Adapting to Climate Change on Western Public Lands: Addressing the Ecological Effects of Domestic, Wild, and Feral Ungulates

Received: 27 January 2012 / Accepted: 13 September 2012

Abstract Climate change affects public land ecosystems and services throughout the American West and these effects are projected to intensify. Even if greenhouse gas emissions are reduced, adaptation strategies for public lands are needed to reduce anthropogenic stressors of terrestrial and aquatic ecosystems and to help native species and ecosystems survive in an altered environment. Historical and contemporary livestock production—the most widespread and long-running commercial use of public lands—can alter vegetation, soils, hydrology, and wildlife species composition and abundances in ways that exacerbate the effects of climate change on these resources. Excess abundance of native ungulates (e.g., deer or elk) and feral horses and burros add to these impacts. Although many of these consequences have been studied for decades, the ongoing and impending effects of ungulates in a changing climate require new management strategies for limiting their threats to the long-term supply of ecosystem services on public lands. Removing or reducing livestock across large areas of public land would alleviate a widely recognized and long-term stressor and make these lands less susceptible to the effects of climate change. Where livestock use continues, or where significant densities of wild or feral ungulates occur, management should carefully document the ecological, social, and economic consequences (both costs and benefits) to better ensure management that minimizes ungulate impacts to plant and animal communities, soils, and water resources. Reestablishing apex predators in large, contiguous areas of public land may help mitigate any adverse ecological effects of wild ungulates.

Introduction

During the 20th century, the average global surface temperature increased at a rate greater than in any of the previous nine centuries; future increases in the United States (US) are likely to exceed the global average (IPCC 2007a; Karl and others 2009). In the western US, where most public lands are found, climate change is predicted to intensify even if greenhouse gas emissions are reduced dramatically (IPCC 2007b). Climate-related changes can not only affect public-land ecosystems directly, but may exacerbate the aggregate effects of non-climatic stressors, such as habitat modification and pollution caused by logging, mining, grazing, roads, water diversions, and recreation (Root and others 2003; CEQ 2010; Barnosky and others 2012).

One effective means of ameliorating the effects of climate change on ecosystems is to reduce environmental stressors under management control, such as land and water uses (Julius and others 2008; Heller and Zavaleta 2009; Prato 2011). Public lands in the American West provide important opportunities to implement such a strategy for three reasons: (1) despite a history of degradation, public lands still offer the best available opportunities for ecosystem restoration (CWWR 1996; FS and BLM 1997; Karr 2004); (2) two-thirds of the runoff in the West originates on public lands (Coggins and others 2007); and (3) ecosystem protection and restoration are consistent with laws governing public lands. To be effective, restoration measures should address management practices that prevent public lands from providing the full array of ecosystem services and/or are likely to accentuate the effects of climate change (Hunter and others 2010). Although federal land managers have recently begun considering how to adapt to and mitigate potential climate-related impacts (e.g., GAO 2007; Furniss and others 2009; CEQ 2010; Peterson and others 2011), they have not addressed the combined effects of climate change and ungulates (hooved mammals) on ecosystems.

Climate change and ungulates, singly and in concert, influence ecosystems at the most fundamental levels by affecting soils and hydrologic processes. These effects, in turn, influence many other ecosystem components and processes—nutrient and energy cycles; reproduction, survival, and abundance of terrestrial and aquatic species; and community structure and composition. Moreover, by altering so many factors crucial to ecosystem functioning, the combined effects of a changing climate and ungulate use can affect biodiversity at scales ranging from species to ecosystems (FS 2007) and limit the capability of large areas to supply ecosystem services (Christensen and others 1996; MEA 2005b).

In this paper, we explore the likely ecological consequences of climate change and ungulate use, individually and in combination, on public lands in the American West. Three general categories of large herbivores are considered: livestock (largely cattle [*Bos taurus*] and sheep [*Ovis aries*]), native ungulates (deer [*Odocoileus* spp.] and elk [*Cervus* spp.]), and feral ungulates (horses [*Equus caballus*] and burros [*E. asinus*]). Based on this assessment, we propose first-order recommendations to decrease these consequences by reducing ungulate effects that can be directly managed.

Climate Change in the Western US

Anticipated changes in atmospheric carbon dioxide (CO_2), temperature, and precipitation (IPCC 2007a) are likely to have major repercussions for upland plant communities in western ecosystems (e.g., Backlund and others 2008), eventually affecting the distribution of major vegetation types. Deserts in the southwestern US, for example, will expand to the north and east, and in elevation (Karl and others 2009). Studies in southeastern Arizona have already attributed dramatic shifts in species composition and plant and animal populations to climate-driven changes (Brown and others 1997). Thus, climate-induced changes are already accelerating the ongoing loss of biodiversity in the American West (Thomas and others 2004).

Future decreases in soil moisture and vegetative cover due to elevated temperatures will reduce soil stability (Karl and others 2009). Wind erosion is likely to increase dramatically in some ecosystems such as the Colorado Plateau (Munson and others 2011) because biological soil crusts—a complex mosaic of algae, lichens, mosses, microfungi, cyanobacteria, and other bacteria—may be less drought tolerant than many desert vascular plant species (Belnap and others 2006). Higher air temperatures may also lead to elevated surface-level concentrations of ozone (Karl and others 2009), which can reduce the capacity of vegetation to grow under elevated CO_2 levels and sequester carbon (Karnosky and others 2003).

Air temperature increases and altered precipitation regimes will affect wildfire behavior and interact with insect outbreaks (Joyce and others 2009). In recent decades, climate change appears to have increased the length of the fire season and the area annually burned in some western forest types (Westerling and others 2006; ITF 2011). Climate induced increases in wildfire occurrence may aggravate the expansion of cheatgrass (*Bromus tectorum*), an exotic annual that has invaded millions of hectares of sagebrush (*Artemisia* spp.) steppe, a widespread yet threatened ecosystem. In turn, elevated wildfire occurrence facilitates the conversion of sagebrush and other native shrub-perennial grass communities to those dominated by alien grasses (D'Antonio and Vitousek 1992; Brooks 2008), resulting in habitat loss for imperiled greater sage-grouse (*Centrocercus urophasianus*) and other sagebrush-dependent species (Welch 2005). The US Fish and Wildlife Service (FWS 2010) recently concluded climate change effects can exacerbate many of the multiple threats to sagebrush habitats, including wildfire, invasive plants, and heavy ungulate use. In addition, the combined effects of increased air temperatures, more frequent fires, and elevated CO_2 levels apparently provide some invasive species with a competitive advantage (Karl and others 2009).

By the mid-21st century, Bates and others (2008) indicate that warming in western mountains is very likely to cause large decreases in snowpack, earlier snowmelt, more winter rain events, increased peak winter flows and flooding, and reduced summer flows. Annual runoff is predicted to decrease by 10–30 % in mid-latitude western North America by 2050 (Milly and others 2005) and up to 40 % in Arizona (Milly and others 2008; ITF 2011). Drought periods are expected to become more frequent and longer throughout the West (Bates and others 2008). Summertime decreases in streamflow (Luce and Holden 2009) and increased water temperatures already have been documented for some western rivers (Kaushal and others 2010; Isaak and others 2012).

Snowmelt supplies about 60–80 % of the water in major western river basins (the Columbia, Missouri, and Colorado Rivers) and is the primary water supply for about 70 million people (Pederson and others 2011). Contemporary and future declines in snow accumulations and runoff (Mote and others 2005; Pederson and others 2011) are an important concern because current water supplies, particularly during low-flow periods, are already inadequate to satisfy demands over much of the western US (Piechota and others 2004; Bates and others 2008).

High water temperatures, acknowledged as one of the most prevalent water quality problems in the West, will likely be further elevated and may render one-third of the current coldwater fish habitat in the Pacific Northwest unsuitable by this century's end (Karl and others 2009). Resulting impacts on salmonids include increases in virulence of disease, loss of suitable habitat, and mortality as well as increased competition and predation by warmwater species (EPA 1999). Increased water temperatures and changes in snowmelt timing can also affect amphibians adversely (Field and others 2007). In sum, climate change will have increasingly significant effects on public-land terrestrial and aquatic ecosystems, including plant and animal communities, soils, hydrologic processes, and water quality.

Ungulate Effects and Climate Change Synergies

Climate change in the western US is expected to amplify "combinations of biotic and abiotic stresses that compromise the vigor of ecosystems—leading to increased extent and severity of disturbances" (Joyce and others 2008, p. 16). Of the various land management stressors affecting western public lands, ungulate use is the most widespread (Fig. 1). Domestic livestock annually utilize over 70 % of lands managed by the Bureau of Land Management (BLM) and US Forest Service (FS). Many public lands are also used by wild ungulates and/or feral horses and burros, which are at high densities in some areas. Because ungulate groups can have different effects, we discuss them individually.

Livestock

History and Current Status

Livestock were introduced to North America in the mid-sixteenth century, with a massive influx from the mid-1800s through early 1900s (Worster 1992). The deleterious effects of livestock—including herbivory of both herbaceous and woody plants and trampling of vegetation, soils, and streambanks—prompted federal regulation of grazing on western national forests beginning in the 1890s (Fleischner 2010). Later, the 1934 Taylor Grazing Act was enacted "to stop injury to the public grazing lands by preventing overgrazing and soil deterioration" on lands subsequently administered by the BLM.

Total livestock use of federal lands in eleven contiguous western states today is nearly 9 million animal unit months (AUMs, where one AUM represents forage use by a cow and calf pair, one horse, or five sheep for one month) (Fig. 2a). Permitted livestock use occurs on nearly one million square kilometers of public land annually, including 560,000 km^2 managed by the BLM, 370,000 km^2 by the FS, 6,000 km^2 by the National Park Service (NPS), and 3,000 km^2 by the US Fish and Wildlife Service (FWS).

Livestock use affects a far greater proportion of BLM and FS lands than do roads, timber harvest, and wildfires combined (Fig. 3). Yet attempts to mitigate the pervasive effects of livestock have been minor compared with those aimed at reducing threats to ecosystem diversity and productivity that these other land uses pose. For example, much effort is often directed at preventing and controlling wildfires since they can cause significant property damage and social impacts. On an annual basis, however, wildfires affect a much smaller portion of public land than livestock grazing (Fig. 3) and they can also result in ecosystem benefits (Rhodes and Baker 2008; Swanson and others 2011).

The site-specific impacts of livestock use vary as a function of many factors (e.g., livestock species and density, periods of rest or non-use, local plant communities, soil conditions). Nevertheless, extensive reviews of published research generally indicate that livestock have had numerous and widespread negative effects to western ecosystems (Love 1959; Blackburn 1984; Fleischner 1994; Belsky and others 1999; Kauffman and Pyke 2001; Asner

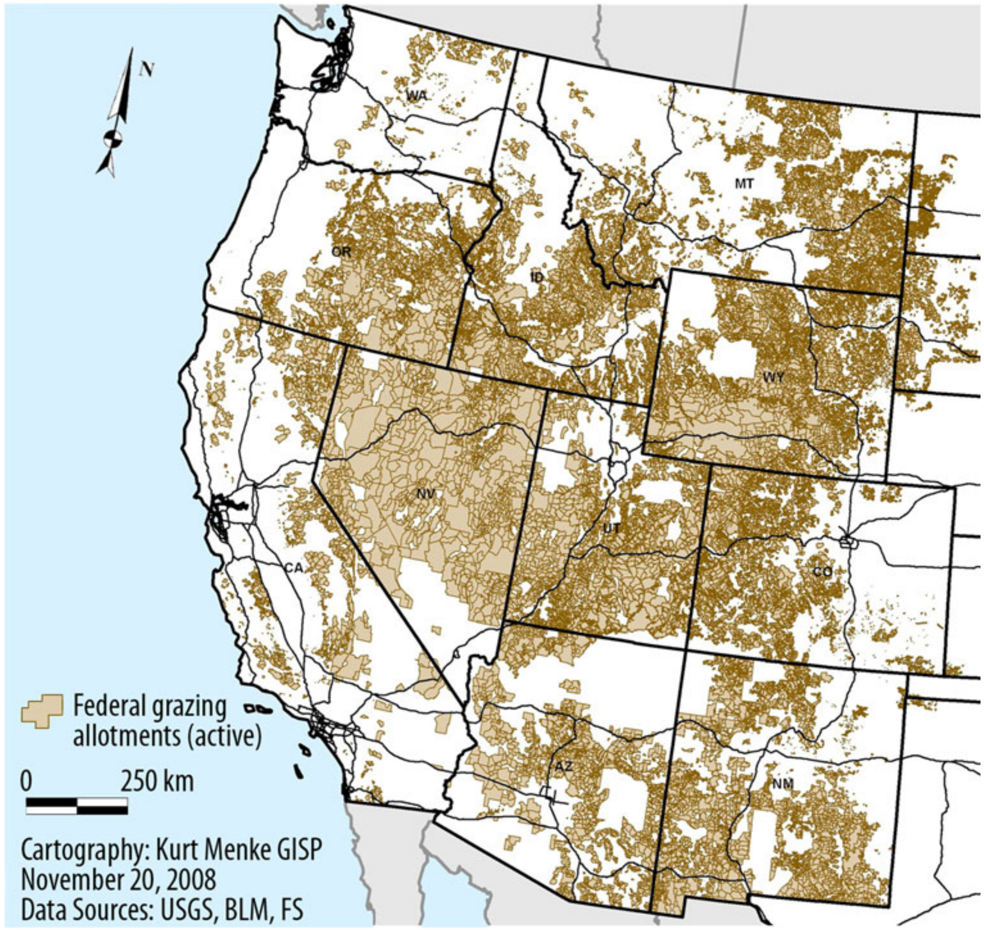

Fig. 1 Areas of public-lands livestock grazing managed by federal agencies in the western US (adapted from Salvo 2009)

and others 2004; Steinfeld and others 2006; Thornton and Herrero 2010). Moreover, public-land range conditions have generally worsened in recent decades (CWWR 1996, Donahue 2007), perhaps due to the reduced productivity of these lands caused by past grazing in conjunction with a changing climate (FWS 2010, p. 13,941, citing Knick and Hanser 2011).

Plant and Animal Communities

Livestock use effects, exacerbated by climate change, often have severe impacts on upland plant communities. For example, many former grasslands in the Southwest are now dominated by one or a few woody shrub species, such as creosote bush (*Larrea tridentata*) and mesquite (*Prosopis glandulosa*), with little herbaceous cover (Grover and Musick 1990; Asner and others 2004; but see Allington and Valone 2010). Other areas severely affected include the northern Great Basin and interior Columbia River Basin (Middleton and Thomas 1997). Livestock effects have also contributed to severe degradation of sagebrush-grass ecosystems (Connelly and others 2004; FWS 2010) and widespread desertification, particularly in the Southwest (Asner and others 2004; Karl and others 2009). Even absent desertification, light to moderate grazing intensities can promote woody species encroachment in semiarid and mesic environments (Asner and others 2004, p. 287). Nearly two decades ago, many public-land ecosystems, including native shrub steppe in Oregon and Washington, sagebrush steppe in the Intermountain West, and riparian plant communities, were considered threatened, endangered, or critically endangered (Noss and others 1995).

Simplified plant communities combine with loss of vegetation mosaics across landscapes to affect pollinators, birds, small mammals, amphibians, wild ungulates, and other native wildlife (Bock and others 1993; Fleischner 1994; Saab and others 1995; Ohmart 1996). Ohmart and Anderson (1986) suggested that livestock grazing may be the major factor negatively affecting wildlife in eleven western states. Such effects will compound the problems of adaptation of these ecosystems to the dynamics of climate change (Joyce and others 2008, 2009). Currently, the widespread and ongoing declines of many North American bird populations that use grassland and grass–shrub habitats affected by grazing are “on track to become a prominent wildlife conservation crisis of the 21st century” (Brennan and Kuvlesky 2005, p. 1).

Soils and Biological Soil Crusts

Livestock grazing and trampling can damage or eliminate biological soil crusts characteristic of many arid and semiarid regions (Belnap and Lange 2003; Asner and others 2004). These complex crusts are important for fertility, soil stability, and hydrology (Belnap and Lange 2003). In arid and semiarid regions they provide the major barrier against wind erosion and dust emission (Munson and others 2011). Currently, the majority of dust emissions in North America originate in the Great Basin, Colorado Plateau, and Mojave and Sonoran Deserts, areas that are predominantly public lands and have been grazed for nearly 150 years. Elevated sedimentation in western alpine lakes over this period has also been linked to increased aeolian deposition stemming from land uses, particularly those associated with livestock grazing (Neff and others 2008).

If livestock use on public lands continues at current levels, its interaction with anticipated changes in climate will likely worsen soil erosion, dust generation, and stream pollution. Soils whose moisture retention capacity has been reduced will undergo further drying by warming temperatures and/or drought and become even more susceptible to wind erosion (Sankey and others 2009). Increased aeolian deposition on snowpack will hasten runoff, accentuating climate-induced hydrological changes on many public lands (Neff and others 2008). Warmer temperatures will likely trigger increased fire occurrence, causing further reductions in cover and composition of biological soil crusts (Belnap and others 2006), as well as vascular plants (Munson and others 2011). In some forest types, where livestock grazing has contributed to altered fire regimes and forest structure (Belsky and Blumenthal 1997; Fleischner 2010), climate change will likely worsen these effects.

Water and Riparian Resources

Although riparian areas occupy only 1–2 % of the West’s diverse landscapes, they are highly productive and ecologically valuable due to the vital terrestrial habitats they provide and their importance to aquatic ecosystems (Kauffman and others 2001; NRC 2002; Fleischner 2010). Healthy riparian plant communities provide important corridors for the movement of plant and animal species

(Peterson and others 2011). Such communities are also crucial for maintaining water quality, food webs, and channel morphology vital to high-quality habitats for fish and other aquatic organisms in the face of climate change. For example, well-vegetated streambanks not only shade streams but also help to maintain relatively narrow and stable channels, attributes essential for preventing increased stream temperatures that negatively affect salmonids and other aquatic organisms (Sedell and Beschta 1991; Kondolf and others 1996; Beschta 1997); maintaining cool stream temperatures is becoming even more important with climate change (Isaak and others 2012). Riparian vegetation is also crucial for providing seasonal fluxes of organic matter and invertebrates to streams (Baxter and others 2005). Nevertheless, in 1994 the BLM and FS reported that western riparian areas were in their worst condition in history, and livestock use—typically concentrated in these areas—was the chief cause (BLM and FS 1994).

Livestock grazing has numerous consequences for hydrologic processes and water resources. Livestock can have profound effects on soils, including their productivity, infiltration, and water storage, and these properties drive many other ecosystem changes. Soil compaction from livestock has been identified as an extensive problem on public lands (CWWR 1996; FS and BLM 1997). Such compaction is inevitable because the hoof of a 450-kg cow exerts more than five times the pressure of heavy earth-moving machinery (Cowley 2002). Soil compaction significantly reduces infiltration rates and the ability of soils to store water, both of which affect runoff processes (Branson and others 1981; Blackburn 1984). Compaction of wet meadow soils by livestock can significantly decrease soil water storage (Kauffman and others 2004), thus contributing to reduced summer base flows. Concomitantly, decreases in infiltration and soil water storage of compacted soils during periods of high-intensity rainfall contribute to increased surface runoff and soil erosion (Branson and others 1981). These fundamental alterations in hydrologic processes from livestock use are likely to be exacerbated by climate change.

The combined effects of elevated soil loss and compaction caused by grazing reduce soil productivity, further compromising the capability of grazed areas to support native plant communities (CWWR 1996; FS and BLM 1997). Erosion triggered by livestock use continues to represent a major source of sediment, nutrients, and pathogens in western streams (WSWC 1989; EPA 2009). Conversely, the absence of grazing results in increased litter accumulation, which can reduce runoff and erosion and retard desertification (Asner and others 2004).

Historical and contemporary effects of livestock grazing and trampling along stream channels can destabilize streambanks, thus contributing to widened and/or incised channels (NRC 2002). Accelerated streambank erosion and channel incision are pervasive on western public lands used by livestock (Fig. 4). Stream incision contributes to desiccation of floodplains and wet meadows, loss of floodwater detention storage, and reductions in baseflow (Ponce and Lindquist 1990; Trimble and Mendel 1995). Grazing and trampling of riparian plant communities also contribute to elevated water temperatures—directly, by reducing stream shading and, indirectly, by damaging streambanks and increasing channel widths (NRC 2002). Livestock use of riparian plant communities can also decrease the availability of food and construction materials for keystone species such as beaver (*Castor canadensis*).

Livestock effects and climate change can interact in various ways with often negative consequences for aquatic species and their habitats. In the eleven ecoregions encompassing western public lands (excluding coastal regions and Alaska), about 175 taxa of freshwater fish are considered imperiled (threatened, endangered, vulnerable, possibly extinct, or extinct) due to habitat-related causes (Jelks and others 2008, p. 377; GS and AFS 2011). Increased sedimentation and warmer stream temperatures associated with livestock grazing have contributed significantly to the long-term decline in abundance and distribution and loss of native salmonids, which are imperiled throughout the West (Rhodes and others 1994; Jelks and others 2008).

Water developments and diversions for livestock are common on public lands (Connelly and others 2004). For example, approximately 3,700 km of pipeline and 2,300 water developments were installed on just 17 % of the BLM's land base from 1961 to 1999 in support of livestock operations (Rich and others 2005). Such developments can reduce streamflows thus contributing to warmer stream temperatures and reduced fish habitat, both serious problems for native coldwater fish (Platts 1991; Richter and others 1997). Reduced flows and higher temperatures are also risk factors for many terrestrial and aquatic vertebrates (Wilcove and others 1998). Water developments can also create mosquito (e.g., *Culex tarsalis*) breeding habitat, potentially facilitating the spread of West Nile virus, which poses a significant threat to sage grouse (FWS 2010). Such developments also tend to concentrate livestock and other ungulate use, thus locally intensifying grazing and trampling impacts.

