impact Statement for the planning rule recognizes the limits of the coarse-filter approach stating, "initially at least, some amount of direct species measurement may be needed to assess the effectiveness of the ecological conditions provided under the coarse-filter approach in achieving the goal of conserving the biological diversity of the area" (USFS 2012:124). The impact statement goes on to propose that fine-filter strategies "can be focused on the few species of special concern whose habitat requirements are not fully captured by coarse-filter attributes." However, this language understates the importance of a complementary fine-filter approach. Research indicates that the coarse-filter approach is unlikely to provide a reliable basis for multi-species conservation planning (Cushman et al. 2008), only limited testing of the approach's validity has occurred (Noon et al. 2009), and the monitoring of a select group of species using a fine-filter approach is necessary to determine the efficacy of coarse-filter approaches (Committee of Scientists 1999, Flather et al. 2009). A recent review of the degree to which coarse-filter models can be used to infer animal occurrence concluded that ". . . the observed error rates were high enough to call into question any management decisions based on these models" (Schlossberg and King 2009:609). These authors went on to state, ". . . [coarse-filter] models oversimplify how animals use habitats, and the dynamic nature of animal populations" (Schlossberg and King 2009:609).

Defaulting to vegetation type as a descriptor of a species' habitat has a long history in ecology. It has been driven largely by pragmatism—vegetation is much easier to measure and characterize than prey resources or nest sites, for example. The practice continues because detailed vegetation maps exist for most of the United States based on either extensive ground-surveys or remotely sensed imagery (e.g., USFS LandFire Program). However, vegetation is often a poor proxy for more influential, but difficult to measure resources, and the frequent failure of vegetation-based habitat models to predict a species' distribution and abundance may be because of limitations of this assumed relationship (Van Horne 2002, Cushman et al. 2008). Even with more detailed data on habitat characteristics, unmeasured and unknown factors will still affect populations. For these reasons, population status of focal and at-risk species must be directly assessed. Therefore, a coarse-filter approach based primarily on dominant vegetation communities will have limited ability to predict the distribution and abundance of many wildlife species and effectively address the diversity provisions of the NFMA; this requires both coarse- and fine-filter approaches.

Selecting Species for Fine-Filter Assessment

Striking a balance between coarse-and fine-filter assessments of biological diversity has challenged forest managers for decades. Even if the fine-filter approach was restricted to vertebrates, monitoring the status of all species is not feasible, thus previous planning rules have restricted USFS requirements to an assessment of a small subset of species occurring across the planning area. This pragmatic constraint was recognized in the 1982 planning rule with the designation of management indicator species, species assumed to reflect the effects of management on their populations as well as the populations of many unmeasured species. However, the notion that a single species can serve as an indicator for a suite of species is an untested premise and generally not supported by research studies or ecological theory (Noon et al. 2009, Cushman et al. 2010). The concept that some species act as direct surrogates of others is untenable unless those species share similar population drivers (Cushman et al. 2010).

Instead of management indicator species, the second Committee of Scientists recommended the use of "focal species" (Committee of Scientists 1999) to evaluate status and trends of plant and animal diversity, generally. The Committee of Scientists proposed that focal species would commonly be selected on the basis of their functional role in ecosystems (e.g., they serve keystone functions [Mills et al. 1993], they are indicators of exposure to key stressors [Caro and O'Doherty 1999], they have a role as engineers of ecological processes [Jones et al. 1994], or play an important role in food web dynamics [Soule et al. 2005]). For federal public lands, Noon et al. (2009) suggest a combined coarse-filter and fine-filter approach, with the latter focusing on monitoring threatened, at-risk, and rare species, along with a modest number of focal species selected with complementary and comprehensive functional roles as described above. Systematic approaches exist for identifying and prioritizing an informative subset of species for fine-filter assessment and monitoring. For example, Regan et al. (2008) suggest selecting species based on existing schemes, such as The World Conservation Union (IUCN) Red List, Nature Serve, Partners in Flight databases, and federal or state listings, combined with an assessment of the degree and spatial and temporal characteristics of known threats. Nevertheless, uncertainties regarding the ability to generalize inferences drawn from any subset of species make the selection process of fundamental importance to the successful implementation of the fine-filter approach.

Improved Techniques for Fine-Filter Monitoring

One argument against direct assessment of wildlife populations is that it is not financially feasible. Traditional monitoring programs and viability analyses have been based on estimates of demographic parameters such as abundance, density, survival, and reproductive rates (Beissinger and McCullough 2002). Estimates of these parameters are expensive, require extensive field surveys, often involve capture and marking of individual animals, and are available for only a small number of species. However, indirect estimates of a species' status and trend based on their spatial distribution can provide defensible surrogate measures (MacKenzie and Nichols 2004, Manley et al. 2004). Focusing on distribution, rather than traditional measures of population size and growth rate, greatly increases the efficiency of broad-scale monitoring programs (Noon et al. 2012). Advancements in wildlife monitoring, based on detection/non-detection data, including the use of sign surveys, genetic evaluation, and historical presence–absence survey data decrease the cost of monitoring changes in distribution, which can be inferred from the proportion of sample units at which the species is detected (MacKenzie et al. 2006). One of the most significant advances in detection/non-detection monitoring is the ability to confirm the presence of a species at a survey site based on its genetic signature (e.g., in hair or scat; Waits 2004, Schwartz et al. 2006). The July 2005 issue of the *Journal of Wildlife Management* devoted a special section to the application of presence–absence sampling in wildlife monitoring (Vojta 2005), including an application to National Forest System lands (Manley et al. 2005). One variable estimated by these models is the area occupied by a species, a measure of a species' spatial distribution. Temporal and spatial patterns in detection/non-detection monitoring data allow inference to changes in animal abundance (MacKenzie and Nichols 2004), the single most influential parameter that provides insights into likelihood of species persistence (Lande 1993). Thus, previous arguments citing the practical limitations of the fine-filter approach are blunted by recent technical and statistical research, much of it inspired by the difficulty and expense of implementing earlier approaches to fine-filter assessments under the 1982 planning rule.

Political and Administrative Barriers to Effective Biodiversity Conservation Planning

In the past, very few if any management indicator species have been monitored in a manner that would allow a reliable assessment of their response to management (Noon et al. 2009). Managers cite the lack of monitoring data as a critical limitation in understanding cumulative impacts to species (Schultz 2012). Aside from cost and the technical challenges discussed above, funding and implementation of reliable, species-specific monitoring has been a significant challenge on National Forest System lands because of political reasons. Maintaining the political and fiscal will to support long-term monitoring programs is difficult (Doremus 2008, Biber 2011). In addition to the challenges of chronic under-funding, management agencies face disincentives to implementing robust species-level monitoring plans because monitoring data may reveal the negative impacts of management. For example, documenting the impacts of timber harvest or fuels reduction activities on sensitive wildlife species often highlights conflicts between different agency mandates, each of which enjoys strong political and social support. In addition, funds allocated to monitoring may draw funds away from projects that result in immediate job creation, the provision of marketable goods such as timber, the attainment of fuels reduction and restoration goals, or other accomplishments that can be reported to Congress in a timely manner. Furthermore, an agency could face legal challenges if it makes enforceable monitoring commitments that it does not have the funding to implement. However, at least as they are typically drafted, monitoring plans are difficult to enforce in court, obviating the need to fully implement intended programs. The judiciary usually finds commitments to monitor land-use plans not subject to review under the parameters of administrative law, and even when reviewed in court, determinations regarding the adequacy of monitoring data are traditionally left to the expertise of administrative agencies (Biber 2011).

Several other issues make understanding management effects on wildlife populations problematic. For example, the USFS has often monitored impacts to species at the project level (Schultz 2010), a spatial scale with generally small population-level effects. Small effect sizes require high statistical power for their detection. The disparity between the scale at which population responses can be detected and the scale of individual management actions leads to persistent problems in assessing impacts to species viability (Ruggiero et al. 1994). Monitoring impacts to habitat must be done cumulatively and at multiple spatial scales to assess whether small-scale habitat changes affect individual organisms, interrupt landscape connectivity affecting multiple populations, or synergistically interact with other small-scale disturbances, resulting in broad-scale effects.

Finally, the integrity of any monitoring plan, coarse- or fine-filter, depends on the articulation of clearly stated objectives and triggers to management actions. A trigger point is a threshold value for a monitoring state variable (e.g., percent area occupied by a given focal species within a national forest planning area) that, when exceeded, triggers a particular management response. A monitoring program without triggers selected a priori to call attention to trends provides little more than a retrospective time series of data with no feedback—and therefore little value—to the management decision-making process (Noon 2003). Furthermore, the efficacy of a monitoring program cannot be assessed at adoption without pre-defined trigger points. Trigger points can be most objectively set up-front, before the difficult management changes that might result from crossing such points are proximate. This is especially true if effects are analyzed exclusively at project scales, masking broader trends. In such cases, declines in population size or habitat quality, for example, may occur incrementally with no recognition of impact until a decline in species status is clearly established via listing under the ESA (Schultz 2010). To provide value to the forest planning process, a monitoring program must establish, a priori, the magnitude of change in the monitoring state variable that would trigger a review of management practices.

In summary, a comprehensive wildlife assessment framework would include a combination of both coarse- and fine-filter approaches. It would commit to monitoring at-risk and focal species using recent advances in monitoring approaches that make species-specific monitoring more financially feasible and efficient than it has been in the past (Noon et al. 2012). As required for effective and meaningful adaptive management, monitoring would occur at multiple spatial scales and use pre-defined triggers to meaningfully evaluate the consequences of management actions and to inform future management decisions.

AN OVERVIEW OF THE 2012 PLANNING RULE'S DIVERSITY PROVISIONS

The planning framework for the 2012 final rule involves a 3-step process: assessment; plan development, amendment, and revision; and monitoring (36 CFR §219.5 [2012]). It requires the use of the "best available scientific information to inform the planning process" (36 CFR §219.3 [2012]) and identifies restoration and watershed protection as agency priorities, while emphasizing the contributions of sound forest management to ecological, social, and economic sustainability (36 CFR §219.8 [2012]). Because restoration requires: 1) an assessment of the current system state relative to desired future conditions; 2) measurement of the system state subsequent to management activities; and 3) a comparison of the observed to desired state, restoration is critically dependent on monitoring. In this section, we discuss the approach in the 2012 rule and the alternatives that were considered but not selected in the agency's decision process.

Assessment and Planning

Section 219.9 outlines the approach for providing for diversity of plant and animal communities. It explains that the USFS is adopting "a complimentary ecosystem and species-specific approach," or a combined coarse- and fine-filter approach. Paragraph (a) outlines the coarse-filter requirements to maintain ecosystem integrity and diversity: plans "must include plan components . . . to maintain or restore the ecological integrity of terrestrial and aquatic ecosystems and watersheds in the plan area" and "maintain or restore the diversity of ecosystems or habitat types throughout the plan area" (ecological integrity and diversity are defined in §219.19 of the 2012 rule). Plan components must function to maintain or restore ecosystem structure, function, composition, connectivity, key ecosystem characteristics, rare species communities, and native tree diversity. A commitment to restore or maintain landscape connectivity to facilitate movement, migration, and dispersal is a significant addition to the planning rule. Paragraph (b) outlines the fine-filter approach. It begins by explaining that the responsible official must determine whether the plan components under part (a), the coarse-filter requirements, will provide the necessary conditions to contribute to the recovery of species listed as threatened or endangered under the ESA, or species that are proposed or candidate species for listing. Additionally, the responsible official must determine whether the coarse-filter approach is sufficient for maintaining viable populations of "species of conservation concern." These are species known to occur in the plan area, other than those listed, proposed, or identified as candidate species under the ESA, that are selected by the Regional Forester based on "substantial concern about the species' capability to persist over the long-term in the plan area" (36 CFR §219.9[c] [2012]). If the coarse-filter is deemed to be insufficient, the responsible official must include species-specific plan components (e.g., buffer areas around nest sites), that will contribute to the recovery of populations of species of conservation concern, as well as federally listed, proposed, and candidate species. If the coarse-filter is assumed adequate, no further species-level consideration is employed in planning. Yet how responsible officials will be held accountable for such decisions is unclear. The burden of proof for determining the effectiveness of the coarse-filter approach is not addressed. These species-specific requirements represent the USFS commitment to the fine-filter approach in section 219.9.

Notably, the new rule eliminates the requirement for maintaining viable wildlife populations, in contrast to the 1982 rule's viability provision for vertebrates and the provisions of the 2000 rule that would have extended the requirement to other species. Since the agency only commits to maintaining the viability of species of conservation concern, under the 2012 rule the USFS has no obligation to address the decline of any species not listed, proposed, or a candidate under the ESA, unless the responsible official, in this case the Regional Forester, expresses substantial concern about its persistence. Thus, any number of species could pass from secure to endangered status before any federal intervention would be required. However, in contrast to the 1982 rule, the agency can commit to maintaining viable populations of non-vertebrates by identifying them as species of conservation concern.

Historically, the diversity provisions of the NFMA have been one of the most controversial aspects of the planning rule, and the issue of how the USFS should address the clearly established public values associated with wildlife conservation often has been overshadowed by legal and technical arguments about the practicality of specific approaches to viability assessment. For example, over the course of the drafting and judicial review of multiple rules, considerable disagreement existed as to whether a requirement to maintain viable populations of all species, or just vertebrate species, or just at-risk species was an attainable goal. Understandably, the USFS has been reluctant to commit the agency to a species viability standard with which demonstrating compliance is difficult. At any point in time, all species have some non-zero probability of extinction; thus, viability can never be guaranteed. Viability is a probabilistic concept that invokes a specific level of risk over a stated time horizon, and proponents of the viability standard have had difficulty explaining to the public—and sometimes to their colleagues in wildlife management—how probabilistic events can be addressed in legally enforceable standards.