Greenhouse Gas Emissions and Energy Balances

Livestock production impacts energy and carbon cycles and globally contributes an estimated 18 % to the total anthropogenic greenhouse gas (GHG) emissions (Steinfeld and others 2006). How public-land livestock contribute to

Fig. 4 Examples of long-term grazing impacts from livestock, unless otherwise noted: **a** bare soil, loss of understory vegetation, and lack of aspen recruitment (i.e., growth of seedlings/sprouts into tall saplings and trees) (Bureau of Land Management, Idaho), **b** bare soil, lack of ground cover, lack of aspen recruitment and channel incision (US Forest Service, Idaho), **c** conversion of a perennial stream to an intermittent stream due to grazing of riparian vegetation and subsequent channel incision; channel continues to erode during runoff events (Bureau of Land Management, Utah), **d** incised and widening stream due to loss of streamside vegetation and bank collapse from trampling (Bureau of Land Management, Wyoming), **e** incised and widening stream due to loss of streamside vegetation and bank collapse from trampling (US Forest Service, Oregon), and **f** actively eroding streambank from the loss of streamside vegetation due to several decades of excessive herbivory by elk and, more recently, bison (National Park Service, Wyoming). *Photographs* **a** J Carter, **b** G Wuerthner, **c** and **d** J Carter, **e** and **f** R Beschta

these effects has received little study. Nevertheless, livestock grazing and trampling can reduce the capacity of rangeland vegetation and soils to sequester carbon and contribute to the loss of above- and below-ground carbon pools (e.g., Lal 2001b; Bowker and others 2012). Lal (2001a) indicated that heavy grazing over the long-term may have adverse impacts on soil organic carbon content, especially for soils of low inherent fertility. Although Gill (2007) found that grazing over 100 years or longer in subalpine areas on the Wasatch Plateau in central

Utah had no significant impacts on total soil carbon, results of the study suggest that "if temperatures warm and summer precipitation increases as is anticipated, [soils in grazed areas] may become net sources of CO_2 to the atmosphere" (Gill 2007, p. 88). Furthermore, limited soil aeration in soils compacted by livestock can stimulate production of methane, and emissions of nitrous oxide under shrub canopies may be twice the levels in nearby grasslands (Asner and others 2004). Both of these are potent GHGs.

Reduced plant and litter cover from livestock use can increase the albedo (reflectance) of land surfaces, thereby altering radiation energy balances (Balling and others 1998). In addition, widespread airborne dust generated by livestock is likely to increase with the drying effects of climate change. Air-borne dust influences atmospheric radiation balances as well as accelerating melt rates when deposited on seasonal snowpacks and glaciers (Neff and others 2008).

Other Livestock Effects

Livestock urine and feces add nitrogen to soils, which may favor nonnative species (BLM 2005), and can lead to loss of both organic and inorganic nitrogen in increased runoff (Asner and others 2004). Organic nitrogen is also lost via increased trace-gas flux and vegetation removal by grazers (Asner and others 2004). Reduced soil nitrogen is problematic in western landscapes because nitrogen is an important limiting nutrient in most arid-land soils (Fleischner 2010).

Managing livestock on public lands also involves extensive fence systems. Between 1962 and 1997, over 51,000 km of fence were constructed on BLM lands with resident sage-grouse populations (FWS 2010). Such fences can significantly impact this wildlife species. For example, 146 sage-grouse died in less than three years from collisions with fences along a 7.6-km BLM range fence in Wyoming (FWS 2010). Fences can also restrict the movements of wild ungulates and increase the risk of injury and death by entanglement or impalement (Harrington and Conover 2006; FWS 2010). Fences and roads for livestock access can fragment and isolate segments of natural ecological mosaics thus influencing the capability of wildlife to adapt to a changing climate.

Some have posited that managed cattle grazing might play a role in maintaining ecosystem structure in shortgrass steppe ecosystems of the US, if it can mimic grazing by native bison (*Bison bison*) (Milchunas and others 1998). But most public lands lie to the west of the Great Plains, where bison distribution and effects were limited or nonexistent; livestock use (particularly cattle) on these lands exert disturbances without evolutionary parallel (Milchunas and Lauenroth 1993; MEA 2005a).

Feral Horses and Burros

Feral horses and burros occupy large areas of public land in the western US. For example, feral horses are found in ten western states and feral burros occur in five of these states, largely in the Mojave and Sonoran Deserts and the Great Basin (Abella 2008; FWS 2010). About half of these horses and burros are in Nevada (Coggins and others 2007), of which 90 % are on BLM lands. Horse numbers peaked at perhaps two million in the early 1900s, but had plummeted to about 17,000 by 1971, when protective legislation (Wild, Free-Ranging Horses and Burros Act [WFRHBA]) was passed (Coggins and others 2007). Protection resulted in increased populations and today some 40,000 feral horses and burros utilize $\sim$ 130,000 km^2 of BLM and FS lands (DOI-OIG 2010; Gorte and others 2010). Currently, feral horse numbers are doubling every four years (DOI-OIG 2010); burro populations can also increase rapidly (Abella 2008). Unlike wild ungulates, feral equines cannot be hunted and, unlike livestock, they are not regulated by permit. Nor are their numbers controlled effectively by existing predators. Accordingly, the BLM periodically removes animals from herd areas; the NPS also has undertaken burro control efforts (Abella 2008).

In sage grouse habitat, high numbers of feral horses reduce vegetative cover and plant diversity, fragment shrub canopies, alter soil characteristics, and increase the abundance of invasive species, thus reducing the quality and quantity of habitat (Beever and others 2003; FWS 2010). Horses can crop plants close to the ground, impeding the recovery of affected vegetation. Feral burros also have had a substantial impact on Sonoran Desert vegetation, reducing the density and canopy cover of nearly all species (Hanley and Brady 1977). Although burro impacts in the Mojave Desert may not be as clear, perennial grasses and other preferred forage species likely require protection from grazing in burro-inhabited areas if revegetation efforts are to be successful (Abella 2008).

Wild Ungulates

Extensive harvesting of wild (native) ungulates, such as elk and deer, and the decimation of large predator populations (e.g., gray wolf [*Canis lupus*], grizzly bear [*Ursus arctos*], and cougar [*Puma concolor*]) was common during early EuroAmerican settlement of the western US. With continued predator control in the early 1900s and increased protection of game species by state agencies, however, wild ungulate populations began to increase in many areas. Although only 70,000 elk inhabited the western US in the early 1900s (Graves and Nelson 1919), annual harvest data indicate that elk abundance has increased greatly since the about the 1940s (Fig. 2b), due in part to the loss of apex predators (Allen 1974; Mackie and others 1998). Today, approximately one million elk (Karnopp 2008) and unknown numbers of deer inhabit the western US where they often share public lands with livestock.

Because wild ungulates typically occur more diffusely across a landscape than livestock, their presence might be expected to cause minimal long-term impacts to vegetation. Where wild ungulates are concentrated, however, their browsing can have substantial impacts. For example, sagebrush vigor can be reduced resulting in decreased cover or mortality (FWS 2010). Heavy browsing effects have also been documented on other palatable woody shrubs, as well as deciduous trees such as aspen (*Populus tremuloides*), cottonwood (*Populus* spp.), and maple (*Acer* sp.) (Beschta and Ripple 2009).

Predator control practices that intensified following the introduction of domestic livestock in the western US resulted in the extirpation of apex predators or reduced their numbers below ecologically effective densities (Soulé and others 2003, 2005), causing important cascading effects in western ecosystems (Beschta and Ripple 2009). Following removal of large predators on the Kaibab Plateau in the early 20th century, for example, an irruption of mule deer (*O. hemionus*) led to extensive over-browsing of aspen, other deciduous woody plants, and conifers; deterioration of range conditions; and the eventual crash of the deer population (Binkley and others 2006). In the absence of apex predators, wild ungulate populations can significantly limit recruitment of woody browse species, contribute to shifts in abundance and distribution of many wildlife species (Berger and others 2001; Weisberg and Coughenour 2003), and can alter streambanks and riparian communities that strongly influence channel morphology and aquatic conditions (Beschta and Ripple 2012). Numerous studies support the conclusion that disruptions of trophic cascades due to the decline of apex predators constitute a threat to biodiversity for which the best management solution is likely the restoration of effective predation regimes (Estes and others 2011).

Ungulate Herbivory and Disturbance Regimes

Across the western US, ecosystems evolved with and were sustained by local and regional disturbances, such as fluctuating weather patterns, fire, disease, insect infestation, herbivory by wild ungulates and other organisms, and hunting by apex predators. Chronic disturbances with relatively transient effects, such as frequent, low-severity fires and seasonal moisture regime fluctuations, helped maintain native plant community composition and structure. Relatively abrupt, or acute, natural disturbances, such as insect outbreaks or severe fires were also important for the maintenance of ecosystems and native species diversity (Beschta and others 2004; Swanson and others 2011). Livestock use and/or an overabundance of feral or wild ungulates can, however, greatly alter ecosystem response to disturbance and can degrade affected systems. For example, high levels of herbivory over a period of years, by either domestic or wild ungulates, can effectively prevent aspen sprouts from growing into tall saplings or trees as well as reduce the diversity of understory species (Shepperd and others 2001; Dwire and others 2007; Beschta and Ripple 2009).

Natural floods provide another illustration of how ungulates can alter the ecological role of disturbances. High flows are normally important for maintaining riparian plant communities through the deposition of nutrients, organic matter, and sediment on streambanks and floodplains, and for enhancing habitat diversity of aquatic and riparian ecosystems (CWWR 1996). Ungulate effects on the structure and composition of riparian plant communities (e.g., Platts 1991; Chadde and Kay 1996), however, can drastically alter the outcome of these hydrologic disturbances by diminishing streambank stability and severing linkages between high flows and the maintenance of streamside plant communities. As a result, accelerated erosion of streambanks and floodplains, channel incision, and the occurrence of high instream sediment loads may become increasingly common during periods of high flows (Trimble and Mendel 1995). Similar effects have been found in systems where large predators have been displaced or extirpated (Beschta and Ripple 2012). In general, high levels of ungulate use can essentially uncouple typical ecosystem responses to chronic or acute disturbances, thus greatly limiting the capacity of these systems to provide a full array of ecosystem services during a changing climate.

The combined effects of ungulates (domestic, wild, and feral) and a changing climate present a pervasive set of stressors on public lands, which are significantly different from those encountered during the evolutionary history of the region's native species. The intersection of these stressors is setting the stage for fundamental and unprecedented changes to forest, arid, and semi-arid landscapes in the western US (Table 1) and increasing the likelihood of alternative states. Thus, public-land management needs to focus on restoring and maintaining structure, function, and integrity of ecosystems to improve their resilience to climate change (Rieman and Isaak 2010).

Federal Law and Policy

Federal laws guide the use and management of public-land resources. Some laws are specific to a given agency (e.g., the BLM's Taylor Grazing Act of 1934 and the FS's

Table 1 Generalized climate change effects, heavy ungulate use effects, and their combined effects as stressors to terrestrial and aquatic ecosystems in the western United States

Climate change effects	Ungulate use effects	Combined effects
Increased drought frequency and duration	Altered upland plant and animal communities	Reduced habitat and food-web support; loss of mesic and hydric plants, reduced biodiversity
Increased air temperatures, decreased snowpack accumulation, earlier snowmelt	Compacted soils, decreased infiltration, increased surface runoff	Reduced soil moisture for plants, reduced productivity, reductions in summer low flows, degraded aquatic habitat
Increased variability in timing and magnitude of precipitation events	Decreased biotic crusts and litter cover, increased surface erosion	Accelerated soil and nutrient loss, increased sedimentation
Warmer and drier in the summer	Reduced riparian vegetation, loss of shade, increased stream width	Increased stream temperatures, increased stress on cold-water fish and aquatic organisms
Increased variability in runoff	Reduced root strength of riparian plants, trampled streambanks, streambank erosion	Accelerated streambank erosion and increased sedimentation, degraded water quality and aquatic habitats
Increased variability in runoff	Incised stream channels	Degraded aquatic habitats, hydrologically disconnected floodplains, reduced low flows

National Forest Management Act [NFMA] of 1976), whereas others cross agency boundaries (e.g., Endangered Species Act [ESA] of 1973; Clean Water Act [CWA] of 1972). A common mission of federal land management agencies is “to sustain the health, diversity, and productivity of public lands” (GAO 2007, p. 12). Further, each of these agencies has ample authority and responsibility to adjust management to respond to climate change (GAO 2007) and other stressors.

The FS and BLM are directed to maintain and improve the condition of the public rangelands so that they become as productive as feasible for all rangeland values. As defined, “range condition” encompasses factors such as soil quality, forage values, wildlife habitat, watershed and plant communities, and the present state of vegetation of a range site in relation to the potential plant community for that site (Public Rangelands Improvement Act of 1978). BLM lands and national forests must be managed for sustained yield of a wide array of multiple uses, values, and ecosystem services, including wildlife and fish, watershed, recreation, timber, and range. Relevant statutes call for management that meets societal needs, without impairing the productivity of the land or the quality of the environment, and which considers the “relative values” of the various resources, not necessarily the combination of uses that will give the greatest economic return or the greatest unit output (Multiple-Use Sustained-Yield Act of 1960; Federal Land Policy and Management Act of 1976 [FLPMA]).

FLPMA directs the BLM to “take any action necessary to prevent unnecessary or undue degradation” of the public lands. Under NFMA, FS management must provide for diversity of plant and animal communities based on the suitability and capability of the specific land area. FLMPA also authorizes both agencies to “cancel, suspend, or modify” grazing permits and to determine that “grazing uses should be discontinued (either temporarily or permanently) on certain lands.” FLPMA explicitly recognizes the BLM’s authority (with congressional oversight) to “totally eliminate” grazing from large areas (> 405 km^2) of public lands. These authorities are reinforced by law providing that grazing permits are not property rights (*Public Lands Council v. Babbitt* 2000).

While federal agencies have primary authority to manage federal public lands and thus wildlife *habitats* on these lands, states retain primary management authority over resident *wildlife*, unless preempted, as by the WFRHBA or ESA (*Kleppe v. New Mexico* 1976). Under WFRHBA, wild, free-roaming horses and burros (i.e., feral) by law have been declared “wildlife” and an integral part of the natural system of the public lands where they are to be managed in a manner that is designed to achieve and maintain a thriving natural ecological balance.

Restoring Ungulate-Altered Ecosystems

Because livestock use is so widespread on public lands in the American West, management actions directed at ecological restoration (e.g., livestock removal, substantial reductions in numbers or length of season, extended or regular periods of rest) need to be accomplished at landscape scales. Such approaches, often referred to as passive restoration, are generally the most ecologically effective and economically efficient for recovering altered ecosystems because they address the root causes of degradation and allow natural recovery processes to operate (Kauffman and others 1997; Rieman and Isaak 2010). Furthermore, reducing the impact of current stressors is a “no regrets” adaptation strategy that could be taken now to help enhance

Fig. 5 Examples of riparian and stream recovery in the western United States after the removal of livestock grazing: Hart Mountain National Antelope Refuge, Oregon, in **a** October 1989 and **b** September 2010 after 18 years of livestock removal; Strawberry River, Utah, in **c** August 2002 after 13 years of livestock removal and **d** July 2003 illustrating improved streambank protection and riparian productivity as beaver reoccupy this river system; and San Pedro River, Arizona in **e** June 1987 and **f** June 1991 after 4 years of livestock removal. *Photographs* **a** Fish and Wildlife Service, Hart Mountain National Antelope Refuge, **b** J Rhodes, **c** and **d** US Forest Service, Uintah National Forest, **e** and **f** Bureau of Land Management, San Pedro Riparian National Conservation Area

ecosystem resilience to climate change (Joyce and others 2008). This strategy is especially relevant to western ecosystems because removing or significantly reducing the cause of degradation (e.g., excessive ungulate use) is likely to be considerably more effective over the long term, in both costs and approach, than active treatments aimed at specific ecosystem components (e.g., controlling invasive plants) (BLM 2005). Furthermore, the possibility that passive restoration measures may not accomplish all ecological goals is an insufficient reason for *not* removing or reducing stressors at landscape scales.

For many areas of the American West, particularly riparian areas and other areas of high biodiversity, significantly reducing or eliminating ungulate stressors should, over time, result in the recovery of self-sustaining and ecologically robust ecosystems (Kauffman and others 1997; Floyd and others 2003; Allington and Valone 2010; Fig. 5). Indeed, various studies and reviews have concluded that the most effective way to restore riparian areas and aquatic systems is to exclude livestock either temporarily (with subsequent changed management) or long-term (e.g., Platts 1991;BLM and FS 1994; Dobkin and others

1998; NRC 2002; Seavy and others 2009: Fleischner 2010). Recovering channel form and riparian soils and vegetation by reducing ungulate impacts is also a viable management tool for increasing summer baseflows (Ponce and Lindquist 1990; Rhodes and others 1994).

In severely degraded areas, initiating recovery may require active measures in addition to the removal/reduction of stressors. For example, where native seed banks have been depleted, reestablishing missing species may require planting seeds or propagules from adjacent areas or refugia (e.g., Welch 2005). While active restoration approaches in herbivory-degraded landscapes may have some utility, such projects are often small in scope, expensive, and unlikely to be self-sustaining; some can cause unanticipated negative effects (Kauffman and others 1997). Furthermore, if ungulate grazing effects continue, any benefits from active restoration are likely to be transient and limited. Therefore, addressing the underlying causes of degradation should be the first priority for effectively restoring altered public-land ecosystems.

The ecological effectiveness and low cost of wide-scale reduction in ungulate use for restoring public-land ecosystems, coupled with the scarcity of restoration resources, provide a forceful case for minimizing ungulate impacts. Other conservation measures are unlikely to make as great a contribution to ameliorating landscape-scale effects from climate change or to do so at such a low fiscal cost. As Isaak and others (2012, p. 514) noted with regard to the impacts of climate change on widely-imperiled salmonids: "…conservation projects are likely to greatly exceed available resources, so strategic prioritization schemes are essential."

Although restoration of desertified lands was once thought unlikely, recovery in the form of significant increases in perennial grass cover has recently been reported at several such sites around the world where livestock have been absent for more than 20 years (Floyd and others 2003; Allington and Valone 2010; Peters and others 2011). At a desertified site in Arizona that had been ungrazed for 39 years, infiltration rates were significantly (24 %) higher (compared to grazed areas) and nutrient levels were elevated in the bare ground, inter-shrub areas (Allington and Valone 2010). The change in vegetative structure also affected other taxa (e.g., increased small mammal diversity) where grazing had been excluded (Valone and others 2002). The notion that regime shifts caused by grazing are irreversible (e.g., Bestelmeyer and others 2004) may be due to the relative paucity of large-scale, ungulate-degraded systems where grazing has been halted for sufficiently long periods for recovery to occur.

Removing domestic livestock from large areas of public lands, or otherwise significantly reducing their impacts, is consistent with six of the seven approaches recommended for ecosystem adaptation to climate change (Julius and others 2008, pp. 1-3). Specifically, removing livestock would (1) protect key ecosystem features (e.g., soil properties, riparian areas); (2) reduce anthropogenic stressors; (3) ensure representation (i.e., protect a variety of forms of a species or ecosystem); (4) ensure replication (i.e., protect more than one example of each ecosystem or population); (5) help restore ecosystems; and (6) protect refugia (i.e., areas that can serve as sources of "seed" for recovery or as destinations for climate-sensitive migrants). Although improved livestock management practices are being adopted on some public lands, such efforts have not been widely implemented. Public land managers have rarely used their authority to implement landscape-scale rest from livestock use, lowered frequency of use, or multi-stakeholder planning for innovative grazing systems to reduce impacts.

While our findings are largely focused on adaptation strategies for western landscapes, reducing ungulate impacts and restoring degraded plant and soil systems may also assist in mitigating any ongoing or future changes in regional energy and carbon cycles that contribute to global climate change. Simply removing livestock can increase soil carbon sequestration since grasslands with the greatest potential for increasing soil carbon storage are those that have been depleted in the past by poor management (Wu and others 2008, citing Jones and Donnelly 2004). Riparian area restoration can also enhance carbon sequestration (Flynn and others 2009).

Socioeconomic Considerations

A comprehensive assessment of the socioeconomic effects of changes in ungulate management on public lands is beyond the scope of this paper. However, herein we identify a few of the *general* costs and benefits associated with implementing our recommendations (see next section), particularly with regard to domestic livestock grazing. The socioeconomic effects of altering ungulate management on public lands will ultimately depend on the type, magnitude, and location of changes undertaken by federal and state agencies.

Ranching is a contemporary and historically significant aspect of the rural West's social fabric. Yet, ranchers' stated preferences in response to grazing policy changes are as diverse as the ranchers themselves, and include intensifying, extensifying, diversifying, or selling their operations (Genter and Tanaka 2002). Surveys indicate that most ranchers are motivated more by amenity and lifestyle attributes than by profits (Torell and others 2001, Genter and Tanaka 2002). Indeed, economic returns from ranching are lower than any other investments with similar risk

(Torrell and others 2001) and public-land grazing's contributions to income and jobs in the West are relatively small fractions of the region's totals (BLM and FS 1994; Power 1996).

If livestock grazing on public lands were discontinued or curtailed significantly, some operations would see reduced incomes and ranch values, some rural communities would experience negative economic impacts, and the social fabric of those communities could be altered (Genter and Tanaka 2002). But for most rural economies, and the West in general, the economic impacts of managing public lands to emphasize environmental amenities would be relatively minor to modestly positive (Mathews and others 2002). Other economic effects could include savings to the US Treasury because federal grazing fees on BLM and FS lands cover only about one-sixth of the agencies' administration costs (Vincent 2012). Most significantly, improved ecosystem function would lead to enhanced ecosystem services, with broad economic benefits. Various studies have documented that the economic values of other public-land resources (e.g., water, timber, recreation, and wilderness) are many times larger than that of grazing (Haynes and others 1997; Laitos and Carr 1999; Patterson and Coelho 2009).

Facilitating adaptation to climate change will require changes in the management of public-land ecosystems impacted by ungulates. *How* ungulate management policy changes should be accomplished is a matter for the agencies, the public, and others. The recommendations and conclusions presented in the following section are based solely on ecological considerations and the federal agencies' legal authority and obligations.

Recommendations

We propose that large areas of BLM and FS lands should become free of use by livestock and feral ungulates (Table 2) to help initiate and speed the recovery of affected ecosystems as well as provide benchmarks or controls for assessing the effects of "grazing versus no-grazing" at significant spatial scales under a changing climate. Further, large areas of livestock exclusion allow for understanding potential recovery foregone in areas where livestock grazing is continued (Bock and others 1993).