Nonetheless, in its 2012 record of decision, the agency commits to maintaining the viability of species of conservation concern, arguing that the combination of coarse- and fine-filter approaches it proposes are scientifically defensible, will adequately protect biodiversity on its lands, and will not be too costly to implement (77 FR 21162). However, the planning rule does not specify how viability will be assessed or what information will be used to assess a species' viability. Additionally, species identified as being of conservation concern could experience sharp range restrictions, since the regulations no longer require viable populations to be well-distributed, as was the case under the 1982 rule. Instead, the new rule defines of a viable population as one that "continues to persist over the long term with sufficient distribution to be resilient and adaptable to stressors and likely future events" (36 CFR §219.19 [2012]).

Finally, the USFS may absolve itself of responsibility for species-level conservation if the agency determines that maintaining a viable population of a species of conservation concern is beyond the capability of the plan area. In this case, which might result from stressors extrinsic to the planning area, such as climate change or the loss of habitat in other regions, the responsible official is required to document the basis for that decision and include plan components that contribute to the maintenance of a viable population across multiple land ownerships, in coordination with other managers and private parties working across jurisdictional boundaries, to the extent practicable.

Monitoring

Monitoring requirements are outlined in section 219.12. The planning rule requires a monitoring program for each National Forest, which can be developed jointly across forests and must be developed in coordination with the Regional Forester and the Research and State & Private branches of the agency. Plan monitoring programs must include questions and indicators; for diversity, these include indicators addressing the status of ecological conditions and the status of focal species, defined in the rule as "a small subset of species whose status permits inference to the integrity of the larger ecological system to which it belongs and provides meaningful information regarding the effectiveness of the plan in maintaining or restoring the ecological conditions to maintain the diversity of plant and animal communities in the plan area. Focal species would be commonly selected on the basis of their functional role in ecosystems" (36 CFR § 219.19 [2012]). Regional Foresters are to develop "broader-scale monitoring" for questions that are relevant at scales larger than the planning area. In all cases, monitoring information is to be compiled, evaluated, made available to the public, and used to inform adaptive management of the plan area. Thus, the new rule adopts, for the first time, a multi-scaled approach for monitoring and codifies the intent, although not the process, for implementing a transparent and data-driven approach to adaptive management. Although the adoption of a focal species approach based on functional roles in sustaining ecosystem processes reflects the logic of the 2000 rule, the 2012 rule draws no connection between the monitoring of focal species and the conservation of their roles in the ecosystem. The new rule does not include a requirement to maintain the viability of focal species, despite the fact that it is the status of these species that is meant to indicate whether the USFS is successfully maintaining and restoring ecosystem diversity and integrity. Additionally, the 2012 rule does not provide a requirement to monitor species of conservation concern, despite their established vulnerability to local extirpation. Consequently, the fine-filter approach to monitoring is explicitly separated from the fine-filter approach for biodiversity conservation.

Alternatives Not Selected

Although a review of the key provisions of the planning rule provides direct insight into the place of wildlife conservation in the future of forest planning and management, examination of the alternatives not selected reveals the underlying logic, pivotal choices, and philosophical foundations of the Forest Service's interpretation of the NFMA and reconceptualization of its institutional role and responsibilities to the public. The USFS considered several other alternatives in its Programmatic Environmental Impact Statement, in addition to the selected alternative (i.e., the final rule), which was a modified version of Alternative A. Alternative B closely followed the 1982 rule, notably in regards to the viability provision (". . . fish and wildlife habitat shall be managed to maintain viable populations of existing native and desired non-native vertebrate species in the planning area . . ." [36 CFR 219.19]). The agency provides a lengthy rationale for not selecting Alternative B, focusing on the defects of the 1982 viability provision (see 77 FR 21162:21168). This rationale also pertains to the selection of the final rule (modified Alternative A), which dropped the 1982 viability provision with the exception of "species of conservation concern" (see below). The agency states the 1982 rule "included planning procedures that do not reflect current science or result in unrealistic or unattainable expectations because of circumstances outside of the Agency's control, particularly for maintaining the diversity of plant and animal species" (77 FR 21162:21169). The USFS further justifies dropping the requirement to maintain species viability by stating, "[T]here are limitations on the Agency's authority and the inherent capability of the land" (77 FR 21162:21169). It notes that forest clearing in South America and habitat fragmentation in the Rocky Mountains on private land affect the agency's ability to maintain viable populations on National Forest System lands. For reasons such as these, the agency notes, the USFS cannot ensure a species' existence in the planning area when circumstances outside of its control may be contributing to population declines. It also notes that managing for the habitat of a single species sometimes impinges on management requirements for a species listed under the

ESA, or on other necessary activities the agency must undertake to comply with statutory requirements. Furthermore, the agency writes, some forests simply cannot support viable populations of species that are rare and far-ranging, like wolverines (*Gulo gulo*), and require more habitat than is available on a single National Forest unit.

Alternative C included no specific provisions for biodiversity conservation beyond the minimum requirements of the NFMA. This alternative was highly discretionary, leaving decisions about the requirements for assessment, planning, and monitoring to the USFS Directives' System (i.e., the agency's handbook and manual), whose provisions are not legally binding. The high degree of discretion in this alternative, according to the agency, would have resulted in too much variation in implementation: "There would be no certainty with regard to the inclusion of any plan components beyond the minimum required by this Alternative, and a potential lack of consistency across the National Forest System" (77 FR 21162:21170).

Alternative D "was designed to evaluate additional protections for watersheds and an alternative approach to addressing the diversity of plant and animal communities" (77 FR 21162:21170). This alternative required watershed-scale assessments of climate change vulnerability and designation of key watersheds to anchor the assessment and maintenance of the ecological status of aquatic, riparian, and terrestrial components of watersheds (USFS 2012). Establishing connectivity between habitats and discrete populations of species would also have been required. The alternative maintained and extended the 1982 viability requirement, stating the National Forests would provide for viable populations of native and desired non-native species in each planning area. The USFS was required to use the best available science to determine ecological conditions necessary to support viable populations, as informed by the "current and likely future viability of focal species within the planning area" (USFS 2012:F-9). To address the agency's concern that it cannot ensure the viability of populations on its lands, Alternative D included language that required the Secretary of Agriculture to provide notice to the public and allow for public comment if the agency determined it could not provide for viable populations of native or desired non-native species in a plan area. Furthermore, the agency was required to provide for viability of such a population to the maximum extent practicable and to take no actions that would increase the likelihood of extirpation of a population in the planning area. As with the selected alternative, Alternative D required monitoring of the status and trends of focal species, but with the additional requirement that triggers be identified for focal species' monitoring that would initiate a review of planning and management decisions to achieve compliance with the viability standard. This alternative explicitly stated that population surveys of focal species would be conducted using presence–absence data, occupancy modeling, genetic monitoring, or count-based methods. Alternative D was not selected because of the high anticipated planning and monitoring costs (77 FR 21162). The record of decision states that many plans already incorporate elements of this alternative, but that it is too prescriptive to allow for efficient, effective, and flexible management of all National Forests (77 FR 21162).

Finally, Alternative E was highly prescriptive in terms of requirements for public notification, assessment, and monitoring. It would have required specific monitoring questions, indicators, and triggers for changes in management action. The diversity requirements would have been similar to those in the selected alternative, but with more emphasis on monitoring of species' status and trends. The alternative was rejected for the same reasons as Alternative D.

MANAGEMENT IMPLICATIONS AND RECOMMENDATIONS FOR IMPLEMENTING THE 2012 PLANNING RULE

In theory, the new planning rule could be implemented in a robust way, drawing on the best available science to protect plant and animal diversity on National Forest System lands. However, the primary change introduced by the 2012 rule is the considerable discretion afforded centralized authorities, particularly at the regional level, in how general provisions will be implemented. Based on the management history of the USFS, numerous aspects of the 2012 planning rule are of concern, primarily because they defer many fundamental details to the interpretation of officials who may lack scientific background and disciplinary depth in wildlife biology and may have disincentives to prioritize wildlife. A number of scientists and scientific societies (including The Wildlife Society) commented on the draft rule and noted that it leaves more decisions about diversity conservation to agency discretion than did the 1982 rule. Forest Service officials must strike a fine balance between prescriptive standards and discretion or flexibility in a rule that is meant to guide planning years into the future on the entire National Forest System. Although some discretion is necessary, a rule must be sufficiently prescriptive to ensure that the National Forests do not implement a loosely written and unenforceable standard with so much variability across management units as to compromise the conservation of biological diversity.

Discretion, Authority, and Responsibility in Wildlife Conservation

Highly discretionary mandates are especially problematic for protecting resources such as wildlife that, without clear substantive requirements, have historically received less attention in land management. The 1897 Organic Act gives the USFS wide discretion by providing an open-ended mandate to secure water flows and provide timber. The Multiple Use Sustained Yield Act (MUSYA), passed in 1960, expanded the factors that the USFS must consider in planning, including wildlife conservation. However, the language in the MUSYA does not require the USFS to conserve wildlife in any specific fashion, only to consider the wildlife resource when planning for multiple-use. The concept of multiple-use, according to the courts, "breathes discretion at every pore" (*Perkins v. Bergland* 1979). Wildlife never gained serious consideration in forest management under the MUSYA, in part because of the agency's deference to state wildlife agencies, which have generally focused on game species and sport fisheries.

We have consistently heard many USFS personnel argue that their primary responsibility is to manage the habitat on USFS lands, whereas actual populations are the domain of the states. However, the USFS clearly has the power to manage wildlife on its lands. The United States Constitution's Property Clause (Art IV, section 3) gives Congress proprietary and sovereign powers over its property, and it may delegate decisions regarding federal lands to executive agencies. The Supreme Court has repeatedly observed that this power over federal land is "without limitations" (*United States v. San Francisco* 1940). The Court's expansive reading of the Property Clause also extends to managing wildlife on federal lands. The dispositive case is *Kleppe v. New Mexico* (1976), where the Court states, "the 'complete power' that Congress has over public lands necessarily includes the power to regulate and protect the wildlife living there" (426 U.S. 529: 541). Of course, the states also manage wildlife on federal lands, but as made clear in *Kleppe*, "those powers exist only in so far as [their] exercise may be not incompatible with, or restrained by, the rights conveyed to the Federal government by the Constitution." (426 U.S. 529: 545). Though the USFS seldom chooses to assert its full wildlife management powers, the Courts continue to emphasize the Property Clause's application to wildlife (see, e.g., *Wyoming v. United States* 2002).

Concerns about wildlife were one of the central factors precipitating the passage of the NFMA in 1976, and the USFS has a clear responsibility under the Act to manage for biodiversity. The Act's legislative history shows that its diversity provision was meant to require "Forest Service planners to treat the wildlife resource as a controlling, coequal factor in forest management and, in particular, as a substantive limitation on timber production" (Wilkinson and Anderson 1987:296). When the NFMA was passed, it included language stating that the USFS has a responsibility to be "a leader in assuring that the Nation maintains a natural resource conservation posture that will meet the requirements of our people in perpetuity" (16 U.S.C. §1600[6]) and an explicit requirement to protect plant and animal diversity. To ensure that the agency's new requirements were effectively translated into administrative regulations, Congress required the agency to convene a Committee of Scientists to inform the writing of these regulations, which were finalized in 1982 (16 U.S.C. §1604[h][1]).

Timber harvest on the National Forests, nonetheless, continued to increase steadily, until the late 1980s. At that time, citizen enforcement, frequently manifest through appeals and litigation based on substantive provisions like the 1982 rule's viability standard and the ESA, was a major factor that led to significant declines in timber production (from >13 million board feet/year in the late 1980s to <2 million in the early 2000s). Legal exposure created by the suite of substantive requirements to protect biological diversity under the NFMA and ESA forced the agency to address wildlife conservation, something that had not come to pass under the MUSYA. However, even in the 1990s, pressure to prioritize timber production over the protection of wildlife remained strong because of internal biases, financial incentives, and Congressional intervention (Wilkinson 1992, Government Accountability Office 1997, Corbin 1999).

Although agency culture and priorities have shifted over time, biodiversity conservation still may conflict with activities like timber harvest, fuels reduction, recreation, or energy development, all of which the USFS has strong economic and political incentives to promote. Literature in political science and economics predicts that when given conflicting tasks by Congress, such as the multiple use mandate, agencies systematically prioritize high incentive and measurable goals over those that are lower incentive and more difficult to measure (Biber 2009). A highly discretionary NFMA diversity regulation could lead the USFS to prioritize higher incentive and measurable goals that are supported by political interests.

Given this reality, even when regulations for protecting plant and animal diversity are well meaning and scientifically sound, if they are not specific, measurable, binding, and enforceable, history suggests that effective wildlife conservation planning will end up as a secondary objective (Houck 1997). Specific, mandatory language is needed to protect wildlife on the National Forests, a point not lost on the first Committee of Scientists, who wrote the following in 1979, "It is simply not possible to carry out the planning requirements of NFMA in accordance with a set of regulations that contain nothing but generalities" (44 FR 53967: 53968). Such specificity, said the Committee, is what the NFMA requires. Historically, the NFMA's diversity provision and its associated regulations have provided an effective counterbalance to competing agency demands and political pressures. However, without more specific requirements, the administrative discretion in the 2012 rule's diversity provisions will lead to varied implementation across management units, give managers who are not committed to wildlife conservation the leeway to pursue other management goals without concern for biodiversity, and leave managers who are committed to protecting biodiversity without a solid, legal framework to help them withstand internal and external pressures to prioritize other factors.

Although the diversity provisions in the 2012 planning rule itself are highly discretionary, the agency, through the Directives system, could adopt standards and practices for wildlife conservation that are more prescriptive and would help to ensure that the rule is implemented in a more robust fashion and informed by the best available science. We urge the agency to implement the rule in a manner that closes the gap between the stated purpose of maintaining ecological integrity and diversity, and the highly general and discretionary operational provisions in the rule that are meant to achieve these purposes. The Wildlife Society and other professional organizations can play an important role in guiding this process, and for this purpose, we offer a series of recommendations that would strengthen the key wildlife provisions in the 2012 rule.