While lowering grazing pressure rather than discontinuing use might be effective in some circumstances, public land managers need to rigorously assess whether such use is compatible with the maintenance or recovery of ecosystem attributes such as soils, watershed hydrology, and native plant and animal communities. In such cases, the contemporary status of at least some of the key attributes and their rates of change should be carefully monitored to ascertain whether continued use is consistent with ecological recovery, particularly as the climate shifts (e.g., Karr and Rossano 2001, Karr 2004; LaPaix and others 2009). To the extent possible, assessments of recovering areas should be compared to similar measurements in reference areas (i.e., areas exhibiting high ecological integrity) or areas where ungulate impacts had earlier been removed or minimized (Angermeier and Karr 1994; Dobkin and others 1998). Such comparisons are crucial if scientists and managers are to confirm whether managed systems are attaining restoration goals and to determine needs for intervention, such as reintroducing previously extirpated species. Unfortunately, testing for impacts of livestock use at landscape scales is hampered by the lack of large, ungrazed areas in the western US (e.g., Floyd and others 2003; FWS 2010).

Shifting the burden of proof for continuing, rather than significantly reducing or eliminating ungulate grazing is warranted due to the extensive body of evidence on ecosystem impacts caused by ungulates (i.e., consumers) and the added ecosystem stress caused by climate change. As Estes and others (2011, p. 306) recommended: "[T]he burden of proof [should] be shifted to show, for any ecosystem, that consumers do (or did) not exert strong cascading effects" (see also Henjum and others 1994; Kondolf 1994; Rhodes and others 1994). Current livestock or feral

Table 2 Priority areas for permanently removing livestock and feral ungulates from Bureau of Land Management and US Forest Service lands to reduce or eliminate their detrimental ecological effects

Watersheds and other large areas that contain a variety of ecotypes to ensure that major ecological and societal benefits of more resilient and healthy ecosystems on public lands will occur in the face of climate change
Areas where ungulate effects extend beyond the immediate site (e.g., wetlands and riparian areas impact many wildlife species and ecosystem services with cascading implications beyond the area grazed)
Localized areas that are easily damaged by ungulates, either inherently (e.g., biological crusts or erodible soils) or as the result of a temporary condition (e.g., recent fire or flood disturbances, or degraded from previous management and thus fragile during a recovery period).
Rare ecosystem types (e.g., perched wetlands) or locations with imperiled species (e.g., aspen stands and understory plant communities, endemic species with limited range), including fish and wildlife species adversely affected by grazing and at-risk and/or listed under the ESA
Non-use areas (i.e., ungrazed by livestock) or exclosures embedded within larger areas where livestock grazing continues. Such non-use areas should be located in representative ecotypes so that actual rates of recovery (in the absence of grazing impacts) can be assessed relative to resource trend and condition data in adjacent areas that continue to be grazed
Areas where the combined effects of livestock, wild ungulates, and feral ungulates are causing significant ecological impacts

ungulate use should continue only where stocking rates, frequency, and timing can be demonstrated, in comparison with landscape-scale reference areas, exclosures, or other appropriate non-use areas, to be compatible with maintaining or recovering key ecological functions and native species complexes. Furthermore, such use should be allowed only when monitoring is adequate to determine the effects of continued grazing in comparison to areas without grazing.

Where wild native ungulates, such as elk or deer, have degraded plant communities through excessive herbivory (e.g., long-term suppression of woody browse species [Weisberg and Coughenour 2003; Beschta and Ripple 2009; Ripple and others 2010]), state wildlife agencies and federal land managers need to cooperate in controlling or reducing those impacts. A potentially important tool for restoring ecosystems degraded by excessive ungulate herbivory is reintroduction or recolonization of apex predators. In areas of public land that are sufficiently large and contain suitable habitat, allowing apex predators to become established at ecologically effective densities (Soulé and others 2003, 2005) could help regulate the behavior and density of wild ungulate populations, aiding the recovery of degraded ecosystems (Miller and others 2001; Ripple and others 2010; Estes and others 2011). Ending government predator control programs and reintroducing predators will have fewer conflicts with livestock grazing where the latter has been discontinued in large, contiguous public-land areas. However, the extent to which large predators might also help control populations of feral horses and burros is not known.

Additionally, we recommend removing livestock and feral ungulates from national parks, monuments, wilderness areas, and wildlife refuges wherever possible and managing wild ungulates to minimize their potential to adversely affect soil, water, vegetation, and wildlife populations or impair ecological processes. Where key large predators are absent or unable to attain ecologically functional densities, federal agencies should coordinate with state wildlife agencies in managing wild ungulate populations to prevent excessive effects of these large herbivores on native plant and animal communities.

Conclusions

Average global temperatures are increasing and precipitation regimes changing at greater rates than at any time in recent centuries. Contemporary trends are expected to continue and intensify for decades, even if comprehensive mitigations regarding climate change are implemented immediately. The inevitability of these trends requires adaptation to climate change as a central planning goal on federal lands.

Historical and on-going ungulate use has affected soils, vegetation, wildlife, and water resources on vast expanses of public forests, shrublands, and grasslands across the American West in ways that are likely to accentuate any climate impacts on these resources. Although the effects of ungulate use vary across landscapes, this variability is more a matter of degree than type.

If effective adaptations to the adverse effects of climate change are to be accomplished on western public lands, large-scale reductions or cessation of ecosystem stressors associated with ungulate use are crucial. Federal and state land management agencies should seek and make wide use of opportunities to reduce significant ungulate impacts in order to facilitate ecosystem recovery and improve resiliency. Such actions represent the most effective and extensive means for helping maintain or improve the ecological integrity of western landscapes and for the continued provision of valuable ecosystem services during a changing climate.

Acknowledgments We greatly appreciate reviews by D.S. Dobkin, S.C. Fouty, J.B. Kauffman, and W.S. Platts of an early draft. We also appreciate the comments, questions, and suggestions provided by two anonymous reviewers. This work was supported by grants to the Geos Institute from the Wilburforce and Wyss foundations and by a Kline Law Faculty Research Fund grant.

Abstract

Surface fire intensity (kilowatts per metre) and crown fire initiation were predicted using Rothermel's 1972 and Van Wagner's 1977 fire models with fuel data from 47 upland subalpine conifer stands varying in age from 22-258 yr and 35 yr of daily weather data (fuel moisture and wind speeds). Rothermel's intensity model was divided into a fuel component variable and weather component variable, which were then used to examine the relative roles of fuel and weather on surface fire intensity (kilowatts per metre). Similar variables were defined in the crown fire initiation model of Van Wagner. Both surface fire intensity and crown fire initiation were strongly related to the weather components and weakly related to the fuel components, due to much greater variability in weather than fuel, and stronger relationship to the fire behavior mechanisms for weather than for fuel. Fire intensity was correlated to annual area burned; large area burned years had higher fire intensity predictions than smaller area burned years. The reason for this difference was attributed directly to the weather variable frequency distribution, which was shifted towards more extreme values in years in which large areas burned. During extreme weather conditions, the relative importance of fuels diminishes since all stands achieve the threshold required to permit crown fire development. This is important since most of the area burned in subalpine forests has historically occurred during very extreme weather (i.e., drought coupled to high winds). The fire behavior relationships predicted in the models support the concept that forest fire behavior is determined primarily by weather variation among years rather than fuel variation associated with stand age.

S2 Table. Authors, sites, the Weibull mean ITFI estimate, and the calibrated or predicted PMFI/FR for the merged 342-site dataset.

Notes
† Observations are in increasing order of calibrated/predicted PMFI/FR within each state
‡ Missing observations in this column occur because some calibration cases did not have an FHX file and did not report this statistic in the publication.
§ Mean ITFI could not be estimated, but mean CFI-all could be, is reported here, and was used to estimate PMFI/FR
¶ Mean ITFI could not be estimated, but mean CFI-10% could be, is reported here, and was used to estimate PMFI/FR

ABSTRACT: Appropriate response to recent, widespread bark beetle (*Dendroctonus* spp.) outbreaks in the western United States has been the subject of much debate in scientific and policy circles. Among the proposed responses have been landscape-level mechanical treatments to prevent the further spread of outbreaks and to reduce the fire risk that is believed to be associated with insect-killed trees. We review the literature on the efficacy of silvicutural practices to control outbreaks and on fire risk following bark beetle outbreaks in several forest types. While research is ongoing and important questions remain unresolved, to date most available evidence indicates that bark beetle outbreaks do not substantially increase the risk of active crown fire in lodgepole pine (*Pinus contorta*) and spruce (*Picea engelmannii*)-fir (*Abies* spp.) forests under most conditions. Instead, active crown fires in these forest types are primarily contingent on dry conditions rather than variations in stand structure, such as those brought about by outbreaks. Preemptive thinning may reduce susceptibility to small outbreaks but is unlikely to reduce susceptibility to large, landscape-scale epidemics. Once beetle populations reach widespread epidemic levels, silvicultural strategies aimed at stopping them are not likely to reduce forest susceptibility to outbreaks. Furthermore, such silvicultural treatments could have substantial, unintended short- and long-term ecological costs associated with road access and an overall degradation of natural areas.

Index terms: bark beetles, *Dendroctonus*, forest health, forest management, wildfire

INTRODUCTION

Forests in the western United States are being affected by the largest outbreaks of bark beetles in at least a century, which has caused concern about forest health and wildfire risk and led to proposals for tree removal in natural areas such as roadless forests. Such proposals stem in part from the rationale that bark beetle outbreaks increase wildfire risks due to increased dead fuels and that widespread treatment in beetle-affected forests is needed to lower such risks. Here, we review available peer-reviewed literature to determine if: (1) bark beetle outbreaks are associated with a higher incidence of wildfires in forest types in the central Rockies; and (2) if silvicultural treatments are effective at lowering beetle-associated tree mortality before, during, and after outbreaks. We briefly review the impacts that additional logging roads associated with broad-scale tree removal may have on the ecology of roadless natural areas. Our results may have broader policy implications in western forests as concerns over insect outbreaks have led to proposals to reduce environmental protections in favor of widespread thinning and post-disturbance tree removal.

INTERACTIONS AMONG FOREST INSECTS AND FIRES

We examined the long-standing belief that insect outbreaks lead to increased risk of fire (USDA Forest Service 2011). A large body of literature indicates that the occurrence of large, severe fires in subalpine, lodgepole pine (*Pinus contorta*), and spruce (*Picea engelmannii)*-fir (*Abies* spp.) forests is strongly contingent on climatic conditions, especially drought (e.g., Kipfmueller and Baker 2000; Romme et al. 2006; Sibold and Veblen 2006; Schoennagel et al. 2007; Jenkins et al. 2008; Simard et al. 2008, 2011).

The debate on how outbreaks affect fire risk and hazard is ongoing, but recent work emphasizes that the effect of outbreaks on subsequent fire risk is complex and is contingent on time since last outbreak and on biophysical setting. To date, the majority of studies have found no increase in fire occurrence, extent, or severity following outbreaks of spruce beetle (*Dendroctonus rufipennis*) and mountain pine beetle (*Dendroctonus ponderosae*) in Colorado, Wyoming, and other areas (Bebi et al. 2003; Kulakowski et al. 2003; Bigler et al. 2005; Kulakowski and Veblen 2007; Jenkins et al. 2008; Simard et al. 2008, 2011).

Theoretically, the effect of outbreaks on subsequent fires may vary with the time since the outbreak occurred (Romme et al. 2006). For example, it is reasonable to expect that foliar moisture in trees killed by beetles will decrease and canopy density will be reduced during and immediately after an outbreak. In subsequent years, canopy density may be further reduced as dead needles and small branches fall from killed trees reducing canopy bulk density, but increasing surface fire hazard (i.e., the type, volume, and arrangement of fuels that determines the ease of ignition and resistance to control regardless of the fuel type's weather-influenced moisture content). Although such a relationship may theoretically increase the risk of surface fires, studies on the influence of outbreaks on subsequent stand-replacing fires, over a range of years since outbreak, have found little or no increase in surface or canopy fire occurrence, extent, or severity (Bebi et al. 2003; Kulakowski et al. 2003; Bigler et al. 2005; Kulakowski and Veblen 2007; Jenkins et al. 2008; Simard et al. 2008, 2011) (Table 1).

Fire and Mountain Pine Beetle Outbreaks in Lodgepole Pine Forests

Although outbreaks of mountain pine beetle do alter fuel structure (Page and Jenkins 2007; Klutsch et al. 2009; Simard et al. 2011), the actual effects of these changes in fuels on subsequent fire risk (i.e., the chance that a fire might start based on all causative agents such as fuel hazard, ignition source, and weather) are complex, contradictory, and appear counterintuitive. For instance, lodgepole stands in which > 50 % of susceptible trees were killed by beetles in the 5 to 15 years preceding the 1988 Yellowstone fires had a higher incidence of crown fire than stands in which mortality was not as high (Turner et al. 1999). In contrast, stands with low to moderate beetle mortality (< 50% tree kill) had a lower incidence of high-severity crown fires. However, it is unclear whether these differences in fire behavior were primarily the result of the outbreak or of pre-outbreak stand structure (Simard et al. 2008), because beetle mortality occurred preferentially in older stands that were, in turn, inherently more likely to burn at high severity than younger stands because of differences in fuel structures even in the absence of beetle activity (Renkin and Despain 1992).

Other studies have found that beetle-kill may have decreased the hazard of high-severity crown fire by reducing the continuity of the canopy. For example, beetle-killed lodgepole pine stands, characterized by lower stand density, were affected by

Table 1. Forest types and relations between fire and insects in the Rocky Mountains.

Forest Type	Location	Insect-fire link	Citation
Lodgepole	Yellowstone	Beetle killed stands had significantly lower fire severity.	Omi 1997
Lodgepole	Yellowstone	Stands with higher mortally from bark beetles had higher incidence of crown fires. Stands with low to moderate beetle mortality had a lower incidence of crown fires.	Turner et al. 1999
Lodgepole	Yellowstone	Stands affected by outbreak in 1972-1975 were associated with a slightly higher probability of fire. Stands affected by outbreak in 1980-1983 were not more likely to burn.	Lynch et al. 2006
Lodgepole	Yellowstone	The probability of active crown fire in stands recently affected by beetles was significantly lower than in stands not affected by beetles.	Simard et al. 2011
Lodgepole and spruce	Colorado	Bark beetle outbreak did not affect the extent or severity of fire.	Kulakowski and Veblen 2007
Lodgepole and spruce	Intermountain west	Modeling study predicted a reduced risk of active crown fire 5 to 60 years after outbreaks.	Jenkins et al. 2008
Spruce	Colorado	Bark beetles caused no increase in the numbers of fires.	Bebi et al. 2003
Spruce	Colorado	Beetle-affected stands were not more susceptible to a low-severity fire.	Kulakowski et al. 2003
Spruce	Colorado	Previous bark beetle outbreaks had only a minor influence on fire severity.	Bigler et al. 2005
Spruce	Central Rocky Mountains	Modeling studies predicted reductions in the probability of active crown fire after bark beetle outbreaks.	DeRose and Long 2009

significantly lower fire severity compared to adjacent burned areas that had not been affected by beetles in the 3400-hectare Robinson Fire that burned in Yellowstone National Park in 1994 (Omi 1997). Lynch et al. (2006) also examined the influence of previous beetle activity on the 1988 Yellowstone fires by testing whether beetle-affected stands were more likely to have burned than those stands not affected by beetles. Stands affected by outbreak from 1972 to 1975 had a higher probability of burning, but the increase was relatively minor (about 11% greater compared to areas unaffected by beetles). In contrast, stands that were affected by outbreak from 1980 to 1983 were not more likely to burn in comparison to unaffected stands (Lynch et al. 2006).

It has been hypothesized that the risk of fire may increase only during and immediately after outbreaks of bark beetles when the dry red needles are still on the trees (Romme et al. 2006). However, Kulakowski and Veblen (2007) found that ongoing outbreaks of mountain pine beetle (and spruce beetle) did not affect the extent or severity of fire and suggested that changes in fuels brought about by outbreaks may be overridden by climatic conditions. Simard et al. (2011) examined fuel conditions for 35 years following outbreaks of mountain pine beetle in Yellowstone National Park. They documented reduced canopy moisture content after an outbreak, which was coupled with reduced canopy bulk density. In simulation models of fire behavior, under intermediate wind conditions (40 to 60 kilometers per hour), the probability of active crown fire in stands recently affected by beetles was significantly lower than in stands not affected by beetles (Simard et al. 2011). In addition, if winds were below 40 kph or above 60 kph, stand structure had little effect on fire behavior. Thus, although the canopy was drier immediately after an outbreak, no increase in fire risk was observed, likely because of the more important effect of reductions in canopy bulk density. Other modeling studies also have predicted a reduced risk of active crown fire 5 to 60 years after outbreaks, due to decreased canopy bulk density (Jenkins et al. 2008). In sum, outbreaks of bark beetles in lodgepole pine may have little or no effect on subsequent fires and may in some cases actually reduce the risk of fire.

Fire and Spruce Beetle in Subalpine Spruce-Fir Forests

There is increasing evidence that spruce beetle outbreaks have little or no affect on the occurrence or severity of fires in spruce-fir forests (Simard et al. 2008). It is well established that in this forest type, extensive fires are highly dependent on infrequent, severe droughts (e.g., Schoennagel et al. 2007). Under such extreme drought conditions, increased dead fuels from bark beetle outbreaks appear to play only a minor role, if any, in increasing fire risk. For instance, after a 1940s spruce beetle outbreak that resulted in dead-standing trees over thousands of hectares of subalpine forests in the White River National Forest of western Colorado, there was no increase in the numbers of fires compared to unaffected subalpine forests (Bebi et al. 2003). Beetle-affected stands were not more susceptible to a low-severity fire that spread through adjacent forests several years after the outbreak subsided (Kulakowski et al. 2003). During the extreme drought of 2002, large fires affected extensive areas of Colorado, including some spruce-fir stands that were previously affected by the 1940s outbreak of spruce beetle. Despite the expectation that these outbreaks would have led to an increased risk of severe fires, they had only a minor influence on fire severity (Bigler et al. 2005). Likewise, ongoing outbreaks of spruce beetle (and mountain pine beetle) had no detectable effect on the extent or severity of fires in 2002 (Kulakowski and Veblen 2007). These empirical findings are consistent with modeling studies that predict reductions in the probability of active crown fire for one to two decades after high-severity bark beetle outbreaks in pure stands of Engelmann spruce (*Picea engelmannii)* (DeRose and Long 2009). Other modeling studies have likewise predicted a reduced risk of active crown fire 5 to 60 years after outbreaks, due to decreased canopy bulk density (Jenkins et al. 2008).

The emerging view is that for lodgepole pine and spruce-fir forests: (1) the effect of bark beetle outbreaks on fuels is complex; and (2) weather and climate are more important in influencing fire risk and behavior the effects of insect outbreaks. When evaluating the influence of bark beetle outbreaks, it is important to recognize that outbreaks not only reduce foliar moisture content and increase the volume of dead wood, which can increase fire hazard, but that outbreaks also reduce canopy density, which can decrease fire risk (Simard et al. 2011). Therefore, when assessing the risk of wildfires following outbreaks, it is essential to recognize the relative importance of weather and climate to overall fire risk.

EFFICACY OF BARK BEETLE CONTAINMENT MEASURES

Prior to Outbreaks

The effectiveness of thinning to reduce forest susceptibility to bark beetles is believed to be related to tree vigor (Fettig et al. 2007); which may increase as moisture stress is decreased, and which in turn may make trees less susceptible to insect infestation. The premise is that if the trees are healthy and vigorous, they may be able to "pitch out" the attacking beetles, essentially flooding the entrance site with resin that can push out or drown the beetle (Figure 1).

Some studies have suggested that competition for light and water may reduce the vigor of surviving trees and increase susceptibility to bark beetle attacks (Fettig et al. 2007) and that thinning may, therefore, improve outbreak resistance. For instance, low-vigor ponderosa pine (*Pinus ponderosa)* in central Oregon was more often attacked by beetles than high-vigor trees during early stages of outbreaks (Larsson et al. 1983). Similarly, beetle activity has been associated with high tree densities in ponderosa pine and Douglas-fir *(Pseudotsuga* sp.) stands (Negrón et al. 2001; Negrón and Popp 2004). Ponderosa pine study plots in Colorado's Front Range infested by mountain pine beetle had significantly higher tree basal area and density (Negrón and Popp 2004). Douglas-fir beetles (*D. pseudotsugae*) more often attacked stands

Figure 1. Mountain pine beetle being pitched out. Photo taken by Whitney Cranshaw, Colorado State University, Bugwood.org.

containing a high percentage of basal area represented by high densities of Douglas-fir and slow growth during the five years prior to attack in Colorado's Front Range (Negrón et al. 2001).

Studies that have looked directly at thinning and its effects on tree vigor in Western forests have shown mixed results. While some studies have found that thinning reduces stand susceptibility in some circumstances (Fettig et al. 2007), other research has found bark beetles do not preferentially infest trees with declining growth. For example, Sánchez-Martínez and Wagner (2002) found that ponderosa pine forests of northern Arizona growing in dense stands were not more likely to be colonized by bark beetles.
Under some circumstances, thinning may alleviate tree stress at the stand level but is unlikely to be effective at mitigating susceptibility against extensive or severe outbreaks (Safranyik and Carroll 2006). Preisler and Mitchell (1993) found that thinned plots of lodgepole pine in Oregon were initially unattractive to mountain pine beetles; but when large numbers of attacks occurred, colonization rates were similar to those in unthinned plots. Similarly, Amman et al. (1988) studied the effects of spacing and diameter of trees and concluded that tree mortality was reduced as basal area was lowered. However, if the stand was in the path of an ongoing mountain pine beetle epidemic, spacing and density of trees had little effect (Amman et al. 1988).

While thinning has the potential to reduce tree stress, which can reduce susceptibility to insect attack, it also has the potential to bring about other conditions that can increase susceptibility. For example, thinning may injure surviving trees and their roots, which can provide entry points for pathogens and ultimately reduce tree resistance to other organisms (Hagle and Schmitz 1993; Paine and Baker 1993; Goyer et al. 1998). Although thinning can be effective in maintaining adequate growing space and resources, there is accumulating evidence to suggest that tree injury, soil compaction, and temporary stress due to changed environmental conditions caused by thinning may increase susceptibility of trees to bark beetles and pathogens (Hagle and Schmitz 1993).