Coarse-Filter Contributions

Coarse-filter approaches, typically focused at broader spatial scales than fine-filter strategies, are aimed at communities, ecosystems, or landscapes (Schwartz 1999). Their central role in the 2012 rule complements fine-filter provisions and commits the USFS to multi-scaled assessment and monitoring efforts. Coarse-filter conservation strategies often rely on habitat predictors (e.g., dominant vegetation and landform) derived from satellite imagery (e.g., the California Wildlife Habitat Relationships System, http://www.dfa.ca.-gov/biogeodata/cwhr). Under this approach, all appropriate habitats within a planning unit that intersect the species' geographic range are typically assumed to support the species. This assumption is often based on anecdotal occurrence data because the spatial extent of coarse-filter strategies often constrains the agency's ability to implement probability-based survey designs. The consequence is that commission errors are likely, which can lead to the erroneous conclusion that animal diversity is being maintained when it is not. Although these concerns limit the ability the coarse-filter approach to serve as a substitute for fine-filter assessments, a management objective to sustain dominant vegetation communities and their successional stages at broad spatial scales is an essential aspect of a comprehensive approach for sustaining biological diversity. In the context of the diversity requirements of the 2012 rule, measures of the effectiveness of the coarse-filter are presented in terms of species' metrics (e.g., number of rare and imperiled species conserved, presence of apex consumers, species richness, etc.). Therefore, verifying the efficacy of the coarse-filter approach requires some level of direct species-level assessment, and a comprehensive diversity policy requires a carefully balanced coarse-filter/fine-filter strategy.

Implementing the Fine-Filter Approach

We are concerned with the limited commitment to conduct fine-filter (species-level) assessments in the new rule. We found little scientific evidence to suggest that maintaining the diversity and integrity of a combination of habitat types "will provide the ecological conditions for the long-term persistence of most species within the plan area" (36 CFR §219.9). The Committee of Scientists stated, "Habitat alone cannot be used to predict wildlife populations" and "diversity is sustained only when individual species persist; the goals of ensuring viability and providing for diversity are inseparable" (Committee of Scientists 1999, Chapter 3:19,38). For this reason, the fine-filter species assessment is critical.

The rule is inaccurate in the way it portrays its coarse- and fine-filter approaches. It claims that the coarse-filter approach, along with the inclusion of fine-scale habitat management requirements for species that are not adequately protected, constitutes a combined coarse-filter/fine-filter approach. This discussion misconstrues fine-filter species conservation approaches, which entail direct assessment at the species level, including monitoring state variables such as a species' abundance, density, survival, birth rate, or occupancy. Managing fine-scale habitat components for a given species is not the same as fine-filter assessment.

The USFS defines focal species, in part, based on their functional significance to ecosystem processes (36 CFR §219.19[2012]). The planning rule requires the selection and monitoring of focal species "to assess the ecological conditions required under §219.9 . . ." (§219.12[a][5][iii]), and it is this aspect of the rule that holds the most promise as a genuine, complimentary fine-filter approach to wildlife conservation planning. The USFS defines ecological conditions as "the biological and physical environment that can affect the diversity of plant and animal communities, the persistence of native species, and the productive capacity of ecological systems" (36 CFR §219.19[2012]). An emphasis on monitoring species with known or suspected functional significance to ecosystems process and sustainability is appropriate. Ecosystem resilience is strongly related to native species diversity and functional redundancy (the degree to which multiple species perform similar ecosystem functions [Naeem et al. 2009]). In general, ecosystems with greater native species diversity are more resistant to disturbance, recover more quickly following disturbance, and are less likely to experience irreversible changes than species-poor communities (Cottingham et al. 2001, Hooper et al., 2005, Naeem et al. 2009). Furthermore, species loss ranks among the most severe global change stressors, with effects comparable to those of climate warming, acidification, and elevated carbon dioxide (Hooper et al. 2012). Therefore, it is inconsistent with the stated intent of §219.9 to maintain or restore ecological conditions not to include a commensurate requirement to maintain viable populations of focal species.

Another central requirement of the 2012 rule is the mandate to contribute to the recovery of proposed, candidate, and listed ESA species and to protect viable populations of species of conservation concern. Section 219.9 requires that species-specific habitat management components be built into plans if the responsible official determines that coarse-filter approaches are insufficient for maintaining viable populations of species of conservation concern, and ESA species, within the plan area. We are concerned that, as presently construed, the rule does not require the monitoring of these species. Thus, it is unclear what information will be used to determine if a species maintains a viable population within the plan area, or if it requires additional species-specific conservation actions. Because the coarse-filter approach may be insufficient to provide insights into the status and trend of species (Cushman et al. 2008), some direct species-level monitoring is necessary. Without such monitoring, the USFS's approach is problematic; by the time evidence of further decline for these already at-risk species is found, threats may have significantly increased.

Ideally, the rule would have committed to population-level monitoring and viability for both focal species and species of conservation concern. Extending the viability requirement to focal species, selected in part because of their known or suspected functional significance, is a logical way to address the ecosystem integrity goals of the rule. Further, monitoring species of conservation concern will provide essential information to assess their viability. These changes, incorporated into the Directives, would connect the commitment to species-level conservation with the mandate for adaptive management and bring greater cohesion to the disjointed diversity provisions in the 2012 rule. In addition, all species-level monitoring should include trigger points so that significant declines in either focal species or species of conservation concern would initiate reviews of management policies.

Selecting Species of Conservation Concern and Focal Species

The process for selecting focal species and identifying species of conservation concern, separately or in concert, is not detailed in the rule. The rule simply states that the selection of species of conservation concern will be based on the best available science and evidence of substantial concern about their long-term persistence in the plan area. The Record of Decision indicates that further guidance will be provided in the Directives, but that the Department of Agriculture expects species to be identified based on existing classifications of risk, such as NatureServe conservation status or those listed as threatened or endangered under state law (77 FR 21162:21218). In addition to referencing NatureServe and state law, we recommend the agency also consider IUCN red-list species that are not already listed under the ESA, and high priority species identified in State Wildlife Action Plans; if such species are not selected, a rationale for failing to designate them as species of conservation concern should be required.

Criteria for focal species selection include the species' functional roles in the ecosystem and sensitivity to changing conditions, management activities, particular threats, or desired ecological conditions (77 FR 21162). This is consistent with recommendations of the most recent Committee of Scientists' Report (Committee of Scientists 1999). Additional guidance in the Directives will be necessary to establish and maintain consistency and efficacy across management units in the selection of focal species. Noon et al. (2009) provide useful guidance on focal species selection for fine-filter assessments on federal public lands. Furthermore, we see no reason that species identified as species of conservation concern cannot also be identified as focal species, providing a ready avenue for conceptual integration of the fine-filter approaches under the new planning rule.

Establishing a step-down process to identify and prioritize species for fine-filter monitoring that reflects the reality of Forest Service monitoring budgets remains a major challenge. This topic goes beyond the scope of our paper, but to initiate discussion, we suggest that identifying the core species (Magurran and Henderson 2003) that are 1) persistent members of a given management unit; 2) functionally significant; and 3) at risk in that unit may be a first step in developing a manageable species set.

Developing Informative Monitoring Programs

The planning rule requires forests to develop monitoring programs that will include a set of questions and indicators to track change, measure management effectiveness, and assess progress towards desired future conditions. The rule only commits to monitoring focal species, which as mentioned above, may include species of conservation concern (the fine-filter approach). It also requires monitoring a select set of ecological conditions in accordance with the objectives of §219.9 (the coarse-filter approach). The Regional Forester is required to develop a broad-scale monitoring plan to address issues relevant at a scale larger than a single National Forest. The content of the broad-scale monitoring plan is at the discretion of the Regional Forester, and s/he is required to coordinate with other jurisdictions, other branches of the USFS, and the public. Additionally, monitoring plans may be coordinated across units. The responsible officials are to conduct biennial evaluations of monitoring information and adjust management activities as necessary.

At the outset, the discussion of species monitoring in the Record of Decision (77 FR 21162:21232–21233) is confusing and suggests a critical misunderstanding by the USFS of environmental monitoring. The Record of Decision (77 FR 21162:21233) states, "The final rule does not require monitoring species population trends. Species population trend monitoring is costly, time intensive, and may not provide conclusive or relevant information." This perspective is at odds with the general understanding in the scientific literature of environmental monitoring. For example, Suter (1993:505) states that monitoring is the "measurement of environmental characteristics over an extended period of time to determine status or trends in some aspect of environmental quality." Monitoring of an appropriate state variable (e.g., occupancy) is conducted at regular intervals to assess both the current state and time trend in some ecological resource (e.g., a species' population [Noon 2003, Nichols and Williams 2006])—that is, the stated purpose of monitoring is to estimate temporal trends.

Provisions in the rule encourage the development of robust monitoring strategies. However, our primary concern is whether these strategies will be developed, funded, implemented, and designed in such a way that they inform adaptive planning. As noted previously, monitoring has been chronically underfunded by federal agencies. The rule requires development of a monitoring plan but does not specify a particular standard of quality or utility of monitoring data. Since Congress annually sets the agency's budget, the USFS cannot commit to funding monitoring at a particular dollar amount. However, committing a certain percentage of planning dollars to monitoring may be possible so that the USFS can address its commitment to adaptive management.

Following the United States Supreme Court's decision in *Norton v. SUWA* (2004), enforcing monitoring requirements of federal land use plans is difficult. In language easily extendible to NFMA plans, that case held that commitments to monitor in Bureau of Land Management land use plans are not generally binding or reviewable under the parameters of administrative law. The Court noted that monitoring requirements could perhaps be written in such a way as to make them enforceable, if they were written as clear and binding commitments. In some cases, when monitoring activities are clearly required before undertaking certain activities, monitoring can be enforceable in court (Blumm and Bosse 2007). However, because requiring or enforcing funding levels or data quality standards for monitoring programs is generally difficult, oversight will be necessary to ensure that monitoring occurs in a way that it clearly assesses management and restoration actions.

We recommend that multi-party oversight boards be established to aid in the design of monitoring programs, contribute to the selection and prioritization of monitoring state variables, provide science consistency checks, provide interpretations of the monitoring data, suggest when changes to management practices are needed, and advocate for consistent funding. Because monitoring data will unlikely be subject to judicial review, oversight from a multi-party stakeholder monitoring board could increase the likelihood that monitoring will provide reliable information and useful insights into future decision making (Nie and Schultz 2012). Such boards must consider how monitoring data will inform decision making and the level of statistical certainty required to trigger a change in management actions.

All species-level monitoring should include trigger points so that significant declines in either focal species or species of conservation concern will initiate reviews of management policies. If trigger points are not identified, monitoring data may not feed back into adaptive planning and decision making (Noon 2003). Triggers will be critical for species-level monitoring and for any evaluation of species viability. Monitoring enforceability also would be substantially increased if forest plans included requirements that before approving any major projects, such as those requiring an Environmental Impact Statement, the responsible official find that monitoring programs are being implemented and that no trigger points have been exceeded without corrective action.

Maintaining Current Populations and Adequate Distribution of Species

Whether the planning rule intentionally allows for local extirpation of species or range reductions in cases where this might be avoided is unclear, but the decline and loss of species from the planning area is an allowable outcome of USFS management under the new rule. Aside from the loss of a broader viability requirement, this is the most significant change from the 1982 rule: the replacement of language requiring that viable populations be well-distributed, with the definition of a viable population as one that "continues to persist over the long term with sufficient distribution to be resilient and adaptable to stressors and likely future events" (36 CFR §219.19 [2012]). The impact of the change stems from the fact that what constitutes a "sufficient distribution" is not defined in the rule, providing broad discretion to the responsible official and obfuscating the well-established relationship between geographic distribution and persistence likelihood (e.g., Harris and Pimm 2008).

Furthermore, the rule establishes that the USFS does not need to protect viable populations, as required in the 1982 rule, if this is not within the "inherent capability of the plan area," a vague concept that is never defined in measurable terms. In this case, the USFS is held to a much lower conservation standard: documenting the rationale for such a determination and working across land ownerships to create management standards and guidelines to maintain or restore conditions that will contribute to maintaining a viable population of the species within its range (36 C.F.R. §219.9(b)(2)(i) [2012]). The USFS also states, "the individuals of a species of conservation concern that exist in the plan area will be considered to be members of one population of that species" (77 FR 21162:21217). In light of this, whether the agency is committing to maintaining a viable population of a species of conservation concern when it is not within the inherent capability of a single plan area to protect a viable population is not entirely clear. Depending on how the agency interprets these standards, it might never have to commit to maintaining a viable population of a low-density, wide-ranging species, but it might have to commit to maintaining multiple viable populations of species with more constricted ranges.

To address ambiguities in the 2012 viability requirements, we recommend that the USFS explicitly recognize the importance of maintaining a wide geographic distribution for species viability. Species that are widely distributed across the landscape are much less likely to experience spatially correlated disturbance events (den Boer 1981). Maintaining the distribution and viability of rare or widely distributed species and populations will require close coordination among administrative units. Guidance should be included in the Directives indicating that the agency should assess viability (perhaps employing more efficient distributional analyses based on occupancy [Noon et al. 2012]) across ownerships and plan units, when this will enhance the likelihood of persistence for individual species. When the USFS determines that maintaining a viable population of a species is not within the inherent capability of the plan area, the agency should solicit scientific comment and review. This review will help ensure that the agency is aware of all relevant scientific information that may conflict with their determination and will better prepare the agency to defend its decisions against possible legal challenge. In cases where the USFS determines that providing for a viable population of a species that relies upon National Forest System lands for its habitat is not within the capability of the plan area, we recommend that the agency task itself with restoring populations, to the maximum extent practicable. At the least, a standard should be included in the Directives that directs the agency not to authorize or permit activities that reduce the viability of any species of conservation concern.