From an adaptive management standpoint, it is most prudent to implement thinning in appropriate settings (e.g., already degraded areas in need of restoration) with sufficient controls that would lead to an improved understanding of the efficacy of these approaches, particularly under a range of climatic conditions. It is also important to consider how such strategies may alter normal stand structure. For example, thinning in Engelmann spruce forests is likely to create novel conditions that would be atypical for these ecosystems due to their naturally high tree densities (Daubenmire 1943). Further, thinning forest stands before epidemics is not likely to prevent major outbreaks, due to the inherent difficulties of manipulating stand structure over large enough areas and the overriding influence of climatic stress in driving outbreaks.

During Outbreaks

There is general agreement that silvicultural treatments cannot effectively stop outbreaks once a large-scale insect infestation has started. Citing multiple sources, Hughes and Drever (2001) found that most control efforts have had little effect on the final size of outbreaks. In another review, Romme et al. (2006) point out that once an extensive outbreak has started, timber management is unlikely to stop it. Control of such outbreaks is theoretically possible, but it would require treatment of almost all of the infected trees (Hughes and Drever 2001). Amman and Logan (1998) point to failed attempts to use direct control measures, such as pesticides and logging, after an infestation starts. They suggest that by the early 1970s, it was apparent that attempts to control the extensive mountain pine beetle outbreaks that were occurring in the northern Rockies, by directly killing the beetles, were not working.

If a bark beetle infestation is relatively restricted and concentrated in a limited area, it may be feasible to reduce the impact of that outbreak by removing infested trees from a forest stand, or by thinning a stand to reduce stress of trees competing for limited nutrients, sunlight, and moisture. However, specific climatic conditions are believed to be required for beetle populations to reach epidemic levels. As such, a small population of beetles is not sufficient for an outbreak to occur and would not necessarily lead to an outbreak. Conversely, under climatic conditions favorable for an outbreak, bark beetle outbreaks can erupt simultaneously in numerous, dispersed stands across the landscape. Thus, even if a growing population of beetles is successfully removed from one stand or the stand is thinned to increase vigor, under climatic conditions suitable for outbreaks, beetles from other stands are likely to spread over a landscape. Given that climate typically favors beetle populations and stresses trees over very large areas, successfully identifying and treating stands over a large enough region to have a significant impact on the overall infestation is impractical and costly.

Following Outbreaks

Post-disturbance harvest is common practice on forest lands and is designed to remove trees or other biomass in order to produce timber or other resources. This type of resource extraction has the potential to inadvertently lead to heightened insect activity (Nebeker 1989; Hughes and Drever 2001; Romme et al. 2006). In particular, snags and fallen logs contribute to the protection of soils and water quality and provide habitat for numerous cavity- and snag-dependent species (Romme et al. 2006), many of which prey on bark beetles and other economically destructive insects. Therefore, outbreaks could be prolonged because of a reduction in the beetle's natural enemies (Nebeker 1989), including both insects and bird species that feed on mountain pine beetles (Koplin and Baldwin 1970; Shook and Baldwin 1970; Otvos 1979). Furthermore, post-disturbance harvest can damage soil and roots by compacting them (Lindenmayer et al. 2008) leading to greater water stress in trees, which may reduce conifer regeneration by increasing sapling mortality (Donato et al. 2006) and, in general, may cause more damage to forests than that caused by natural disturbance events (DellaSala et al. 2006).

ROAD BUILDING FOR BARK BEETLE CONTROL

A broad scale program to treat forests that have been affected by bark beetle will require an extensive road system, which will likely have significant impacts to forest and aquatic ecosystems.

In general, the major physical results of roads on the terrestrial environment are increases in forest fragmentation and disruption of the movement of organisms and flow of ecological processes across the landscape (Lindenmayer and Fisher 2006). Aquatic systems have been impacted through the disruption of natural infiltration of water into the soil and increased runoff to streams (Forman and Alexander 1998). These effects have been particularly pronounced in mountainous regions, especially on high gradient streams and headwaters (Ziegler et al. 2001). Increased sediment input to streams can result in changes to channel morphology and channel substrate, as well as the creation of shallow pools (Beschta 1978). These changes to stream structure, an indirect effect of road construction, often adversely affect native fish habitat. Thus, any road network constructed to thin or harvest insect-infested stands will have to be carefully engineered to prevent increased sedimentation rates or alteration of hill slope processes (Beschta 1978). While proper engineering can help mitigate some negative effects, it does not mitigate the overall impact of roads on hydrologic processes, water flow, and fragmentation of wildlife habitat.

CONCLUSIONS AND RECOMMENDATIONS

Climate change and other factors are leading to unprecedented changes in western forest ecosystems (Logan et al. 2003; Carroll et al. 2004; Breshears et al. 2005; Bentz et al. 2009). One consequence of recent and predicted climate change is increased bark beetle activity leading to tree mortality over large areas (Logan and Powell 2001; Williams and Liebhold 2002; Carroll et al. 2004). Such ongoing outbreaks have led to widespread public concern about increased fire risk; however, outbreaks of mountain pine beetle and spruce beetle do not appear to substantially increase the risk of subsequent fire under most conditions. Instead, fire risk in spruce-fir and lodgepole pine is strongly tied to warm and dry conditions, such as those of recent decades. Insect containment measures have yielded mixed results and may pose significant risks to forested ecosystems. We recommend that priority be given to removing hazardous trees, which were killed by fire or insects and that might fall across roads or in campgrounds in areas of high human use to limit damages and potential loss of life. Moreover, in order to reduce existing and future risks of fire, it would be prudent to concentrate fuel reduction measures in the wildland-urban interface by creating defensible space, as the 40-meter zone around homes and structures has been shown to be critical to a home's ignitability (Cohen 1999). Thus, to be effective at reducing fire hazard to communities, tree-cutting can be directed at removing all flammable material (not just economically valuable timber) in the immediate vicinity of homes and settlements.

Abstract: High tree mortality due to drought and insects often is assumed to increase fire severity once ignition occurs. In 2002-2003, coniferous forests in the San Bernardino Mountains, California experienced a significant tree mortality event due to drought and an outbreak of western pine beetles (*Dendroctonus brevicomis*). In October 2003, fire burned approximately 5,860 ha of conifer forest types in many beetle- and drought-affected stands where most pre-fire dead trees had retained needles. We used pre- and post-fire GIS data to examine how fire severity was affected by pre-fire tree mortality, vegetation characteristics, and topography. We found no evidence that pre-fire tree mortality influenced fire severity. These results indicate that widespread removal of dead trees may not effectively reduce higher-severity fire in southern California's conifer forests. We found that sample locations dominated by the largest size class of trees (≥61 cm diameter at breast height (dbh)) burned at lower severities than locations dominated by trees 28-60 cm dbh. This result suggests that harvesting larger-sized trees for fire-severity reduction purposes is likely to be ineffective and possibly counter-productive.

INTRODUCTION

Tree mortality due to drought and insect attacks is common in western coniferous forests [1], but may be increasing in recent years in some areas [2, 3]. Bark beetles (Coleoptera: Scolytidae) are common native insects that kill firs and pines, and are capable of large-scale population increases following disturbances such as droughts [4, 5]. Dense forests are considered relatively more susceptible to insect mortality [6, 7], and recent studies have concentrated on how prescribed fire and thinning affect susceptibility of trees to insects [5, 8, 9]. However, few data are available on the influence of tree mortality on fire behavior.

Stands with high tree mortality due to drought and insects often are presumed to burn at higher severity during fires, increasing the mortality of dominant overstory vegetation in the stand [10, 11]. This assumption is based on expectations of greater dead fine and coarse fuel loads, including canopy fuels, resulting from pre-fire mortality [11]. The hypothesis that insect-caused tree mortality increases fire severity has relied upon two principal assumptions: (1) dead needles remaining on trees could increase the amount and vertical continuity of fine, dry fuels [11, 12]; and (2) tree mortality could open the canopy and intensify seasonal desiccation of understory fuels [12]. However, the few empirical studies testing this hypothesis have not found support for it. A widespread low-severity fire in subalpine forest in the White River National Forest, Colorado did not burn any stands affected by spruce beetle (*Dendroctonus rufipennis*) outbreaks that occurred several decades prior to the fire [13]. Furthermore, a regional analysis of 303 fires in the White River National Forest found that beetle-affected stands did not burn at higher severities than unaffected stands in fires occurring several decades after the outbreak [12].

The hypothesis that stands with recent high tree mortality due to drought or insects have an elevated probability of burning at higher severity when a fire occurs has never been empirically tested. We examined whether fire severity in two large fires that occurred in the midst of a tree mortality event was influenced by the number of trees killed by drought and insects. Specifically, we investigated whether pre-fire tree mortality increased fire severity in stands after ignition occurred. We did not examine the probability of fire igniting in a stand over broad spatial and temporal scales [e.g., 12, 14].

Beginning in rainfall year 1998-1999, southern California entered a period of major drought and higher temperatures. In 2000, the San Bernardino National Forest began to document unusually high mortality of incense-cedars (*Calocedrus decurrens*), and in 2001 slightly increased mortality was witnessed in ponderosa (*Pinus ponderosa*), Coulter (*P. coulteri*) and Jeffrey (*P. jeffreyi*) pines (L. Merrill, USDA Forest Service, unpublished data 2003).[1] In 2002, an outbreak of western pine beetles (*D. brevicomis*)

1874-3986/09

resulted in what the USDA Forest Service identified as 'above background' mortality levels of ponderosa and Coulter pines, and many other conifer tree species were dying from drought alone (L. Merrill, USDA Forest Service, unpublished data 2003). In the first half of 2003, both western pine beetles and mountain pine beetles (*D. ponderosae*) were actively colonizing and killing thousands of conifer trees. By April 2003, the San Bernardino National Forest had mapped approximately 70,000 ha with elevated levels of conifer mortality (L. Merrill, USDA Forest Service, unpublished data 2003).

In late October 2003, one year after the beginning of the beetle population outbreak, two large human-ignited fires merged together in the San Bernardino Mountains and burned 5,863 ha of conifer and conifer-hardwood forest types, including stands with high levels of tree mortality due to drought and insects (Fig. **1**). The Old and Grand-Prix fires were driven by hot Santa Ana winds which typically sweep through southern California during the fall [15]. No widespread harvest of the beetle- and drought-killed trees had occurred at the time of the fires.

MATERIALS AND METHODOLOGY

We selected the San Bernardino Mountains study area because of the existence of Geographic Information System (GIS) layers depicting structural characteristics of vegetation, topography, pre-fire tree mortality immediately prior to the fires, and fire severity, allowing us to investigate the influence of numbers of recently dead trees on fire severity. We simultaneously investigated the effects of topography (slope and aspect), tree size, and canopy cover on fire severity in burned stands, because these factors also are known to influence fire behavior [16, 17].

Conifer forests in the San Bernardino Mountains consist of mixed-evergreen forests [18] below 1,500 m, and ponderosa pine, Jeffrey pine, Coulter pine, white fir (*Abies concolor*)–sugar pine (*P. lambertiana*), and bigcone Douglas-fir (*Pseudotsuga macrocarpa*) stands above 1,500 m [19, 20]. Various combinations of white fir, Jeffrey pine, ponderosa pine, Coulter pine, sugar pine, incense-cedar, and black oak *(Quercus kelloggii*) occur at higher elevations, and canyon live oak (*Q. chrysolepis*) and bigcone Douglas-fir

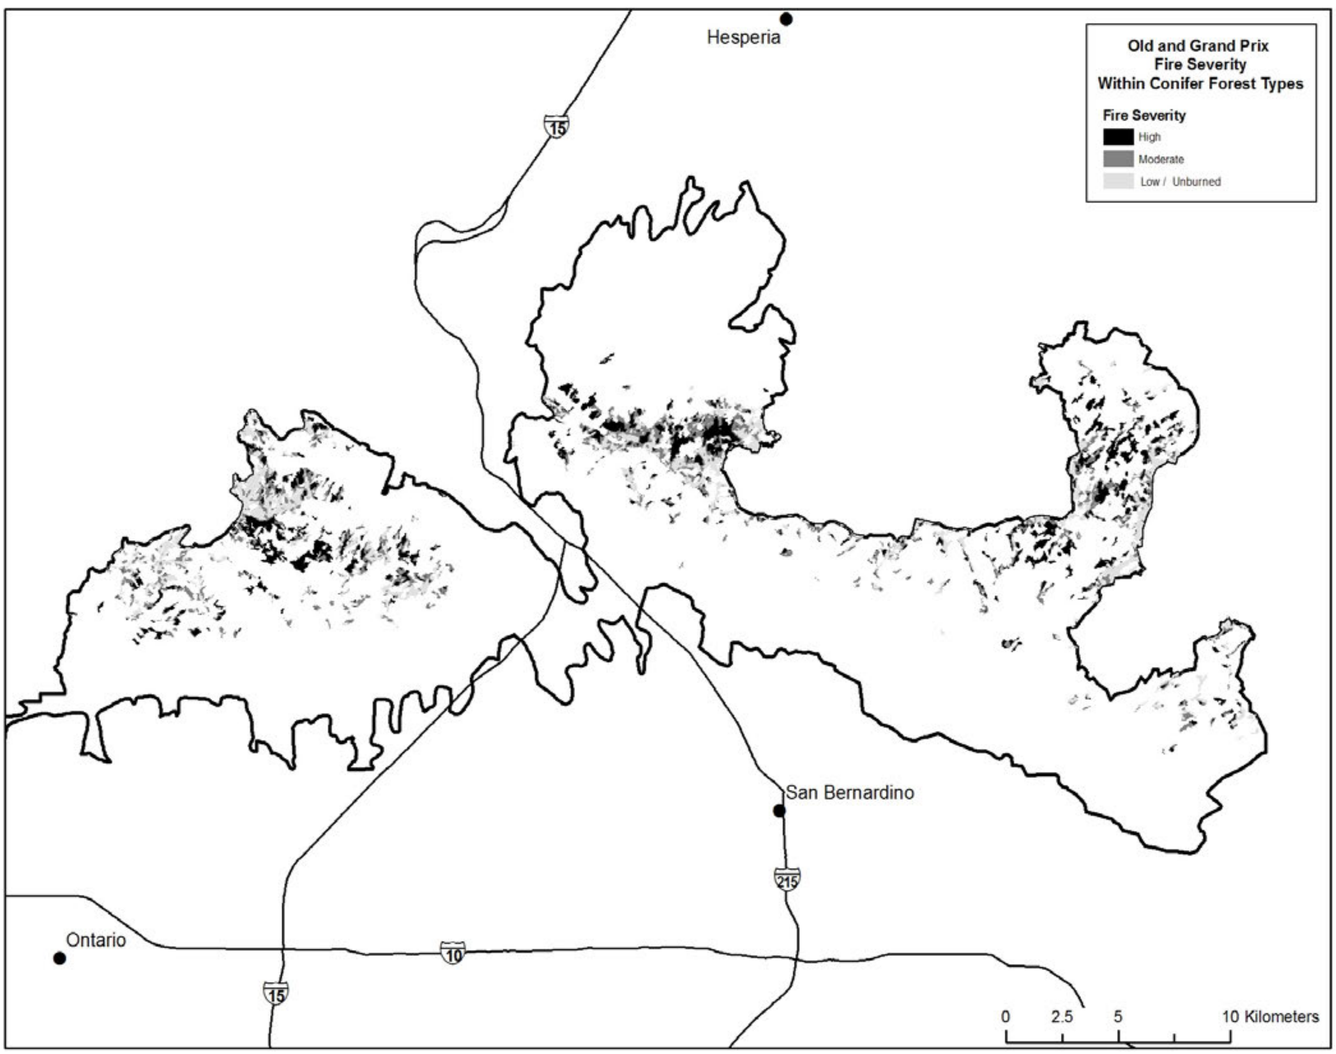

Fig. (1). Perimeters of the 2003 Old and Grand-Prix fires and RdNBR fire severity (low/unburned, moderate, moderate/high) within conifer forest types (Jeffrey Pine, Sierra Mixed Conifer, Montane Hardwood-Conifer). White areas within the fire perimeter are non-conifer vegetation.

dominate at lower elevations [21]. Historic fire return intervals in these forests were variable, with some forest types exhibiting relatively longer fire-free intervals associated with mixed-severity fire effects [20].

We acquired GIS data on vegetation type and structure [22] and pre-fire tree mortality [23] from the USDA Forest Service and GIS data on fire severity [24] and topography [25] from the US Geological Survey. The detailed methodology used by the agencies to create these GIS maps was explained in the metadata for the layers, and is summarized here. Our variables of interest were vegetation type, size of dominant trees, canopy cover, slope, aspect, number of dead trees per ha prior to the fire, and fire severity.

Vegetation type, size class of dominant trees, and canopy cover were derived from a map of existing vegetation from 2002-2003 (EVEG Tiles) [22]. The vegetation layer was generated using a combination of automated systematic procedures, remote-sensing classification, and photo editing and ground surveys to reduce bias while mapping large areas. Minimum mapping size for contrasting vegetation conditions based on cover type, vegetation type, tree cover, and diameter class was 1 ha and pixel size was 30 m.

Cover types were delineated using Landsat Thematic Mapper imagery into the following broad classes: (1) Conifer = >10% conifer cover as dominant type; (2) Mix = >10% tree cover and 20-90% hardwood cover; (3) Hardwood = >10% hardwood cover as dominant type; (4) Shrub = >10% shrub cover as dominant type; (5) Grass = >10% grass cover as dominant type; (6) Barren = <10% cover of any natural vegetation; (7) Agriculture; (8) Urban; and (9) Ice/snow. Attributes including tree cover from above and overstory tree diameter interpreted from aerial photography and satellite imagery were then mapped within the cover type classes and used to develop additional classifications. We used California Wildlife Habitat Relations (WHR) [26] to describe specific vegetation types, canopy cover, and tree size-class. "*WHR vegetation type,*" is derived primarily from CALVEG cover type and relative cover of conifer and hardwood trees for mixed vegetation types. For our study area, the *WHR vegetation types* consisted of Jeffrey Pine, Sierra Mixed Conifer, Montane Hardwood-Conifer, Eastside Pine, and Closed-cone Pine-Cypress. "*WHR density*" is a measure of tree density indexed by percent canopy cover and included: Sparse (10.0-24.9%), Poor (25.0-39.9%), Moderate (40.0-59.9%), and Dense ($\geq$60%). "*WHR size*" identified size classes of overstory trees. *WHR size* included the following three classes: WHR size 3 = dominated by trees 15-27 cm dbh; WHR size 4 = dominated by trees 28-60 cm dbh; WHR size 5 = dominated by trees $\geq$61 cm dbh.

The GIS layer depicting tree mortality was created from annual aerial surveys conducted by the USDA Forest Service. Current-year tree mortality from 2001-2003 was sketch-mapped by an aerial observer who quantified the number of yellow to reddish brown trees. Polygons were categorized by mortality type (drought or insect kill) and number of trees affected per acre (we converted acres to hectares for this study). Generally, areas with <1 tree per acre of mortality were considered to have background levels of mortality and were not usually mapped during the flight. The resulting layer is a vector data set of polygons each associated with a level of tree mortality for that year. Each year's layer was non-cumulative with respect to numbers of dead trees; however, we used only the 2003 GIS map in our analyses because (1) prior to 2003, few polygons showed above-background levels of mortality within the fire perimeter and (2) we were interested only in very recent mortality since these trees were most likely to have retained dead needles to potentially contribute to fire severity. Therefore, the actual number of all dead trees in a given polygon was likely higher than reported herein.

The fire severity GIS data of the 2003 Old and Grand Prix fires were derived from Landsat Thematic Mapper data. Pre-fire and post-fire data were used to create a Relative delta Normalized Burn Ratio (RdNBR) image, which portrays fire severity to vegetation within a fire while accounting for variation in pre-fire live tree cover, as described in Miller and Thode [27]. Because we were interested in ascertaining whether pre-fire tree mortality influenced fire severity, we used a relative rather than absolute index. Absolute dNBR measures how much vegetation was killed by the fire, while RdNBR measures the amount of vegetation killed in relation to the amount of pre-fire vegetation [27]. Miller and Thode [27] found that RdNBR more accurately classified high-severity fire effects than dNBR in heterogeneous landscapes with variable amounts of pre-fire vegetation, such as our study area in the San Bernardino Mountains. Higher RdNBR values are correlated with more severe burning of vegetation. The RdNBR image was classified into 4 classes of fire severity based on cutoff thresholds informed by field data collected on understory, midstory, and overstory vegetation one year post-fire on several fires from 2001 through 2004 using Composite Burn Index (CBI) protocols [27]. We used CBI classifications because they provide information about fire effects on all vegetation strata from the forest floor to the upper canopy, and are a useful and easily understood measurement for managers.

The fire severity map identified 4 classes of fire severity. "*Unchanged*" included areas in which conditions one year after the fire were indistinguishable from pre-fire conditions. "*Low Severity*" represented areas of surface fire with little change in cover and little mortality of the dominant vegetation. "*Moderate Severity*" was between low and high and represented a mixture of effects on the dominant vegetation. "*High Severity*" represented areas where the dominant vegetation had high to complete mortality of canopy foliage due to the fire. We used this classification system to represent the severity of fire in the forest canopy in our analyses. For areas mapped as high severity using RdNBR, we categorized these as "moderate/high severity" because RdNBR measures fire-induced mortality of canopy foliage, rather than tree mortality. The RdNBR high-severity mapping category has a lower threshold of 80% canopy mortality, which equates to 65% tree mortality for trees >20 cm dbh [28]. Basal area mortality would likely be somewhat lower than 65%, since the larger trees that dominate in terms of basal area are less fire-susceptible than the abundant small trees that dominate in terms of tree density [29].

The GIS layers of vegetation type and structure, pre-fire tree mortality, and a Digital Elevation Model [25] were clipped to the Old and Grand Prix fire perimeters. We selected conifer and mixed hardwood-conifer type polygons from within the vegetation layer for analyses. We generated 500 randomly located points throughout the conifer and mixed hardwood-conifer forest types to create a table of sample stand locations. At each sample location we determined the values of the variables: (1) *slope* [%]; (2) *aspect* [degrees]; (3) *mortality* [drought and beetle killed only] expressed as the number of dead trees per ha from year 2003; (4) *WHR vegetation type*; (5) *WHR size*; (6) *WHR density*; and (7) *fire severity*.