Development on private land and other activities external to National Forest System lands may affect species such that the USFS cannot alone ensure their viability. A critical question is to what extent should this compel the USFS to compensate for declines in species status due to factors outside of their control. Recall that the NFMA emphasizes the National Forests' role in conserving resources for the American people, in perpetuity. It does not imply that this objective is restricted to National Forest System lands. There is ample historical precedent for the USFS to consider what is happening outside of its jurisdiction and proactively respond on the National Forests (Nie and Miller 2010). In the view of the first chief of the USFS, Gifford Pinchot, 1 rationale for establishment of the National Forests was to compensate for unsustainable management of resources on private lands (Wilkinson 1992). Pinchot was focused on unsustainable timber harvest at the time, but the reasoning applies widely to other natural resources on USFS lands based on changing public values and priorities. The USFS, in its 2012 rule, emphasizes its responsibility to maintain and restore ecosystem diversity and integrity, and diverse plant and animal communities are fundamental to ecosystem integrity (Naeem et al. 2009). If development on private land is adversely affecting biodiversity, the USFS has a greater, not lesser, responsibility to protect species on its lands. This compensation principle will become even more significant given predictions of private land development in the future, with much of this development projected in the wildland urban interface (Nie and Miller 2010). The National Forests, and federal lands in general, will become more important to wildlife in increasingly developed landscapes. Therefore, the "inherent capacity" clause of the 2012 rule should be used rarely, if at all, and if used, be subject to scientific and public review. The USFS must recognize its increasingly important mission to conserve the nation's forest and grassland ecosystems during the current period of rapid global change and species loss, when unpredictable transformations of ecosystems may be the "new normal" (Barnosky et al. 2012).

Considerations Regarding the Relationship Between the NFMA and the ESA

Important intersections exist between biodiversity conservation requirements under the NFMA and the ESA, which work together as part of this nation's biodiversity conservation policy. Wildlife provisions in forest plans are a significant factor in ESA decision making (see below), and ESA decisions have profound and far-reaching implications for forest management. Ideally, viability protection on National Forests would serve as an early warning signal that a species may be heading towards local extirpation or extinction. A proactive approach to address risks to a species' viability could avoid costly and polarizing ESA decisions that might limit management flexibility for the USFS.

On the National Forests, currently 430 species are listed under the ESA as threatened or endangered, and an additional 60 species are candidates for listing (USFS 2011:14). More than 647,000 ha of terrestrial habitat and 35,000 km of stream habitat on USFS lands are designated as critical habitat under the ESA (USFS 2011:14). For these and other reasons, the 2012 planning rule emphasizes the connections between forest planning and the ESA more than previous regulations:

> The [Department of Agriculture] anticipates that plan components, including standards or guidelines, for the plan area would address conservation measures and actions identified in recovery plans relevant to T&E [threatened and endangered] species. When implemented over time, these requirements would be expected to result in plans that will be proactive in the recovery and conservation of the threatened, endangered, proposed, and candidate species in the plan areas. These requirements will further the purposes of section 7(a)(1) of the ESA, by actively contributing to threatened and endangered species recovery and maintaining or restoring the ecosystems upon which they depend (77 FR 21162:21215).

One way in which the USFS can actively contribute to species conservation and recovery is by providing wildlife and habitat-based standards in individual National Forest plans. The NFMA requires the incorporation of standards and guidelines in land and resource management plans (16 U.S.C. 1694). Standards are mandatory constraints on USFS projects and activities and are used to achieve or maintain desired conditions and planning objectives, to avoid or mitigate undesirable environmental impacts, and to meet applicable legal requirements (76 FR 8480). Guidelines, as commonly applied, also constrain decision making but allow for some deviation from rules as long as the intent of the guideline is achieved (76 FR 8480).

The types of wildlife and habitat-based standards used in forest planning differ in scale, specificity, and complexity. Some standards cover multiple National Forests, such as the Northwest Forest Plan's Aquatic Conservation Strategy (discussed below) and the Inland Native Fish Strategy. The latter, covering at one point 22 National Forests, is used to protect native fish and their habitats in eastern Oregon and Washington, Idaho, western Montana, and portions of Nevada. It does so by using several riparian management objectives, standards, guidelines, and monitoring requirements (USFS 1995). The Inland Native Fish Strategy's standards and guidelines replaced conflicting direction in multiple National Forest plans, except when those forests provided for more protection for inland native fish habitat. Standards can also be applied forest-wide, such as requiring that all snags over a certain size be retained or that a specified percentage of old growth be maintained on a National Forest. Other standards apply to particular management areas or zones as delineated in a land use plan; they often permit or prohibit various uses, such as grazing or the application of herbicides in a municipal watershed zone.

An enduring debate continues over the appropriate role of standards in forest planning. The 2012 rule requires every plan to include standards as 1 of 5 plan components (36 C.F.R. §219.7), but it leaves their application to the discretion of the responsible official, with the expectation that further direction will be provided in the Directives system (77 FR 21162:21206). Regarding the diversity of plant and animal communities, the rule requires standards or guidelines be used "to maintain or restore ecological conditions within the plan area to contribute to maintaining a viable population of the species within its range" (36 C.F.R. §219.9). Standards for wildlife protections should play a significant role in the new forest plans that will be written under the 2012 regulations. Legally binding and enforceable standards promote accountability and provide increased certainty about future management actions. Without them, there is an increased risk that wildlife protections will give way to other agency pressures and priorities.

Forest plan standards can play significant roles in decisions to list or delist a species under the ESA. One of the 5 factors to be considered by the wildlife regulatory agencies that enforce the ESA (the National Oceanic and Atmospheric Agency [NOAA] Fisheries and the U.S. Fish and Wildlife Service [USFWS]) in making ESA listing decisions is "the inadequacy of existing regulatory mechanism[s]" (16 U.S.C. §1533). Vague, voluntary, speculative, and unenforceable measures found in plans are generally not considered a sufficient regulatory mechanism (*Oregon Natural Resources Council v. Daley* 1998). Instead, federal wildlife agencies and the courts typically assess whether a plan contains specific and legally enforceable standards having regulatory force. Forest plan standards also can be relevant for determinations made by the wildlife regulatory agencies under section 7 of the ESA, which requires federal agencies to undergo consultation with the wildlife agencies to ensure their projects will not cause jeopardy to a listed species.

Several cases have been decided in which NOAA Fisheries and the USFWS made a no-jeopardy determination under section 7 of the ESA or decided not to list a particular species because a forest plan contained binding standards and other regulatory mechanisms to protect the petitioned species. One example is the decision not to list the Queen Charlotte goshawk (*Accipiter gentilis laingi*) in southeast Alaska. Roughly 80% of this region is managed by the Tongass National Forest, and petitioners argued that old-growth logging in the region posed a threat to goshawks. Standards and other regulatory mechanisms specified in the 2007 Tongass Land Management Plan were significant factors in the decision by the USFWS to not list the goshawk (72 FR 63133). The USFWS also emphasized the legally binding and enforceable nature of Tongass forest planning standards in its 1997 status review of the species (USFWS 2007), and the Department of the Interior asked the USFS to retain the Conservation Strategy in the 2008 Tongass Forest Plan Amendment. The USFS also recognizes the significance of these wildlife standards. Possible changes to the Strategy, according to Undersecretary of Agriculture Harris Sherman, "could hamper the plan's ability to maintain viable populations of plant and wildlife species [and] this could lead to the need for USFWS to reconsider its previous determinations regarding the goshawk . . ." (Sherman 2011:8).

The Aquatic Conservation Strategy, part of the Northwest Forest Plan, provides another example of the interactions between binding standards and the ESA (USFS and Bureau of Land Management 1994). The purpose of the Aquatic Conservation Strategy is to maintain and restore the ecological health of watersheds in the northwestern National Forests. The Strategy includes several binding standards and guidelines that apply to key watersheds, riparian reserves, required watershed analyses, and watershed restoration. In biological opinions written in accordance with section 7 of the ESA, NOAA Fisheries equates Aquatic Conservation Strategy consistency with no-jeopardy findings, a practice that has satisfied the courts (*Pacific Coast Federation of Fishermen's Associations v. National Marine Fisheries Service* 2001). Standards such as these can be used to protect wildlife while also achieving the restoration and watershed protection purposes of the 2012 rule.

The lack of enforceable standards and clear conservation commitments made in forest plans also has been a factor influencing decisions to list a species. In these cases, NOAA Fisheries and the USFWS determine that a forest plan fails to provide sufficiently certain, binding, and detailed protection to a species to count as an adequate regulatory mechanism. One of the most significant decisions in this regard is provided by the listing of Canada lynx (*Lynx canadensis*) as threatened in 2000 (65 FR 16052). The species was classified as a sensitive species by the USFS before listing, but most National Forests with lynx did not have population viability objectives or management standards and guidelines in place at the time (63 FR 37005). The fact that forest plans in effect at the time did not provide enough protection and guidance for the conservation of the lynx is a primary reason why the species was listed. The USFWS determined that these forest plans permitted several actions that cumulatively could cause a significant threat to lynx persistence across its range (63 FR 37005). The USFS responded to the listing by amending multiple national forest plans to incorporate various lynx standards and guidelines (USFS 2007). Currently, the USFS does not have to engage in ESA consultation with the USFWS on a project-by-project basis if these projects comply with these binding and enforceable lynx standards. Another prominent example is the 2010 decision to list the greater sage-grouse (*Centrocercus urophasianus*) as warranted-but-precluded, meaning the species is warranted for listing but precluded from actually being listed because of funding limitations (75 FR 13910). The USFS manages roughly 8% of the sagebrush habitat significant to the species. Greater sage-grouse were designated by the USFS as a sensitive species on USFS lands across the range of the species, and 14 of these forests designated the bird as a management indicator species (75 FR 13910:13979). But of the 33 National Forests managing greater sage-grouse habitat, "16 do not specifically address sage-grouse management or conservation in their Forest Plans, and only 6 provide a high level of detail specific to sage-grouse management" (75 FR 13910:13980). The lack of detailed protections and the variation among National Forest plans in the greater sage-grouse area was an important factor in making the warranted-but-precluded determination (75 FR 13910).

Enforceable wildlife standards and protections on the National Forests also play a role in delisting species from the ESA. One of the few species to be delisted under the ESA is the Robbin's cinquefoil (*Potentilla robbinsiana*), an endemic plant found in the White Mountains of New Hampshire, in areas managed exclusively by the White Mountain National Forest (67 FR 54968). The USFS was able to assist in the recovery of this species by restricting entry to particular areas of the National Forest, relocating trails, and entering into a Memorandum of Understanding with the USFWS. This Memorandum of Understanding included provisions related to habitat protection and monitoring, and it served as a long-term commitment by the USFS to conserve this plant, irrespective of its status and potential delisting under the ESA (USFS and USFWS 1994). The USFS regulations also prohibited removing, destroying or damaging plants that are classified as threatened, endangered, rare, or unique (36 C.F.R 261.9). All of these specific actions and commitments—the protective actions taken by the White Mountain National Forest, the plant regulations, and the Memorandum of Understanding—served as an adequate regulatory mechanism for delisting the species by the USFWS.

A more controversial example is the proposed delisting of the Yellowstone distinct population segment of grizzly bears (*Ursus arctos horribilis*). The lack of regulatory mechanisms to protect grizzly bear habitat on National Forest System lands was 1 reason why the species was listed in 1975 (40 FR 31734). A conservation strategy for the bear was written pursuant to its recovery plan to provide adequate regulatory mechanisms after the bear's delisting. The USFS amended 6 forest plans to incorporate the habitat standards and other provisions in the conservation strategy. The USFWS considers these standards to be adequate regulatory mechanisms for the purpose of delisting grizzly bears, but much of the debate and litigation over the delisting decision centers on the sufficiency of these standards. A district court found the delisting impermissible, partly because the amended forest plans contained discretionary and legally unenforceable guidelines, rather than binding standards, in the bear's primary conservation area (*Greater Yellowstone Coalition v. Servheen* 2009). The Ninth Circuit disagreed with the lower court on this matter and found the standards, as applied by the USFS within the primary conservation area, to be sufficient under the ESA because they are a legally enforceable part of National Forest plans, and management of these forests must be consistent with their governing forest plans (*Greater Yellowstone Coalition v. Servheen* 2011).

The 2012 rule also requires that forest plans provide the ecological conditions to "contribute to the recovery" of listed threatened and endangered (T&E) species (77 FR 21162:21215, 36 C.F.R. §219.9). The USFS has an expectation that forest plans would use standards or guidelines "to address conservation measures and actions identified in recovery plans relevant to T&E species" (77 FR 21162:21215). Better use of ESA recovery objectives could lead to more proactive, integrated, and strategically coordinated forest plans.

We recommend that more guidance be provided as to how synergies might be developed between forest and ESA recovery planning. Scott et al. (2005:386) show that "most listed species will require continuous management action in order to maintain their recovered status." These "conservation-reliant species" can only be maintained as a self-sustaining population in the wild "if ongoing management actions of proven effectiveness are implemented" (Scott et al. 2005:386). The Memorandum of Understanding and revised forest plan for Robbin's cinquefoil provide this sort of ongoing protection to a conservation-reliant species, and similar standards in forest plans could do the same for other T&E species on the National Forests.

The number of ESA listing decisions will only increase in the future, given the September 2011 settlement between the USFWS and environmental groups requiring the agency to make listing decisions on over 800 species, including 262 candidate species, for which such decisions have been delayed (Center for Biological Diversity 2012). Altogether, another 1,000 listing decisions will possibly have to be made by 2020 (Rylander 2012:10018). Furthermore, conservation scientists, the IUCN, and the Intergovernmental Panel of Climate Change all predict increases in the number of species threatened with extinction (Scott et al. 2010). For these reasons, the impact of ESA listing decisions on National Forest management is likely to increase over time. The use of binding standards in forest plans would likely serve to decrease the number of species listed as threatened and endangered and promote delisting decisions in the future.