We removed 31 locations from our sample due to small sample sizes within specific categories, including: (1) the 5 locations where *WHR size* = 3; (2) 8 locations of various *WHR vegetation types* that had <5 samples in categories; and (3) 18 locations in the Closed-Cone Pine-Cypress type. Final sample size was 469 random points in *WHR types* Jeffrey Pine, Sierra Mixed Conifer, and Montane Hardwood-Conifer (hereafter conifer forest), in *WHR size* classes 4 and 5. *WHR densities* were modified from categorical variables to the mean value of each category (17.5%, 32.5%, 50%, and 80%). Pre-fire tree mortality data was expressed in terms of total number of dead trees per ha in 2003 (immediately prior to the October fires).

We analyzed how fire severity was affected by pre-fire insect and drought mortality along with topography, tree size, and canopy cover variables using two model structures best suited to categorical response variables: binomial and rank-ordered logistic. For the binomial method, we created a generalized linear model (GLM) using a binomial error structure and a logit link function to examine the effects of explanatory variables on the probability that each randomly selected location experienced moderate/high severity fire. The binomial response variable was moderate/high severity burn = 1; and unchanged, low, or moderate severity burn = 0. For the rank-ordered method we performed ordered logistic regression (OLR) to fit an ordered logit model examining how explanatory variables affected the probability that each randomly selected location burned at low, moderate, or moderate/high severity. Our response variable, *fire severity*, was treated as ordinal under the assumption that the levels of *fire severity* have a natural ordering (low to moderate/high), but the distances between adjacent levels are unspecified. All analyses were performed using Stata 8.2 (Stata Corp. 2004, College Station, Texas 77845).

We generated binomial categorical variables for *aspect* (south, east, and west), *WHR type* (Sierra Mixed Conifer and Montane Hardwood-Conifer), and *WHR size* 5, conditioning the model on north-facing slopes of Jeffrey Pine dominated by trees 28-60 cm dbh (*WHR size* 4). *WHR density* was included to control for variation in stand density (canopy cover) within mortality polygons and across the landscape. *Slope*, *aspect*, *WHR size*, and *WHR vegetation type* variables were included because all of these factors can influence fire behavior [16, 17].

We used trend surface analysis to model broadscale spatial pattern in the burn-severity data as a control for spatial autocorrelation. This methodology has two primary aims [30, 31]: (1) to guard against false correlations between fire severity and explanatory variables, as may arise when an unmeasured environmental factor causes a common spatial structure in fire severity and in the measured explanatory variables; and (2) to determine if there is a substantial amount of broadscale spatially structured variation in the fire-severity data that is unexplained by the measured explanatory variables. We fitted a trend surface to fire severity by including variables for x and y spatial coordinates of each sample location, polynomial terms up to the third-degree, and interactions. Prior to analysis, x and y were centered on their respective means to reduce collinearity with higher-order terms [31] and standardized to unit variance. Nonsignificant ($P > 0.05$) trend surface terms were removed by stepwise selection.

RESULTS

Fire severity in the Old and Grand Prix fires was highly variable, as is typical of forest fires, leaving patches of unburned and lightly burned areas intermixed with moderate and moderate/high severity patches (Fig. **1**). Throughout conifer forest, the fires burned 1,882 ha (32%) at moderate/high severity; 2,010 ha (34%) at moderate severity; 1,385 ha (24%) at low severity; and 586 ha (10%) remained unchanged. The distribution of fire severity categories of our sample locations closely matched the distribution of fire severities in conifer forest throughout the study area (32% at moderate/high severity; 34% at moderate severity; 23% at low severity; and 12% remained unchanged). Tree mortality due to drought and beetle infestation prior to the fire ranged from an average of 0 to 21.83 dead trees per ha in each polygon. In smaller patches within a polygon the density of dead trees may have been much higher. Fifty percent of our sample locations had no pre-fire tree mortality above background level. Of the remaining 50% of our sample locations with above-background tree mortality levels, most observations were evenly distributed among four categories: (1) < 2.47; (2) 7.41-12.35; (3) 14.83; and (4) 19.77-22.24 dead trees per ha. The original data were reported in these categories and were expressed in terms of dead trees per acre. We converted acres to hectares to derive our dead tree density values.

The GLM indicated that pre-fire tree mortality due to drought and beetle infestation did not significantly affect the probability that a location within the fire burned at moderate/high severity ($P = 0.88$; Table **1**), while controlling for the effects of topography and vegetation characteristics. Burned locations in Montane Hardwood-Conifer vegetation were significantly more likely ($P = 0.04$) to burn at moderate/high severity than locations in Sierra Mixed Conifer or Jeffrey Pine vegetation. Western aspect decreased the probability of moderate/high severity fire ($P < 0.10$; Table **1**). The pseudo r^2 value was 0.067, indicating that 7% of the variation in probability of high-severity fire was explained by our model.

Similarly, the OLR indicated that pre-fire tree mortality did not increase the probability that a location within the fire area burned at higher severity ($P = 0.53$; Table **2**). Montane Hardwood-Conifer vegetation significantly increased the probability that a location burned at higher severity than Sierra Mixed Conifer or Jeffrey Pine vegetation ($P < 0.001$; Table **2**). Sample locations with western aspect and those dominated by trees $\geq$61 cm dbh were more likely ($P < 0.10$) to burn at lower severities relative to locations with north

aspect or those dominated by trees 28-60 cm dbh (Table **2**). The pseudo r^2 value of 0.04 suggested that 4% of the variation in fire severity among locations was explained by our model.

DISCUSSION

We found that stands with recent high pre-fire tree mortality due to drought and insects did not burn at higher severity in coniferous forests of the San Bernardino Mountains, southern California, in the two fires we examined. Pollet and Omi [32] reported anecdotally that stands of lodgepole pine (*P. contorta*) that experienced an insect epidemic in the 1940s in Yellowstone National Park burned at lower severities compared to adjacent burned areas in the 1994 Robinson Fire. A widespread low-severity fire in subalpine forests in the White River National Forest, Colorado did not burn any beetle-affected stands [13]. Further, Bebi *et al.* [12] found that stands of Engelmann spruce (*Picea engelmannii*) and subalpine fir (*A. lasiocarpa*) in the White River National Forest influenced by a spruce beetle outbreak in the 1940s did not show higher susceptibility to 303 subsequent forest fires that burned after 1950. Our study area differed from these previous sites because most of the trees killed by insects and drought just prior to the fires in the San Bernardino Mountains were still standing and had retained needles. Despite differences in sites and forest types, previous studies and our results provide compelling evidence that when fire does occur, stands with considerable tree mortality due to drought and insects will not burn at higher severity than stands without significant tree mortality, either in the short or long term.

While pre-fire tree mortality had no effect on fire severity in burned stands, we found that sample locations dominated by the largest size class of trees ($\geq$61 cm dbh) burned at lower severities than locations dominated by trees 28-60 cm dbh (Table **2**). This result suggests that harvesting larger-sized trees for fire-severity reduction purposes is likely to be ineffective, and possibly counter-productive. These findings corroborate other recently published studies indicating that retention of the largest trees is likely to maintain normative fire behavior [33-35]. The smallest tree-size classes were not included in our analyses due to low sample sizes, so we could not determine the effects of still smaller tree-size classes on fire severity. An additional limitation on the potential effectiveness of fuel treatments to reduce fire severity in stands with high pre-fire mortality is the low likelihood that such stands will be affected by fire [14].

Weather conditions can supersede the influence of stand structure and fuels on fire behavior in mixed-severity fire regimes [36], which probably accounts for the low r^2 values of our models. We included topographical and stand structure variables, but we had no variables for wind speed, air temperature, and fuel and air moisture levels, for example. Odion and Hanson [36] analyzed the spatial patterns of fire severity for conifer forests in the three largest fires in the Sierra Nevada Mountains, California since 2000, and found that high-severity fire ranged from 10.9 to 28.9% of total area burned. Overall, we documented that 32% of conifer and mixed hardwood-conifer types burned at moderate/high severity in the 2003 Old and Grand Prix fires. The Old and Grand Prix fires may have had relatively high proportions of moderate/high severity due to the extreme fire weather resulting from Santa Ana winds, the lack of large-tree components due to past harvest, or some combination thereof.

ACKNOWLEDGEMENTS

We thank the USDA Forest Service, San Bernardino National Forest, and the US Geological Survey for providing us with their GIS data layers, and two anonymous reviewers for helpful comments. We are grateful to Environment Now for funding this research.

Chapter 4

c0020 ~~Mammal Habitat Selection~~

M.L. Bond
Wild Nature Institute, New Hampshire

s0010 4.1 INTRODUCTION

p0010 Mammals are ecologically and economically important members of the landscapes in which they live. Large herbivores like deer (*Odocoileus* spp.) and elk (*Cervus elaphus*), and predators like bears (*Ursus* spp.) and wolves (*Canis lupus*), are highly conspicuous and well-known "flagship" mammal species, whereas rodents, bats, and mustelids are cryptic but no less important in their ecosystems. Many species have developed broad ecological tolerance from exposure to environmental variation and natural disturbances over long time periods (Lawler, 2003). However, widespread hunting and excessive habitat fragmentation of landscapes by modern-day humans are qualitatively and quantitatively different from the natural disturbances to which these mammals were exposed in the past (Spies and Turner, 1999), and they have resulted in contraction of historical ranges and population declines. In North America alone notable population declines include elk, grizzly bears (*Ursus arctos*), gray wolves, Canadian lynx (*Lynx canadensis*), bighorn sheep (*Ovis canadensis*), beaver (*Castor canadensis*), the larger species of forest mustelids, and several herteromyid rodents.

p0015 Mixed- and high-severity wildfire is a natural disturbance in many vegetation systems of North America, the Mediterranean, Australia, and Africa (see Chapters 1, 2, 8~~, and 9~~). The effects of severe fire on organisms vary spatially and temporally, by habitat type, and by species, but how do these disturbances specifically impact mammals? As with any natural disturbance, some species are adversely affected ("fire-averse" species), others benefit ("fire-loving" or pyrophilous species), and still others have a neutral response to fires.

p0020 The dynamics of populations and communities of mammals after severe fire depend on factors such as the degree of ecological change, time since fire, size and spatial configuration of burned and unburned areas, extent of edge, isolation of habitat patches by urbanization and roads, and invasion of nonnative species (Smith, 2000; Shaffer and Laudenslayer, 2006; Arthur et al., 2012; Diffendorfer et al., 2012; Fontaine and Kennedy, 2012). In theory, mammalian populations

The Ecological Importance of Mixed-Severity Fire: Nature's Phoenix.

should be stable and resilient across the landscape wherever prefire populations and critical habitats are not greatly reduced and/or fragmented by human activities, and where severe fires occur in a spatial and temporal pattern in which a species has evolved (Shaffer and Laudenslayer, 2006). The capability of fire-loving individuals to utilize severely burned areas or for fire-averse populations to recover after fire, however, can be compromised when prefire habitat fragmentation has resulted in small and/or isolated populations and where postfire management actions, such as logging of burned trees and use of herbicides and pesticides, adversely influence population dynamics and habitat use.

p0025 In this chapter I provide an overview of published studies about mammalian responses to mixed- and high-severity fires in forests, woodlands, shrublands, deserts, and grasslands around the world. I describe research on the effects of severe fire on four major taxonomic groups of mammals: bats, small mammals, carnivores, and ungulates. I emphasized peer-reviewed publications, particularly those with robust methodologies and analyses, because these are the accepted standard in science. I also used non-peer-reviewed data when necessary to supplement information from the peer-reviewed literature. I do not cite every published study but instead provide a balanced overview of severe-fire effects on these taxa. I encourage readers to investigate further the scientific literature on habitat use and population responses of mammals to severe fire because the state of the science is constantly evolving.

p0030 Few studies have documented direct effects of fire on wildlife (e.g., mortality from asphyxiation, heat stress, burning, or physiological stress; however, see Singer et al., 1989), wildlife biologists generally agree that direct mortality from fire is typically low and does not significantly influence populations (Smith, 2000). Thus I focus here on the indirect responses ~~of~~ severe fire, such as postfire occupancy, abundance or density, survival, reproduction, and use of habitat (e.g., breeding, resting, foraging). I define "significant effects" according to the generally accepted scientific definition of statistical significance (i.e., at the 0.05 probability level). I exclude studies that simulated or modeled fires, choosing instead to focus on observations of real systems responding to severe wildfire.

p0035 Appendix 4.1 is a summary of published studies by mammalian taxa and directional response to severe wildfire (negative, neutral, positive) over three time periods after fire. I present results from studies comparing unburned habitats with high-severity burn from wildfire (rather than prescribed fire) and without the confounding effect of postfire logging. For small mammals, only species with enough detections to determine directional response were included in the appendix.

s0015 4.2 BATS

p0040 Bats perform unique and critical ecosystem services by consuming vast quantities of insects, thereby transferring nutrients, most notably nitrogen, from foraging to roosting areas via their feces (Gruver and Keinath, 2006). Bats are predators of adult mosquitoes and thus play an important role in controlling

B978-0-12-802749-3.00004-9, 00004

mosquito populations and reducing disease transmission (Reiskind and [illegible]l, 2009). Further, nectar-feeding bats are primary pollinators of many ~~plants~~ species throughout the world (Molina-Freaner and Eguiarte, 2003).

p0045 The current literature on the effects of fire on bats strongly suggests that mixed- and high-severity fires are explicitly beneficial. In a study comparing the relative activity of six phonic groups of mostly rare and sensitive bat species across unburned and moderate- and high-severity burned mixed-conifer stands 1 year after fire in the southern Sierra Nevada, bat activity in burned areas was equivalent to or greater than activity in unburned areas for all groups based on echolocation frequencies (Buchalski et al., 2013). Indeed, two of the phonic groups showed a positive response to high-severity fire but a neutral response to moderate-severity fire, demonstrating the importance of severity-specific responses. The positive response to mixed- and high-severity fire by bats mirrors findings for a range of bird species (see Chapter 3) and provides evidence of a long evolutionary relationship between bats and severe fire.

p0050 Several studies have documented how roosting bats use basal hollows of large trees (Gellman and Zielinski, 1996; Zielinski and Gellman, 1999; Fellers and Pierson, 2002; Mazurek, 2004). (Figure 4.1) Basal hollows are cavities formed by repeated fire scarring and healing (Zielinski and Gellman, 1999). For bats that roost in basal hollows of large trees, high-severity fire may destroy or reduce the longevity of existing roost trees, but it also creates new roost trees. In addition, fire creates gaps in the canopy that increase the amount of solar radiation reaching the subcanopy where bats roost. These warmer temperatures may facilitate thermoregulation (Brigham et al., 1997; Boyles and Aubrey, 2006) and are particularly beneficial to [illegible]ductive females because increased temperatures are associated with increased fetal and neonate growth (Brigham et al., 1997; Johnson et al., 2009). Finally, high-severity fire c[illegible] a "pulse" of insect prey (e.g., aquatic insects (Malison and Baxter, 2010) ~~and~~ moths, beetles, and flies (Schwab, 2006)), as well as new natural edge habitat that provides novel foraging opportunities (Fellers and Pierson, 2002).

p0055 Comparisons of food web components between unburned watersheds [illegible] areas of low- and high-severity fires 5 years after fire in Douglas fir (*Pseudotsuga menziesii*) and ponderosa pine (*Pinus ponderosa*) forests in central Idaho showed high insect biomass in heavily burned areas and correspondingly high bat detection rates (Malison and Baxter, 2010). Notably, high-severity sites had almost five times more biomass of zoobenthic insects and more than three times the number of emerging adult aquatic insects than low-severity sites (and twice as many as unburned areas). The frequency of bat echolocation calls also was significantly greater at high-severity sites than at unburned sites, because aquatic insects emerging from streams into the terrestrial envir[illegible]t are an important food source for bats. In a review of the responses of [illegible]n benthic macroinvertebrates to fire, Minshall (2003) concluded that "[r]esults for macroinvertebrates generally support the belief that fire and similar natural disturbance events are not detrimental to the sustained

maintenance of diverse and productive aquatic ecosystems (i.e., those found in undisturbed forests)" (p. 159). While individual taxa respond differently to the physical changes in stream structure and short-term and long-term postfire changes in vegetation, Minshall noted that streams are inherently unstable and dynamic environments in which disturbance, including high-severity fire, is a regular occurrence, and many species are opportunistic and can shift food resources in response to fire.

p0060 In mid-elevation forests burned at mixed and high severity in western Montana, Schwab (2006) characterized roost sites and sampled potential prey sources for two forest-dwelling, insectivorous bat species, the little brown bat (*Myotis lucifugus*) and the long-eared myotis (*Myotis evotis*). These species roosted in larger-diameter snags (standing dead trees) in high-density stands of fire-killed trees. Proximity to perennial streams also was important in roost site selection for these two species in burned forests. Wildland fire apparently

Comp. by: Gunalan Stage: Revises1 Chapter No.: 4 Title Name: Dellasala
Date:28/4/15 Time:13:45:29 Page Number: 90

B978-0-12-802749-3.00004-9, 00004

created an abundance of roosting sites and insect prey for bats. Although the abundance of Lepidoptera (moths) and Trichoptera (caddis flies) was similar in burned and unburned forests, the abundance of Diptera (flies) and Coleoptera (beetles) was significantly higher in burned forests. Overall, the median capture rate of all insects in the burn was 1.78 times higher than the median capture rate in unburned forests, ~~although~~ there was considerable variability in the composition and abundance of particular species. Eight of the 11 orders of insects were more abundant in burned sites. In addition, beetles, flies, and caddis flies were significantly more abundant in burned than unburned sites in the first year after fire, although they decreased significantly the second year after fire. Thus, retention of burned trees the first year is important for insectivorous bats. In fact, removing burned trees decreased mammalian (and avian) predation on the abundance of insects that occurred 1 year after fire. Snags in unburned forests can be recruited from existing green trees, but in severely burned forests postfire logging eliminates both existing and future snags for nearly a century because few trees are available for snag recruitment until large-diameter trees have regrown (Schwab, 2006).

p0065 As with many bird species, mixed- and high-severity fire in forest ecosystems likely enhances foraging opportunities for bats (Buchalski et al., 2013). Many insect species inhabiting coniferous forests are highly evolved to exploit severely burned forests and are aptly termed "pyrophilous." Certain beetle species in particular are strongly attracted to highly burned forests. Saint-Germain et al. (2004) noted that, "[s]ome insect groups have adapted to recurrent forest fires by evolving sensory organs and life strategies that allow them to exploit these high quality habitats efficiently. Pyrophilous Buprestids of the genera *Oxypteris* and *Merimna* and the Cerambycid *Arhopalus tristis* (F.) have been shown to respond physiologically to smoke and/or heat generated by fire, and use them as signals leading toward the newly created habitat . . . Several other Coleoptera species uncommon in mature forests congregate in exceptionally high densities in burned stands" (p. 583).

p0070 In a study of fire-loving beetle communities in a large fire that burned boreal black spruce (*Picea mariana*) forest in Quebec, Canada, more than half of the 86 taxa captured were restricted to burned stands (Saint-Germain et al., 2004). Moreover, total captures and species richness were higher in burned stands, especially the oldest severely burned forests. Captures were significantly lower the second year after the fire for all burned stands, indicating that the utility of burned forests for these beetles is greatest in the first year following fire.

p0075 Insects utilizing dead trees occur at much lower abundances in low-severity sites, which by definition have far fewer fire-killed trees than high-severity sites. Malison and Baxter (2010) stated that, "[o]ur results suggest that high severity fires do not play the same ecological role as low severity fires and allowing high severity fires to burn (rather than suppressing them) in certain forest types could be important in maintaining ecosystem function" (p. 577). Similarly, in his severely burned study site, Schwab (2006) noted, "26% of all [insect] families captured were restricted to sites within the burn suggesting

Date:28/4/15 Time:13:45:29 Page Number: 91

b0010 **BOX 4.1**

o0010 **(1)** Bats preferentially roost and forage in burned forests.
o0015 **(2)** High-severity fire creates a superabundance of native insect prey.
o0020 **(3)** Bats select denser stands of fire-killed trees for roosting in burned forests and Au7 forage significantly more in forests burned by high-severity fire than in unburned and low-severity fire-affected forests.
o0025 **(4)** Large burned trees for roosting have significant positive benefits for bats.
o0030 **(5)** Postfire logging removes roost trees, reduces the abundance of prey, and reduces habitat suitability for bats.

a unique environment created only after fire." Thus, ecological changes caused by mixed- and high-severity fires cannot be mimicked by low-severity prescribed burns (also see Chapter 13 for similar discussion) (Box 4.1).

s0020 4.3 SMALL MAMMALS

p0110 Small mammals are critically important to ecosystems because they can influence vegetation structure and composition by dispersing seeds and ectomycorrhizal fungi and by aerating soils (Maser et al., 1978). They also provide an essential prey base for carnivores, and the distribution of small mammals can affect the use of space and the habitat selection of their predators (Carey et al., 1992; Ward et al., 1998). Small mammals have comparatively small home ranges and therefore are quite sensitive to habitat change, making them good biological indicators (Haim and Izhaki, 1994). Small mammal assemblages include rodents and insectivores of the families Soricidae (shrews), Talpidae (moles), Aplodontidae (mountain beavers), Sciuridae (squirrels, chipmunks, and marmots), Geomyidae (gophers), Heteromyidae (pocket mice and kangaroo rats), superfamily Muroidea (voles, mice, and woodrats), and Dipodidae (jumping mice). Larger-bodied small mammals include rodents in the Castoridae (beaver) and Erethizontidae (porcupine) families, as well as lagomorphs (pika, hares, and rabbits), and Australian and American marsupials (Marsupialia).

p0115 The occupation of severely burned areas by small mammals is related to regrowth of the vegetation structure with which various species are associated (Torre and Díaz, 2004; Lee and Tietje, 2005; Vamstad and Rotenberry, 2010; Diffendorfer et al., 2012; Kelly et al., 2012; Borchert and Borchert, 2013), as well as with seed and insect production and availability (Coppeto et al., 2006), and cavities created by woodpeckers in snags (Tarbill, 2010). I discuss fire effects on small mammals according to habitat type but give special attention to the deer mouse (*Peromyscus maniculatus*)—an exceptionally "fire-loving" species—in its own section. (Figure 4.2)

f0015 **FIGURE 4.2** Deer mice increase after severe fire in a variety of habita[illegible]er mouse captured two years after forest dominated by Douglas-fir with some lodgepole pine, western larch, and ponderosa pine burned severely in the 2005 Tarkio Fire, Montana. (Photo by Rafal Zwolak (2005)).

s0025 Chaparral and Coastal Sage Scrub

p0120 The chaparral and coastal sage scrub vegetation types in central and southern California support an exceptionally rich diversity of rodents that are well-adapted to a regime of periodic, very-high-intensity fire (see Chapter 7). Many studies have examined small-mammal communities after both prescribed and wildfire in these vegetative types. During intense fires, some individuals among small, less vagile animals may suffer mortality, but many others survive in rock crevices, riparian areas, large downed logs, and underground burrows where temperatures remain cool and the air clean (Chew et al., 1959; Quinn, 1979; Lawrence, 1966; Wirtz, 1995; Smith, 2000). Following fire, small-mammal communities change over time (Diffendorfer et al., 2012; Arthur et al., 2012; Borchert and Borchert, 2013) and space (Schwilk and Keeley, 1998), depending on the vegetation associations of the various species. Species preferring open habitat, including pocket mice (*Chaetodipus* spp.), California voles (*Microtus californicus*), harvest mice (*Reithrodontomys megalotis*), and, especially, kangaroo rats (*Dipodomys* spp.) and deer mice can increase quite dramatically and quickly after severe shrubland fire. Over a period of several years, as shrubs resprout and grow denser and as different food sources become available, small-mammal species preferring a shrubby overstory, including woodrats (*Neotoma* spp.), California mice (*Peromyscus californicus*), brush mice (*Peromyscus boylii*), and cactus mice (*Peromyscus eremicus*), increase in number (Cook, 1959; Wirtz, 1977; Price and Waser, 1984; Brehme et al., 2011; Borchert and Borchert, 2013). Compared with unburned chaparral and grassland, severely burned chaparral had the highest rodent diversity 4 years after a high-intensity wildfire near Mount Laguna in San Diego County (Lillywhite, 1977). Published data are not currently available for lagomorphs in chaparral wildfires, but prescribed burning of chamise (*Adenostoma fasciculatum*) chaparral in northern California increased black-tailed jackrabbit (*Lepus californicus*) densities by 500-1000% the year following fire (Howard, 1995).

s0030 Forests

p0125 Forests offer important habitats for small mammals, especially shrews, mice, tree voles, and squirrels. Mixed- and high-severity fire in forested habitats can have pronounced effects on small-mammal populations by creating or transforming habitat structures such as live and dead trees, shrubs, and coarse woody debris. While some studies have shown that severely burned conifer forests in North America support fewer individuals of some rodents and insectivores immediately after fire compared with adjacent unburned sites (e.g., pinyon mice [*Peromyscus truei*; Borchert et al., 2014] and masked shrews (Sorex cinereus) and southern red-backed voles [*Myodes gapperi*; Zwolak and Forsman, 2007]), numbers begin to rebound several years after fire, often by individuals surviving in unburned refuges within the larger burn perimeter. Northern red-backed voles (*Myodes rutilus*), considered old-growth specialists, began repopulating an intense burn in boreal Alaska from surrounding unburned forest and started reproducing 3 years thereafter (West, 1982).

p0130 Unburned refuges and vegetation changes over time also mediate postfire mammal population dynamics in other forests types, notably *Eucalyptus* forests in Australia. Numbers of bush rats (*Rattus fuscipes*) and agile antechinus (*Antechinus agilis*) were reduced compared with populations in adjacent unburned forests 6 months after severe fire in a mountain ash (*Eucalyptus regnans*) forest, but the population in the burned area was composed of residual animals that had survived the fire rather than animals recolonizing from adjacent forests (Banks et al., 2011). Long-term studies are especially useful because responses relative to time since fire can be quantified. One study examined marsupial population dynamics over a 28-year period following severe wildfire in a southeastern Australia *Eucalyptus* forest reserve (Arthur et al., 2012). Bandicoots (*Isoodon obesulus* and *Perameles nasuta*) increased immediately following the fire, peaked 15 years later, and then declined, associated with an increase and decline of shrub cover. The potoroo (*Potorous tridactylus*) population was similar before and immediately after the fire but began to increase a decade later as tree cover increased. Wombats (*Vombatus ursinus*) exhibited a stable population trend for the first decade after the fire, then slowly declined along with a decline in ground litter cover. Finally, larger macropods (eastern gray kangaroo [*Macropus giganteus*], red-necked wallaby [*Macropus rufogriseus*], and swamp wallaby [*Wallabia biocolor*]) remained at high densities after the fire then declined a decade later as vegetation cover increased.

p0135 Rabbits and hares are associated with shrubs and small conifers that provide cover (Ream, 1981; Howard, 1995). Severe fire temporarily eliminates this habitat structure, but it quickly returns as the vegetation regrows, stimulated by intense fire. Snowshoe hares (*Lepus americanus*) in a boreal forest in Alberta, Canada, moved out of intensely burned sites to surrounding habitat immediately after fire but returned the second summer after the fire when shrubs resprouted, and the postfire population trajectory increased above prefire numbers (Keith and Surrendi, 1971).

p0140 Tree squirrels, including Douglas squirrels (*Tamiasciurus douglasii*) and northern flying squirrels (Glaucomys sabrinus), typically are associated with late-successional coniferous forests in California and the Pacific Northwest in the United States (Carey, 2000); thus they may be adversely affected by intense fire (Zwolak and Forsman, 2007), but few data currently are available to refute or support this hypothesis. Chipmunks and ground squirrels can occupy forests after severe fire where shrubs provide cover and food (Borchert et al., 2014). Townsend's chipmunks (*Neotamias townsendii*) were abundant in early seral forests with dense shrub cover (Campbell and Donato, 2014). Gray-collared chipmunks (*Tamias cinereicollis*) and least chipmunks (*Tamias minimus*) showed no significant response to wildfire in ponderosa pine forests of the southwestern United States (Converse et al., 2006), and the proportion and composition of two chipmunk species, *Tamias amoenus* and *Tamias ruficaudus*, did not differ between severely burned and unburned conifer forest in Montana (Zwolak and Forsman, 2007).

p0145 The increase in the availability, amount, and quality of forage for herbivorous small mammals is an important determinant of the post-severe-fire community. In plots recently burned by large, intense wildfires in a Mediterranean pine-oak woodland in Spain, the abundance of small mammals—mostly mice and shrews—was higher than expected based on vegetation characteristics alone (Torre and Díaz, 2004). The authors attributed small-mammal increases to large quantities of seeds and seedlings in burned sites.

s0035 Deserts

p0150 The role of severe fire and its effects on small mammals in desert grasslands is somewhat controversial (Killgore et al., 2009; Vamstad and Rotenberry, 2010). Most desert systems are not adapted to frequent fire because many species of long-lived perennial desert plants have low recruitment rates and long life spans and lack the ability to resprout. Fire size and frequency in some areas has increased recently because of the invasion of exotic grasses from livestock grazing (Brooks, 2000) and other causes (Burbidge and McKenzie, 1989). In general, most research shows a lack of significant long-term effects of intense fire on the abundance of desert small mammals, although fire can alter community composition. Similar to shrub types in southern California, rodents in the family Heteromyidae increased following a large, intense wildfire in a perennial grassland in southeastern Arizona, whereas species in the family Cricetidae declined immediately after fire, began increasing 4 years after fire, and returned to prefire levels by the sixth year (Bock et al., 2011). Rodent abundance and species richness we[illegible] different between burned and unburned plots after wildfires in Joshua tree woodlands of the Mojave Desert in the American Southwest (Vamstad and Rotenberry, 2010). Merriam's kangaroo rat (*Dipodomys merriami*) dominated the burned sites. As postfire vegetation changed from annuals to sub-shrubs and then to long-lived perennials, however, the composition of rodent species changed and the diversity of rodents increased over time.

p0155 Habitat type is important to fire effects in deserts. In Australia, wildfires in stony desert habitats with sparse grasses have less effect on habitat structure and small mammals than wildfires in sandy desert habitats with denser hummock grass spinifex (*Triodia* spp.) (Pastro et al., 2014). For example, an intense wildfire did not affect the total abundance and species richness of small mammals in the stony (gibber) desert in central Australia, although some species increased and others decreased immediately following fire (Letnic et al., 2013). By contrast, 9 months after intense wildfire in a spinifex grassland in the same region, small-mammal diversity declined compared with before the fire and with prescribed burned areas, although the abundance of animals captured was similar (Pastro et al., 2011). Data were unavailable from wildfires, but hare (*Lepus* spp.) abundance increased by 300% after prescribed burning in East African savanna grasslands (Ogen-Odoi and Dilworth, 1984).

s0040 Deer Mice

p0160 In North America, generalist deer mice are often the most abundant rodent after severe fire in a variety of vegetation types (Borchert et al., 2014). This species responds strongly and positively to high-intensity fire in both shrubland and conifer forests. Deer mice increased significantly over time in moderately and severely burned mixed-conifer forests in the San Bernardino Mountains of southern California over a 5-year period after fire (Borchert et al., 2014). During 2 years subsequent to intense fire, deer mice were invariably the most numerous species in burned study sites in a Douglas-fir-Western larch ~~(*Larix occidentalis* Nutt.)~~ forest in Montana (Zwolak and Forsman, 2008). Converse et al. (2006) attributed increased abundance of deer mice after wildfire in southwestern United States ponderosa pine forests to ~~increased~~ seed production or ~~greater~~ detectability of seeds after fire.

p0165 Dramatic increases in deer mice in severely burned conifer forests were not simply a result of colonization of the burn by animals from surrounding unburned forests. When population densities were low, the vast majority of individually ear-tagged deer mice were found in forest areas after severe fire, and mice appeared regularly in unburned forests only when population densities were high (Zwolak and Forsman, 2008). This finding indicated that severely burned forest was *preferred* deer mouse habitat and that the postfire population increase was intrinsic to the burn; thus the burn itself was a source habitat.

b0015 **BOX 4.2**

o0035 **(1)** After intense wildfire, small-mammal communities are dynamic and associated with vegetation structure at different successional stages.

o0040 **(2)** Intense fire may increase the availability and abundance of seeds and seedlings for herbivorous small mammals.

o0045 **(3)** Unburned refuges and time since fire are important determinants of small-mammal communities following intense fire.

o0050 **(4)** The richness and abundance of small-mammal species is high following intense fire in chaparral and coastal sage scrub communities of southern California. Heteromyid rodents and deer mice often dominate severely burned shrublands, and heteromyids dominate postburn desert grasslands.

o0055 **(5)** Some small-mammal species decrease shortly after intense fire in North American conifer forests, but they can recover to prefire levels within 1 to several years after fire. Deer mice dramatically increase following intense fire.

p0170 Overall, these observations from small-mammal studies in mixed- and severely burned shrublands, forests, and grasslands underscore the important roles played by high-severity fire patches, unburned refuges within a fire area, and the time since fire in population dynamics after severe fire (Box 4.2).

s0045 4.4 CARNIVORES

p0205 Carnivores are critically important "top-down" regulators of ecosystem processes. Elimination of top carnivores unleashes a cascade of adverse effects, including relaxation of predation as a selective force on prey species, spread of disease, explosions of herbivore populations, and subsequent reproductive failure and local extinction of some plants, birds, herptiles, and rodents (Crooks and Soule, 1999; Terborgh et al., 2001). ~~Soulé~~ Large carnivores include ursids (bears), canids (wolves), and larger felids (puma, lions, and jaguars). Medium-sized carnivores, or "mesocarnivores," include canids (coyotes and foxes), Procyonidae (ringtails and raccoons), mustelids (wolverine, marten, fisher, weasels, mink, and badgers), Mephitidae (skunks), and smaller felids (lynx and bobcats). Currently published research on carnivores in mixed and severe wildfires is limited primarily to forested habitats.

s0050 Mesocarnivores and Large Cats

p0210 Many mesocarnivores are associated with forested habitats. Some are habitat generalists, whereas others are forest specialists, riparian associates, or semi-aquatic (Buskirk and Zielinski, 2003). Martens (*Martes* spp.) occur in dense coniferous or deciduous forests across the northern hemisphere. They also regularly use severely burned habitats. Some evidence suggests martens use burns only when postfire trees are not logged. For instance, stone marten (*Martes foina*) were not detected in an intensely burned but extensively postfire-logged Aleppo pine (*Pinus halepensis*) forest in Greece the second and third years after wildfire and logging (Birtsas et al., 2012). These martens were found only in Turkish red pine (*Pinus brutia*) forests burned by wildfire 9 years earlier and not in nearby unburned forests (Soyumert et al., 2010). In coniferous forests of the Alaskan taiga, resident and transient American martens (*Martes americanus*) were captured in a 6-year-old unlogged burn more often than in an island of unburned mature forest surrounded by the burn (Paragi et al., 1996). The authors did not quantify burn severity in their study area but described fire-affected sites as having portions of "severe" burn, and most of the vegetation was in early to mid-seral stages, with dead, fire-scarred trees still standing, consistent with mixed- and high-severity fire. There was no age difference between martens trapped live in the mature forests ~~versus~~ and those trapped in the burn, and marten foraging intensity was greatest in the recently burned area (Paragi et al., 1996). Conversely, martens avoided stands of boreal forests burned from 2 to 20 years prior (Gosse et al., 2005), but the study did not quantify or describe burn severity nor specify whether the burned forest was logged.

p0215 Larger cousins to the marten, fisher (*Martes pennanti* or *Pekania pennanti*) are rare mesocarnivores associated with dense, mature, boreal and mixed conifer-hardwood forests of North America (Powell and Zielinski, 1994). A recent study in the southern Sierra Nevada, however, used scat sampling to detect fisher habitat preferences and demonstrated that the species used denser, mature forests that had experienced moderate- and high-severity fire 10 and 12 years prior and that were not logged after fire (Hanson, 2013) (Figure 4.3). It is likely that both martens and fishers use severely burned forests for foraging rather than denning. These results provide intriguing evidence that even old-forest specialist species are adapted to and can exploit postfire conditions in regions where mixed- and high-severity fire is natural (see Chapter 3, Box 3.1: spotted owls).

p0220 Foxes apparently prefer severely burned forest areas over unburned areas, but they may be less tied to forest structure than martens and fishers and thus less sensitive to postfire logging. Red fox (*Vulpes vulpes*) in Turkish red pine forests were detected more often in the 9-year-old unlogged wildfire area (Soyumert et al., 2010); in postfire-logged Aleppo pine forests in Greece, red foxes were detected most often in severely burned areas, rather than moderately and unburned areas (Birtsas et al., 2012). In 3 of 4 years after intense wildfire in mixed-conifer forests of the San Bernardino Mountains in southern California, gray foxes (*Urocyon cinereoargenteus*) were detected more often in mixed-severity burned over unburned areas, and in two of the years no foxes at all were captured in the unburned area, but coyote (*Canis latrans*) were detected more often in unburned forests (Borchert, 2012). Both gray fox and coyote scats were more numerous in areas burned by intense wildfire than in unburned areas

f0020 **FIGURE 4.3** Representative foraging ~~detection~~ location based upon global positioning system coordinates for a confirmed female Pacific fisher scat detection site several hundred meters into the interior of the largest high-severity fire patch (>5000 ha) in the McNally Fire of 2002, Sequoia National Forest, California. *(Photo by Chad Hanson (2014).)*

2 years after fire in interior chaparral, Madrean evergreen woodland, and ponderosa pine forest in Arizona (Cunningham et al., 2006).

p0225 Striped skunk (*Mephitis mephitis*), ringtail (*Bassariscus astutus*), and raccoon (*Procyon lotor*) were photocaptured only in mixed-conifer forests in southern California burned by high-intensity fire, but each were photographed only once (Borchert, 2012). Bobcat (*Lynx rufus*) were photocaptured in similar numbers in severely burned and unburned forest, but captures in the burned area decreased over time over the 4 years of the study. Finally, mountain lion (*Puma concolor*) were photocaptured more often in severely burned forest, but the overall sample was small (four lion in burned areas, one lion in unburned areas).

s0055 Bears

p0230 Although grizzly bears are flexible in the habitats they use, in British Columbia, Canada, radio-collared grizzly bears strongly selected open forest burned by wildfires 50-70 years earlier at high elevations because these sites supported prolific huckleberries (McLellan and Hovey, 2001). Wildfire also promotes the regeneration of whitebark pine (*Pinus albicaulis*) seeds, another important food source for bears (Kunkel, 2003). Wildfire is not equivalent to logging, as regenerating timber harvests were rarely used by bears in any season (McLellan and Hovey, 2001).

p0235 One study compared the demographics and physiology of black bears (*Ursus americanus*) occupying burns of two ages, 13 and 35 years old, in spruce

(*Picea* spp.) and aspen (*Populus tremuloides*) forests of the Kenai Peninsula of Alaska (Schwartz and Franzmann, 1991). The authors did not specify burn intensity, but they noted that 5% of the older burn was logged after fire for "improvement" of moose (*Alces alces*) habitat, and they pointed out that the more recent fire burned at a greater intensity than the older fire. The density of bears and the percentage of cubs born were similar between the two sites, but all age groups of bears were significantly larger in the recent burn area. Bears in the older burn area consumed more cranberries, whereas the number of moose calves consumed per bear was much larger in the recent burn area, likely explaining the larger size of the bears. Females in the recent burn area also produced litters at a younger age and had a shorter interval between weaning of yearlings than females in the older burn area. Moreover, cub survival was significantly higher in the recent burn area. The vigor of black bear populations was associated with moose abundance, which was significantly enhanced in the 13-year-old fire area.

p0240 Another study compared the demography of a population of black bears in interior chaparral, Madrean evergreen woodland, and ponderosa pine forest, burned by high-intensity wildfire for 3 years after fire using (1) the population in a nearby unburned site for 3 years and (2) results from earlier demographic research on the fire site from 20 years earlier, conducted over a 6-year period (Cunningham and Ballard, 2004). The sex ratio at the 3-year-old burned site was more skewed toward males than in either the unburned reference site or 20 years before the burn. The authors presumed that the fire had reduced the adult female population; however, it is also possible that the female population already had been reduced in the 20 years before the fire occurred, when the population was not monitored. Indeed, an alternative scenario could be that the population of both adult females and males had been declining at Four Peaks before fire, and the fire actually attracted males to the site, who have larger home ranges, thus skewing the sex ratio.

p0245 The above study reported complete reproductive failure in the 3 years after fire at the burned site compared with 36% of cubs surviving to 1 year of age on the unburned control site (Cunningham and Ballard, 2004). More cubs had survived to year 1 at the burned site 20 years before the fire. During the 1970s, however, complete reproductive failure also occurred in the absence of fire during 3 of the 6 years of study. Thus years of complete reproductive failure in that study area were not unusual. Overall, reproductive success was lowest in the burned forest compared with the same site 20 years before fire and an unburned reference site, suggesting the possibility of negative short-term effects of high-intensity fire on black bear reproduction. The mortality of adult bears from hunting, however, was 2.5 times higher in the fire area than in the unburned area (Cunningham et al., 2001), which would be expected to influence cub survival, potentially confounding results. The overall density of black bears in the fire area was higher than prefire densities in the area (Cunningham et al., 2001) (Box ~~4.3 and~~ 4.4).

B978-0-12-802749-3.00004-9, 00004

b0020 **BOX 4.3 Seed Dispersal by Carnivores**

p0250 Fleshy fruits are an important component of the diet of many carnivores, especially during certain seasons when other resources are scarce. Indeed, the germination of many seeds is facilitated by passage through the carnivore gut because it removes the fruit pericarp and scarifies the seed coat (Herrera, 1989). Carnivores are important dispersers of seeds because they have relatively large home ranges and long gut retention times, thus spreading the seeds far from the parent plant. This may be an important mechanism whereby early seral habitats are seeded. For example, in experimental and field tests in severely burned Aleppo pine forest in Spain, Rost et al. (2012) demonstrated that carnivores, including red fox, stone marten, and European badger (*Meles meles*), were important dispersers of Mediterranean hackberry (*Celtis australis*) seeds into the burned areas. These carnivores traveled long distances into the fire area, dispersing seeds more than 1 km from the parent plant. Moreover, seeds collected from scat (i.e., that had passed through the gut) in the burned study area had a significantly greater germination rate than unscarified seeds, both in the greenhouse and in the field.

b0025 **BOX 4.4**

o0060 **(1)** Grizzly bears use areas burned by intense wildfire because of increases in berry production, although results from studies of the effects of intense fire on black bear demographics are equivocal.

o0065 **(2)** Martens and fisher are mesocarnivores that are dense, mature forest specialists for denning and resting but use severely burned forests that were not logged after fire, most likely for foraging.

o0070 **(3)** Foxes regularly use severely burned forests (regardless of postfire logging for one Mediterranean species), but results from research on coyotes are equivocal.

o0075 **(4)** Carnivores are important dispersers of seeds deep into severely burned forest areas.

s0060 4.5 UNGULATES

p0280 As major herbivorous components of ecosystems, ungulates can act as keystone species with profound effects on vegetation development and productivity in forests, woodlands, and grassland ecosystems throughout the world (Hobbs, 1996; Wisdom et al., 2006). Hobbs (1996) stated, “ungulates are not merely outputs of ecosystems, they may also serve as important regulators of ecosystem processes at several scales of time and space” (p. 695). Ungulates, Hobbs further noted, are “important agents of environmental change, acting to create spatial heterogeneity, accelerate successional processes, and control the switching of

Comp. by: Gunalan Stage: Revises1 Chapter No.: 4 Title Name: Dellasala
Date:28/4/15 Time:13:45:30 Page Number: 101

ecosystems between alternative states." Ungulates regulate nitrogen cycling and influence plant size and morphology (Singer et al., 2003). Because grazing and browsing by ungulates affects the biomass, structure, and type of vegetation available to burn, these animals can actually regulate the dynamics of fire (Hobbs, 1996; Wisdom et al., 2006).

p0285 Episodic disturbance agents such as fire strongly interact with ungulate herbivory over space and time. For example, removal of fine fuels by ungulate grazers may reduce the frequency of ground fires but can increase crown fires by enhancing the development of ladder trees, especially when combined with a relatively long absence of fire (Hobbs, 1996). Further, postfire plant regeneration provides forage species that are highly palatable to ungulates, which attracts ungulates to burned areas, where they influence vegetation regrowth after fire (Canon et al., 1987; Wan et al, 2014). Moose rapidly immigrated to burned areas after a large wildfire in mixed coniferous-deciduous forests of northern Minnesota (Peek, 1974). In fact, fire size can moderate the adverse effects of ungulate herbivory on vegetation recovery. Compared with small fires, large fires "swamp" the effects of ungulate herbivory, for example, by providing sufficient new growth production to offset browsing, and enabling woody species such as aspen to grow to tree height (Biggs et al., 2010). In intensively burned ponderosa pine, mixed-conifer, and spruce-fir forests of northern New Mexico, elk selectively foraged on grasses over shrubs (Biggs et al., 2010). In 25 wildfires throughout five national forests in Utah, larger areas of aspen forest that burned with greater severity had the highest growth potential for aspen regeneration, and these high burn-severity conditions stimulated defensive chemicals in plants that lowered the levels of damage done by ungulate browsing (Wan et al., 2014). Wan et al. noted that "this effect may be particularly strong if amplified over large post-fire landscapes by saturating the browse capacity of the ungulate community." (See Box 4.5).

p0290 Positive effects of high-severity fire on ungulates likely are most pronounced in vegetation types that are most adapted to high-intensity fires, such as aspen forests and shrublands. Mountain or bighorn sheep selected intensely burned shrublands up to 15 years after fire in Montana (DeCesare and Pletscher, 2006) and in southern California mountains (Bleich et al., 2008). Wildfire increased the carrying capacity of southern California ~~mountain~~ sheep (*Ovis canadensis nelsoni*) in the San Gabriel Mountains, dramatically increasing the number of animals in this endangered population (Holl et al., 2004). A large natural fire on the eastern slopes of the Sierra Nevada mountains in California improved the winter range of Sierra bighorn sheep (*Ovis canadensis sierrae*) by increasing green forage availability, shifting diet composition to include more forbs, and possibly decreasing predation risk from mountain lions by increasing visibility (Greene et al., 2012). Overall, large, high-severity fire in bighorn sheep shrubland/forest habitats increases forage quality and availability as well as visual openness, which is critical because several populations are listed as endangered.

p0295 Studies investigating the impact of fire on mule deer (*Odocoileus hemionus*), a common herbivore in the western United States, indicate that populations tend to increase after severe fire, especially in chaparral communities. In a review of the literature on ungulate responses to fire, Smith (2000) reported mule deer density in intensely burned chaparral was more than twice as high as that in mature chaparral in California, and it increased 400% the first year after high-intensity fire in chamise chaparral. Density then decreased each year afterward until preburn levels were reached 5-12 years later. Chamise chaparral burned by a large wildfire in California had more deer use per square mile than unburned chamise chaparral (Bendell, 1974). In northern coastal California, mule deer densities in chaparral burned by high-intensity wildfire the year before were four times greater than in unburned chaparral (Taber and Dasmann, 1957). Because the fire described in this study was relatively small, deer may have moved from one area to another rather than actually increasing the population via higher birth rates. Similarly, ~~black-tailed~~ deer in central coastal California strongly preferred burned habitat, with a 400% increase in the density of deer in prescribe-burned chaparral near oak woodlands, relative to preburn density, by the second growing season (Klinger et al., 1989). Here the increase in the use of burned chaparral was attributed to movements of deer from adjacent oak woodlands rather than an intrinsic increase in population size. Heavy use of prescribe-burned chamise chaparral by mule deer was reported in the San Jacinto Mountains of southern California (Roberts and Tiller, 1985).

p0300 Other studies documented postfire increases in the number of mule deer in conifer forests. Visual observations of 543 mule deer indicated a preference for burned over unburned Douglas fir/ninebark and burned ponderosa pine/bluebunch wheatgrass habitat types during winter and spring in the Selway-Bitterroot Wilderness of Idaho, although the authors did not specifically define the burn severity of sites used by deer (Keay and Peek, 1980). Two other studies that documented increases in mule deer in burned forests hypothesized that postfire logging removes protective cover, a critical habitat element for mule deer. Significantly more deer droppings were located in pinyon-juniper woodlands of Arizona burned by high-intensity fire 13 years earlier than in adjacent unburned areas (McCulloch, 1969). The author surmised that the standing forest of dead trees and fallen trunks provided some cover for deer from predators. Both mule deer and elk used intensely burned lodgepole pine ~~(*Pinus contorta*)~~ forests at two sites in Wyoming significantly more than paired clearcut sites of the same ages (9 and 5 years old) based on fecal pellet counts (Davis, 1977). Davis (1977, p. 787) stated: "[D]eer and elk use was greater in burned areas with standing dead timber than in clearcut areas without it. In the Sierra Madre study area, the burned and clearcut plots both had the same number of plant species present, and they both had standing dead timber. However, the burned plot with much more standing dead timber had more deer and elk use. Fire opened up the canopy allowing light to enter, stimulating growth of forage plants, while the dead trees left standing provided good protective cover" (see Figure 4.4).

f0025 **FIGURE 4.4** Mule deer respond positively to high-severity fire in forests. In this photo, mule deer forage on fresh vegetation growing in the first post-fire year following the Rim fire of 2013 on the Stanislaus National Forest, central Sierra Nevada. *(Photo by Chad Hanson (2014).)*

p0305 Available studies generally report increases in the reproductive rates and body condition of female mule deer in burned habitats. The reproductive rate was 1.32 fawns per doe in the first year after wildfire in northern coastal California, compared with 0.77 fawns per doe in unburned chaparral (Taber and Dasmann, 1957). After 3 years, the reproductive rate of deer at the burned site declined to that of deer in the unburned site. Chamise chaparral burned by a large wildfire produced heavier deer, and does had a higher frequency of ovulation, gave birth to more fawns, and wintered in better condition than does in dense, unburned chamise (Bendell, 1974). Another study, however, documented no difference in fawn-to-doe ratios between burned and unburned chaparral interspersed with oak woodlands in central California (Klinger et al., 1989).

p0310 Foraging studies indicate that mule deer populations in chaparral habitats burned by high-intensity fire often increase as a result of the increased availability of browse. *Ceanothus*—a high-quality food for ungulates (Hobbs, 1996)—is abundant after fire because it reproduces from seed that is scarified by burning (Smith, 2000). Thimbleberry (*Rubus parviflorus*) also generally increases after fire (Smith, 2000). Moreover, fire can increase the palatability of foliage for deer as well as the crude protein content (Smith, 2000). The improved quantity and quality of browse may be related to the fire-caused increase in available nutrients in the soil. As such, deer populations often benefit from the increased food production and nutritional value of their food in recently burned areas. Length and surface enlargement factor of papillae (the surface area within the intestine for absorbing nutrients) of necropsied mule deer were greater in those from high-intensity burned than unburned ponderosa pine habitat in the southern Black Hills of South Dakota (Zimmerman et al., 2006). These

B978-0-12-802749-3.00004-9, 00004

physiological factors indicate higher forage quality, such as greater concentration of volatile fatty acids. The authors concluded that fire was beneficial at the mucosal level for mule deer: the increase in forage quality from burning caused a rapid change in papillary morphology, allowing the deer to take up more nutrients.

p0315 Lichens in boreal habitats are preferred winter forage for caribou (*Rangifer tarandus*), yet large wildfires that depleted lichens had no effect on home-range size, range fidelity, or the survival and fecundity of woodland caribou (*Rangifer tarandus caribou*) in Alberta, Canada (Dalerum et al., 2007). Caribou avoided foraging in burned compared with unburned areas (Dalerum et al., 2007; Joly et al., 2010), although burn severity was not quantified, and some of the fires occurred 50 years before study. Lichens are significantly reduced by wildfire and take decades to recover to prefire abundance (Joly et al., 2010) (Box 4.5).

Au20 b0030 **BOX 4.5**

o0080 **(1)** Ungulates interact strongly with episodic disturbances. Many are attracted to severely burned areas because of increased forage palatability and availability, where in turn they influence vegetation regrowth.

o0085 **(2)** Elk, bighorn sheep, and mule deer generally increase after intense fire in shrublands and forests.

o0090 **(3)** The larger the area of high-severity fire, the lower the adverse impact on regrowth of aspen forests from ungulate herbivory.

o0095 **(4)** Caribou may be adversely affected when intense fire reduces lichen used for winter forage.

s0065 4.6 MANAGEMENT AND CONSERVATION RELEVANCE

p0345 The abundance of certain mammal species after fire has direct benefits to land managers in the form of irreplaceable ecosystem and economic services. Bats are voracious predators of insects—many of them consume crop and forest pests—and as such are important regulators of insect populations, including disease-carrying mosquitoes (Reiskind and Wund, 2009). Bats are also critical pollinators of many plants (Molina-Freaner and Eguiarte, 2003). The loss of bats in North America could cost the economy $3.7 billion per year in agricultural losses alone (Boyles et al., 2011). Small mammals aerate the soil and, along with many carnivores, are important dispersers of seeds and fungi (Maser et al., 1978; Rost et al., 2012). Large carnivores are top-down regulators of smaller carnivores and ungulates and are vital to the health and function of natural ecosystems. Ungulates help to cycle nitrogen and provide big-game hunting opportunities and food for humans. Indeed, in 2001 alone, hunting of ungulates and large carnivores in the United States contributed to approximately $25 billion in retail sales and $17 billion in salaries and wages and

employed ~~of~~ 575,000 people (IAFWA, 2002). These animals include mule deer, bighorn sheep, moose, elk, and bear, all of which use or thrive within heavily burned habitats.

p0350 As described here, a great many mammals benefit from mixed- and high-severity fire and play essential roles in postfire ecosystem dynamics. Land managers rarely weigh these benefits when evaluating the impacts of large fires of mixed- and high-severity, however, thus undervaluing their ecological and economic importance. The vital ecosystem services of mammals in postfire areas should be quantified and carefully considered when planning potentially harmful management activities such as postfire logging and common management activities following postfire logging, such as the application of herbicides and rodenticides.

s0070 4.7 CONCLUSIONS

p0355 The extraordinary abundance and diversity of mammals using (e.g., American marten, Pacific fisher, grizzly bear) and even thriving (e.g., deer mice, kangaroo rats, bats, mule deer, elk, bighorn sheep) in severely burned grassland, shrubland, and forested habitats is an important indicator of the high habitat suitability of these areas. Prescribed burning does not provide the expected gains in biological diversity for a range of mammal, reptile, bird, and plant taxa (Pastro et al., 2014). Only large, severe wildfires create significant ecological changes associated with increases in fire-loving species, and, as demonstrated herein, only larger fires can "swamp" the effects of ungulate herbivory on postfire vegetation. ~~Mixed-severity and severe~~ fires globally have unique ecological value that must be weighed against the dominant paradigm that such natural disturbance events are "catastrophic" (Zwolak and Foresman, 2008; also see Chapters 1, 2, and 13). Mammals and other wildlife using intensely burned forests provide myriad ecological services that benefit people and ecosystems alike.

Abstract

Effects of mixed and severe fire on mammals vary spatially and temporally, by habitat type, and by species. Tree voles, masked shrews and some mice decrease, at least temporarily, after severe forest fire, but most bats and ungulates and many small mammals—especially deer mice and kangaroo rats—are strongly attracted to severely burned habitats due to novel foraging opportunities. In heavily burned forests, more insect prey is available for bats, and seeds and sprouting plants feed small mammals. Vegetation re-growth after intense fire produces highly palatable browse for elk, mule deer, and bighorn sheep. Standing dead trees provide cover for deer in severely burned forests, whereas bighorn sheep can more easily perceive predators in heavily burned chaparral. Mesocarnivores, including foxes, martens, and fishers, often are detected in forests that burned intensely. Unburned refugia within larger severe burns, and the time-since-fire, are especially important factors for recolonization by small mammals.

RESEARCH ARTICLE

10.1002/2015JG003165

Key Points:

- Ten years postfire, 85% of fire-killed necromass remain in the forest
- Ten years postfire, fire-killed trees emit 0.6 Mg C ha^{-1} yr^{-1}
- While decomposition from fire-killed trees last decades, their contribution to NEP is small

Abstract A key uncertainty concerning the effect of wildfire on carbon dynamics is the rate at which fire-killed biomass (e.g., dead trees) decays and emits carbon to the atmosphere. We used a ground-based approach to compute decomposition of forest biomass killed, but not combusted, in the Biscuit Fire of 2002, an exceptionally large wildfire that burned over 200,000 ha of mixed conifer forest in southwestern Oregon, USA. A combination of federal inventory data and supplementary ground measurements afforded the estimation of fire-caused mortality and subsequent 10 year decomposition for several functionally distinct carbon pools at 180 independent locations in the burn area. Decomposition was highest for fire-killed leaves and fine roots and lowest for large-diameter wood. Decomposition rates varied somewhat among tree species and were only 35% lower for trees still standing than for trees fallen at the time of the fire. We estimate a total of 4.7 Tg C was killed but not combusted in the Biscuit Fire, 85% of which remains 10 years after. Biogenic carbon emissions from fire-killed necromass were estimated to be 1.0, 0.6, and 0.4 Mg C ha^{-1} yr^{-1} at 1, 10, and 50 years after the fire, respectively; compared to the one-time pyrogenic emission of nearly 17 Mg C ha^{-1}.

1. Introduction

Forest fires have long been recognized as an important component of the global carbon cycle. Among natural processes, combustion ranks second after metabolic respiration in mineralizing terrestrial biomass to the atmosphere, fire mortality ranks second after litter production in transferring live aggrading biomass to decomposing necromass, and the pyrolysis of biomass by forest fires feeds a global pool of black carbon which is largely isolated from the biological cycle [*Singh et al.*, 2012]. The role of forest fire in the carbon cycle is especially important in today's changing climate, not only because of its direct contribution to greenhouse gas emissions but also because a warming climate is expected to increase frequency and intensity of wildfires [*Flannigan et al.*, 2000, 2009; *Moritz et al.*, 2012], pushing the terrestrial biosphere toward a new equilibrium wherein less carbon resides in forest biomass and more resides in the atmosphere. Furthermore, because forest fire behavior is viewed by many as manageable, its control is regularly included as part of comprehensive climate change mitigation strategies [*Campbell et al.*, 2012; *Bradstock et al.*, 2012].

Characterizing and quantifying the effects of fire on the flux of carbon from forests into the atmosphere requires an understanding of both pyrogenic emissions due to immediate combustion and the prolonged biogenic emissions due to the decomposition (heterotrophic mineralization of carbon) by fire-killed necromass. A recent wealth of empirical studies aimed at quantifying combustion across a range of forest fires has allowed us to both constrain estimates of pyrogenic emissions and predict how this flux may change under alternate fire regimes (see reviews by *Sommers et al.* [2014] and *Urbanski* [2014]). By comparison, less attention had been paid to the protracted loss of terrestrial carbon to the atmosphere through the decomposition of fire-killed trees and how this flux is expected vary in relation to fire behavior or change under alternate fire regimes [*Harmon et al.*, 2011a, 2011b; *Ghimire et al.*, 2012].

Carbon emissions via the decomposition of fire-killed trees differ from pyrogenic emissions in several important ways. First, we expect that pyrogenic emissions to be lower in magnitude and less tightly coupled to fire behavior than subsequent carbon emissions via decomposition of fire-killed trees. Since combustion of aboveground biomass in forest fires is typically confined to dead surface fuels and live foliage, pyrogenic carbon emissions in any given fire tend not to exceed 15% of a forest's live and dead biomass [*Campbell et al.*, 2007; *Urbanski*, 2014]. Moreover, since the majority of surface fuels are consumed in nearly all fire conditions, while standing biomass experiences little combustion even in a crown fire, it is difficult for a high-mortality fire to combust much more than twice the amount of carbon than does a low-mortality fire. By contrast, subsequent carbon emissions through decomposition of biomass killed in the fire but not consumed may range from none (e.g., low-severity fires when no trees are killed) to all of the prefire biomass (e.g., high-severity fires when all trees are killed). For this simple reason, cumulative carbon emissions through decomposition of fire-killed trees may exceed pyrogenic emissions and are more dependent on fire behavior than are pyrogenic emissions.

Emissions through decomposition of fire-killed biomass also differ from pyrogenic emissions in their influence on Net Ecosystem Production (NEP). While pyrogenic emissions necessarily contribute to net ecosystem carbon balance, the flux itself is concentrated in time. By contrast, the protracted decomposition of fire-killed trees can contribute to disequilibrium in stand-level NEP for decades [*Bond-Lamberty and Gower*, 2008; *Harmon et al.,* 2011a; *Ghimire et al.,* 2012]. Theoretically, fire-induced disequilibrium in NEP will balance out to zero over sufficiently long time frames or spatial extents (after all, no tree ever escapes death and mineralization, fire only aggregates this inevitable emission in time). However, like many natural disturbances, the majority of area subject to high-mortality forest fire is the result of relatively few, very large events [*Malamud et al.,* 1998; *Reed and McKelvey,* 2002]. As such, the extent required for spatial neutrality in NEP to emerge may easily exceed any meaningful geographic boundary, and the time frame required for neutrality in NEP to emerge may easily exceed the meaningful continuity of any fire regime. Consequently, assessing the effects fire on the carbon exchange between forests and the atmosphere demands not only a mechanistic understanding of combustion, mortality, and decomposition (which we largely have) but also the ability to quantify these processes with enough context specificity to accurately account for individual fire events.

In this study, we evaluate the current and future carbon emissions attributable to the decomposition of trees killed but not combusted in the 2002 Biscuit Fire. This exceptionally large wildfire burned over 200,000 ha of mixed-conifer forest in southwest Oregon. Due to its diversity of forest types, forest age-classes, and severity of fire effects, the Biscuit Fire has served as a valuable case study for evaluating the effects of wildfire on carbon dynamics, including the following: pyrogenic emissions [*Campbell et al.,* 2007], export of soil carbon through erosion [*Bormann et al.,* 2008], and charcoal formation [*Donato et al.,* 2009a; *Heckman et al.,* 2013]. In *Campbell et al.* [2007] we reported biomass combustion for 25 functionally distinct carbon pools. Then, using measures of prefire biomass and fire effects on 180 one hectare inventory plots, we estimated fire-wide pyrogenic emissions. In this current companion study, we report the 10 year decay status of various biomass pools killed, but not combusted, by the Biscuit Fire. Then, using measures of fire mortality on the same 180 inventory plots as before, we estimate current and future fire-wide emissions resulting from the decomposition of fire-killed trees. Our specific objectives are as follows:

1. Quantify mortality, dead tree fall rate, and decomposition rates specific to different species, parts (e.g., root, bole, and branch), physical setting, prefire stand history, and fire effects.
2. Using these stratified parameters, calculate the current cumulative flux of carbon from fire-killed trees into the atmosphere and model its attenuation into the future.
3. Evaluate the current and future carbon emissions from fire-killed trees in the context of commensurate forest regrowth and other regional carbon fluxes, including the pyrogenic emissions from the same fire.

2. Methods

2.1. Study Site

The Biscuit Fire burned at a mix of severities across 200,000 ha of forest in the Siskiyou Mountains of southwestern Oregon and northern California in the summer of 2002, making it the largest contiguous forest fire on record for Oregon (Figure 1). The Siskiyou Mountains are characterized by a wide variety of forest types, from Douglas fir/western hemlock/bigleaf maple communities on mesic sites, to Douglas fir/tanoak on drier sites, to Jeffrey pine on ultramafic substrates *Whittaker* [1960]. A general description of the Biscuit Fire and the forests it affected can be found in *Halofsky et al.* [2011].

2.2. Decomposition of Fire-Killed Trees

As illustrated in Figure 2, decomposition of fire-killed trees was computed as the collective mass loss to the atmosphere, over a specified period, from three primary pools representing different physical orientations:

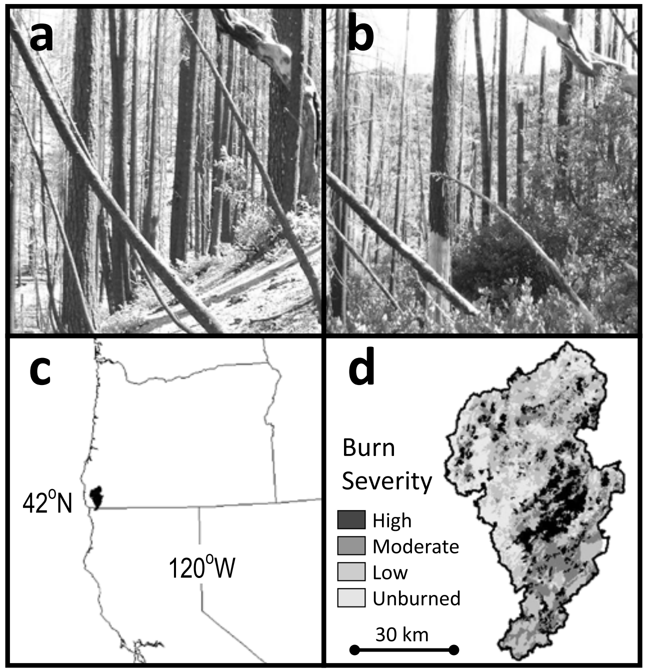

Figure 1. The 2002 Biscuit Fire showing (a) representative fire effects in 2004, (b) the same location in 2012, (c) location of the fire in the U.S. Pacific states of North America, and (d) remotely detected fire severity distribution. High = >90% overstory mortality, unburned = no overstory mortality but typically experiences surface fire.

standing necromass, fallen necromass, and buried necromass (i.e., dead root mass). Three separate rate constants defined mass loss to the atmosphere from standing, fallen, and buried necromass pools, respectively. Two additional rate constants defined transfer of mass from the standing to fallen pool by fragmentation and whole-tree fall, respectively. This three-pool, five-flux model was further stratified by tree part, namely, bole, branch, bark, and foliage (in the standing and fallen pools), and coarse root and fine root (in the buried pool). Boles were further stratified into three diameter classes, and all pools were stratified into three species groups (i.e., pines, non-pine conifers, and hardwoods) and three climatic zones (representing potentially different decomposition regimes) defined by aggregate plant association group and nominally corresponding to mesic, dry, and higher-elevation regions within the Biscuit Fire [*Donato et al.*, 2009b].

To estimate flux rates, we fit empirical observations of mass loss over time to a single-exponential model *Olsen* [1963] of the form:

$$M_t = M_0\left(e^{-kt}\right) \quad (1)$$

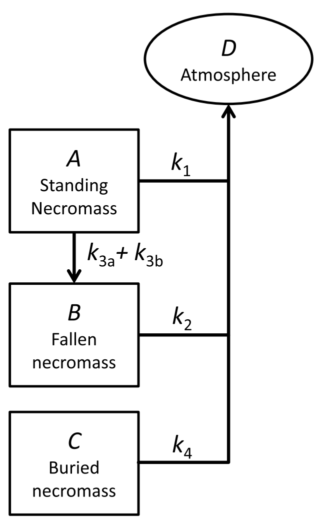

Figure 2. Approach to computing biogenic decomposition of fire-killed necromass. Decomposition was calculated separately for each plant tissue class according to five first-order exponential rate constants. The constant k_1 is the decomposition of necromass in its standing state; k_2 is the decomposition of necromass in its fallen state; k_{3a} and k_{3b} are the transfers between standing and fallen states, via whole-tree fall and fragmentation, respectively; and k_4 is the decomposition of buried roots.

where M_t is the mass of a specified necromass pool at time t, M_0 is the mass of the same pool immediately following its death by fire and any assessed combustion, and t is the elapsed time since the fire (~10 years in this study). In this way, the rate constant k not only describes the cumulative mass loss at year t but can also be used to extrapolate mass loss into the future. The accuracy of such extrapolation does, however, depend on the assumption that loss rates remain constant over time, which may be violated if either the environment in which decay is occurring changes or if discriminating decay renders mixed substrates more recalcitrant over time. Extrapolation of our decay model does not account for climate-driven changes in the decay environment, but our model does account for important changes in decay that occur after wood

Table 1. Methodology and Sampling Design for Determination of Rate Constants[a]

Aerial Decay: $k_1 = \ln(D_0/D_t)/t$, where D_0 = live tree part density, D_t = density of standing fire-killed tree part circa 2012, and t = elapsed time since fire	
Bole	D_t measured for 198 trees, stratified by species group (Douglas fir, pine species, and pacific madrone), diameter class (range 7 to 146 cm DBH), and climatic zone (defined by aggregate plant association group, nominally corresponding to mesic, dry, and higher-elevation regions within the Biscuit fire). Tree-average density was calculated as the average density of three transverse samples (cookies) collected from the lower, middle, and upper third of each tree, weighted by a factor of 0.60, 0.36, and 0.04, respectively, to account for volume proportion by height (derived from the taper equations of *Arney* [2009]). D_0 assumed to be 0.39, 0.45, and 0.58 g cm^{-3} for sugar pine, Douglas fir, and pacific madrone, according to *Maeglin and Wahlgren* [1972], *USFS* [1965], and Wood Data Base, respectively.
Branch	D_t measured for 259 branches stratified by diameter (range 1 to 56 mm) collected from the 198 standing dead trees described above. D_0 measured for 55, similarly stratified live tree branches samples.
Bark	Bark density loss was not directly measured in this study. Based on *Allison and Murphy* [1963], we crudely assumed bark to decompose at one half the rate of bole wood of the same species. Anecdotally, bark from fire-killed trees in this study regularly showed evidence of charring and fragmentation but not any apparent density loss.
Foliage	Aerial decay rates of fire-killed foliage are computationally inconsequential, not only because fire mortality on the Biscuit most often entailed full foliage combustion [*Campbell et al.,* 2007] but also because fall rates of fire-killed foliage approach totality within the first year after mortality such that nearly all decay occurs on the ground. As such, foliage aerial decay rates were arbitrarily set to 0.5 year^{-1}.
Surface Decay: $k_2 = \ln(D_0/D_t)/t$, where D_0 = live tree part density, D_t = density of fire-killed tree part having fallen to ground shortly after fire, and t = elapsed time since fire	
Bole	D_t measured on 60 fallen logs, deduced to have been killed in the Biscuit Fire (by presence of surface charring) and fell within the next year (saw cuts datable to known salvage operations); stratified by species group (see above), diameter class (range 7 to 146 cm DBH), and climatic zone (see above). Density was determined from a single transverse sample (cookie) taken from the center of each log. D_0 as described above for areal bole decay.
Branch	D_t measured for 86 branch samples, stratified by diameter (range 1 to 72 mm) collected from the 60 fallen logs described above. D_0 as described above for areal branch decay
Bark	Crudely assumed to be one half the rate of fallen bole wood (see above for aerial bark decay).
Foliage	Given the short residence times of leaf litter (relative to wood and bark), and the exceptionally small portion of fire-filled biomass represented by uncombusted foliage [*Campbell et al.,* 2007], we chose to avoid the hazard of false accuracy and simply assign foliage decomposition rates the arbitrarily rapid rate of 0.5 year^{-1}.
Whole-tree Fall Rate: $k_{3a} = \ln(C_0/C_t)/t$, where C_0 = count of standing dead trees circa 2004, C_t = count of standing dead trees ca 2013, and t = elapsed time between samples	
Whole tree	Before-and-after stem surveys conducted at 44 independent and dispersed study plots, including a total sample size of >3000 fire-killed trees ranging in size from 2 to 198 cm DBH.
Fragmented Fall Rate: $k_{3b} = \ln(M_0/M_t)/t$, where M_0 = mass of standing tree parts circa 2004, M_t = mass of standing tree parts circa 2012, and t = elapsed time between samples	
Bole	M_0 allometrically modeled from DBH with the assumption that each tree was live and entire. M_t is the same value, corrected to account height loss due to observed breakage. Assessed for each of the 3000 fire-killed trees described above.
Branch	M_0 allometrically modeled from DBH with the assumption that each tree was live and entire. Each fire-killed tree surveyed in 2014 was binned into one of four fragmentation classes through ocular assessment, corresponding to an M_t of 0.05 M_0, 0.15 M_0, 0.60 M_0, and 1.0 M_0, respectively.
Bark	M_0 allometrically modeled from DBH with the assumption that each tree was entire. Each fire-killed tree surveyed in 2014 was binned into one of four fragmentation classes through ocular assessment, corresponding to an M_t of 0.0, 0.25 M_0, 0.75 M_0, and 1.0 M_0, respectively.
Foliage	Practically all uncombusted foliage retained on fire-killed trees fell to the ground within the first year after the fire. To account for this in our decomposition model (constructed only of first-order exponential rate constants) we set the rate constant describing dead foliage fall to 5.0 year^{-1}.
Buried Decay: k_4 = first-order exponential decay constants according to named authors	
Coarse root	k = 0.02 year^{-1} according to *Janisch et al.* [2005] assessment of Douglas fir roots > 1.0 cm diameter.
fine root	k = 0.20 year^{-1} according to *Chen et al.* [2002] and *Fogel and Hunt* [1979] for various tree roots < 1.0 cm diameter.

[a]Dead wood density was determined after oven drying at 95°C to constant mass; an 8% downward correction was then applied to account for oven shrinkage and afford direct comparison with published green tree densities [*Glass and Zelinka*, 2010].

transitions from the aerial to surface environment. Furthermore, by disaggregating our necromass pools (i.e., into bole, branch, bark, foliage, root, species group, and size class) our model minimizes the changes in recalcitrance that any one pool may experience over time [*Freschet*, 2012]. The specific sampling methods used to determine M_t and M_0 for each necromass category are detailed in Table 1. Note that while the form of equation (1) was used in computing all flux rates, at times, density, volume, or count was operationally substituted for mass.

2.3. Initial Fire-Killed Biomass

Within the perimeter of the Biscuit Fire there are 180 regularly spaced permanent federal inventory plots, all of which received postfire measurements in 2003 or 2004 [*Azuma et al.,* 2004]. It is well established that injury caused by fire can sometimes contribute to tree death several years after being burned [*Filip et al.,* 2007].

Our assessment operationally defines fire mortality as trees which died within 1–2 years after the fire. Any subsequent mortality and ensuing decomposition, though perhaps related to fire, was not in this study directly attributed to the Biscuit Fire.

For each tree identified in the inventory plots as having been killed in the Biscuit Fire, we estimated the mass of its fine roots, coarse roots, bole, branch, bark, and foliage as if it were alive and whole. From each of these parts, we then subtracted the proportion estimated to have been combusted in the fire according to *Campbell et al.* [2007] to yield a tree-specific M_0 for each of its component parts. Bole mass was estimated using species- and site-specific allometric equations relating stem diameter to volume and species-specific wood density values [*van Tuyl et al.,* 2005]; foliage and bark mass were estimated directly from species- and site-specific allometric equations [*Means et al.,* 1994]; coarse root mass was assumed to be 0.31 times the bole mass (an average of regionally representative, plot-level ratios, allometrically estimated by *Campbell et al.* [2004a]); and fine root mass was assumed to be 0.16 times the bole mass (an average of regionally representative, plot-level ratios directly sampled by *Campbell et al.* [2004b]). Total biomass was converted to carbon mass assuming a carbon concentration of 0.5 for all woody parts and 0.45 for foliage. These tree-level values for M_0 were then summed across each inventory plot as to be expressed in carbon mass per unit ground area.

2.4. Fire Severity and Scaling Across the Fire

For evaluating the direct effects of fire severity on subsequent carbon emissions, fire severity was calculated, for each of the 180 inventory plots, as the fraction of initial live basal area (including all woody stems $>=$ 2.5 cm diameter breast high (DBH)) killed in the Biscuit Fire. For the purpose of scaling plot-level measurements to the entire Biscuit Fire it was necessary to use a mapped assessment of fire severity. Specifically, plot-level estimates of decomposition were scaled-up to the entire Biscuit Fire according to mapped fire severity classification and whether or not a site had burned in the Silver Fire (a major fire which burned 13 years prior to the Biscuit Fire). Such strata accounted only for variation in M_0 (tree mass killed in the Biscuit Fire), as the rate constants k were assumed to be the same among plots. We employed the same BAER (Burned Area Emergency Response) severity classification map used earlier by *Campbell et al.* [2007]. Since this time, improved maps of Biscuit Fire severity have been built [*Thompson and Spies,* 2009], but we felt it was more important to maintain consistency between our pyrogenic and biogenic accounting. Moreover, since the 180 inventory plots are distributed widely in space and randomly with respect to actual fire effects, misclassification by BAER, or any other severity map, does not bias fire-wide estimates of carbon flux.

2.5. Uncertainty Propagation

For this study, we assumed the inventory-based estimates of fire-killed necromass to be largely accurate and limited our uncertainty analysis to that associated with decomposition rates. To account for this uncertainty, we computed alternate estimates of total carbon emissions using an upper and lower values for the rate constants defining mass loss to the atmosphere. Uncertainty in mass loss from standing and fallen necromass pools (k_1 and k_2 in Figure 2) were based on the upper and lower 95% confidence intervals in dead wood density (among samples collected in 10 years after death). Since we relied on crude literature values for root decay, uncertainty in mass loss from buried necromass pools (k_4 in Figure 2) was generously set to plus and minus 20% density loss at 10 years after death.

3. Results

3.1. Fire Mortality

Prefire live aboveground and belowground biomass among the 180 inventory plots ranged from 1 to 502 (median = 161) Mg C ha^{-1} depending somewhat on site quality but largely disturbance history (i.e., whether sites had experienced late twentieth century fire). Fractional tree mortality, which was largely independent of prefire biomass, ranged from zero to totality. As a result the necromass killed but not combusted among the 180 inventory plots ranged from 0 to 352 (median = 24) Mg C ha^{-1} . Despite smaller trees being more abundant, more often killed, and only somewhat more combusted than larger trees, fire mortality in the form of large-diameter (>30 cm DBH) boles and their associate coarse roots made up greater than 40% of all other fire-killed biomass combined. The remaining uncombusted fire mortality is composed of smaller diameter wood, bark, fine roots, and foliage in that order (Table 2). Overall the Biscuit Fire killed and left uncombusted a total of 10.4 Tg C (an average of 51 Mg C ha^{-1}).

Table 2. Biomass Killed But Not Combusted in Biscuit Fire (kg C ha^{-1})

	Biscuit Fire Severity[a]

[a]As determined by remotely sensed BAER severity classification. Values are the average of 24, 36, 42, and 34 inventory plots for high, moderate, low, and unburned very low severity plots not burned prior in the Silver fire, respectively; and the average of 1, 2, 14, and 5 inventory plots for high, moderate, low, and unburned very low severity plots burned prior in the Silver fire, respectively. Small trees are <10 cm DBH, medium trees are 10–20 cm DBH, and large trees are >20 cm DBH. For our decomposition calculations, conifers were further partitioned into pine and nonpine species (data not shown here), and roots were partitioned into coarse roots and fine roots, consistently computed as 0.66 and 0.34 total root mass, respectively.

3.2. Decomposition Rates

The measured densities of standing and fallen fire-killed wood, from which decomposition rates were calculated, are shown in Figure 3. An analysis of variance performed on the decomposition rates calculated for over 198 sampled tree boles revealed significant effects of species (with Douglas fir decomposing only slightly faster than pine species and pacific madrone) and condition (fallen logs decomposing only slightly faster than standing snags), but nonsignificant effects of geographic zone (mesic, dry, or high elevation) or size (diameter class). The single-exponent decomposition constants (fit to a single 10 year data point and used to subsequently model carbon emissions) are shown in Table 3.

3.3. Tree Fall Rates

As shown in Table 4, a greater fraction of fire-killed biomass fell from the canopy to the ground in 10 years through whole-tree fall than through fragmentation. The proportion of whole trees having fallen after

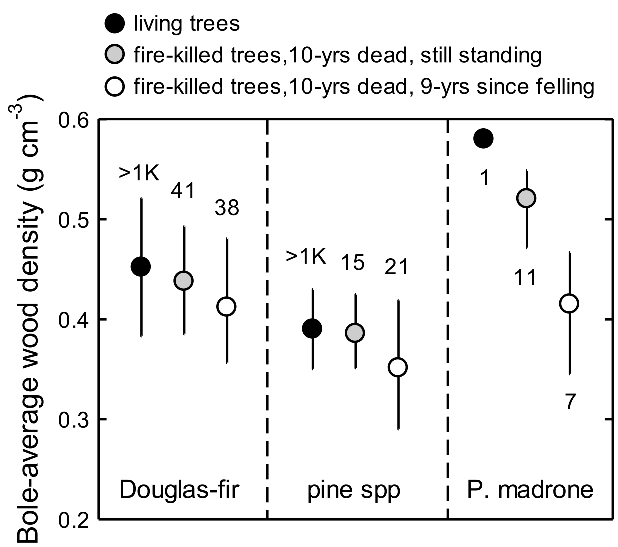

Figure 3. Wood density of green trees (live), fire-killed trees still standing 10 years after death (snags), and fire-killed trees 10 years after death and near immediate falling (logs). Sample size (shown near each symbol) is the number of independent trees sampled, with the density of each being determined as the taper-weighted average density of three cross-sectional subsamples taken along the length of each tree. Variability in wood density among trees is shown as the standard deviation (upper and lower error bars are the average positive and negative residuals of the mean, respectively; except for green trees where only a single symmetrical standard deviation was available from source literature, and green madrone where no variance was reported). Live wood densities are from *Maeglin and Wahlgren* [1972], *US Forest Service* [1965], and *Wood Data Base*, for pine species, Douglas fir, and Pacific madrone, respectively. Dead wood densities are those measured in the present study.

10 years was 20 times greater for smaller diameter trees (<20 cm DBH) than for larger diameter trees. Neither whole-tree fall rate nor fragmentation rate varied according to community type (used here as a proxy for decomposition regime). Across species, size class, and location, 57% of the trees killed in the Biscuit Fire are still standing 10 years after their death and have on average lost only 26% of their postcombustion necromass via fragmentation.

3.4. Biogenic Emissions

The amount of carbon released through the decomposition of fire-killed trees in the first 10 years following the Biscuit Fire is estimated to be 1.3 to 1.6 Tg C (or 6.5 to 7.8 Mg C ha^{-1}). As shown in Table 5, the largest contributing pools were those with the largest initial mass (i.e., bole wood and coarse root), not those with the highest decomposition rates (foliage and fine roots). Extrapolating our 10 year estimates of fall rates and decomposition rates back to the first year following fire and forward to 100 years after fire reveals several emergent patterns. Partitioning emission rates among necromass pools (Figure 4a) illustrates not only differential decay rates (responsible for the inflection point in collective emissions) but also an important 10 year lag in peak emissions from bole, branch, and bark, which results from a particular combination of aerial decay rates, fall rates, and surface decay rates. Total emissions from fire-killed necromass over time exhibit a distinct inflection point approximately five years following the fire (Figure 4b). Such inflection points are indicative of mixed substrate decay and in this case occur when the more labile foliage and fine root pools have become largely exhausted leaving the more recalcitrant wood and coarse roots. Overall, half of the Biscuit-killed necromass will still remain 50 years after the fire, at which time emissions from this single mortality cohort will be approximately 25 Mg C ha^{-1} yr^{-1} (Figure 4c).

The total amount of fire-killed necromass explained 99% of the variation in post fire decomposition among the 180 study plots (Figure 5a), indicating that variation in prefire species composition and tree size class was of

Table 3. Decomposition Constants for Fire-Killed Necromass[a]

	Decomposition Constant k (year^{-1})	
Necromass Pool	Aerial Decay(Standing Snags)	Surface Decay(Fallen Logs and Debris)
	Bole

[a]Fall rate $k = \ln(\text{standing necromass}_{2004}/\text{standing necromass}_{2014})/10$ years. Small trees are <10 cm DBH, medium trees are 10-20 cm DBH, and large trees are >20 cm DBH.

little importance in dictating postfire decomposition. Moreover, since low-biomass stands often experienced high-fractional mortality and high biomass often experienced low-fractional mortality, fire severity (as assessed by fractional basal area mortality) was, by itself, an imprecise predictor postfire carbon emissions (Figure 5b).

4. Discussion

4.1. Fire Mortality

The necromass generated in high-severity portions of the Biscuit Fire (about 103 Mg C ha^{-1}) corresponds well to the 130–200 Mg C ha^{-1} biomass held in mature and old-growth forests of the Klamath ecoregion according to the regional assessment of *Hudiburg et al.* [2009]. Between the ages of 50 and 100, these particular forests are estimated to experience tree mortality rates of just over one-half percent annually [*Hudiburg et al.*, 2009]. As such, when mature forests burned at high severity in the Biscuit, somewhere between 100 and 200 years of future mortality was compressed into a single event. When individual fires of this size and severity occur in high biomass forests, like those of western Oregon, the generation of decomposing necromass is

Table 5. Biogenic Emissions From Fire-Killed Necromass by Carbon Pool and Burn Severity Class

	Carbon Released (kg C ha^{-1} After 10 years)				Fire-Wide Emissions[b] (Tg C Across 202,642 ha, After 10 years)
Necromass Pool	High Severity[a]	Moderate Severity[a]	Low Severity[a]	Unburned Very Low Severity[a]	
Foliage	676	887	949	1163	0.19
Branch	850	365	307	324	0.08

Bole	5450	2125	2095	2362	0.54
Roots	6040	2385	2164	2277	0.58
Total	13421	5982	5683	6294	1.44 (1.31–1.59)[c]

[a]As determined by remotely sensed BAER severity classification.
[b]Fire-wide emissions calculated by weighting the emissions from each burn class by the area of that burn class over the fire perimeter.
[c]Upper and lower estimates based on propagated uncertainty in woody decomposition rate constants.

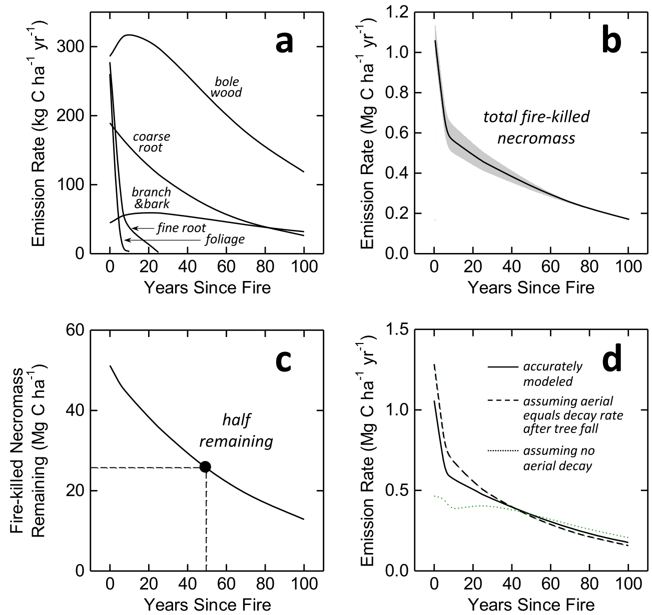

Figure 4. Temporal patterns of carbon emissions from fire-killed necromass, (a) partitioned by pool; (b) total, illustrating inflection point around year 5 and propagated uncertainty in decomposition rates (shaded band = 95% confidence interval); (c) approximate 50 year half-life; and (d) consequences of recognizing differential aerial and surface (fallen) decay rates.

notable at regional and even continental scales. The total amount of carbon transferred by the Biscuit Fire from aggrading living pools into decomposing dead pools was approximately three-quarters the average amount killed annually by wildfire throughout the entire western US (6 Tg C yr^{-1}) [*Hicke et al.,* 2013]. The distribution of fire mortality among different pools (Table 2) is a simple reflection of within-tree allometric proportions sans foliage which is commonly combusted in fire-killed trees. Understandably then, large-diameter wood made up the largest fire-generated necromass pool, more so in forests not recently burned where an even greater proportion of biomass was in the form of bole wood.

Due largely to the wide range of prefire biomass, fractional fire mortality (whether inferred through remote imagery, or direct ground measurement) was a poor predictor of absolute mortality and subsequent carbon emissions. While both intuitive and expected, this observation reminds us of the importance of accurately assessing preburn biomass in mapping and modeling fire effects on carbon dynamics.

4.2. Decay Rates

The wood density decomposition rates reported here fall comfortably within the range reported by other studies in the Pacific Northwest [*Sollins,* 1982; *Harmon et al.,* 1986; *Janisch et al.,* 2005; *Harmon et al.,* 2011b; *Dunn and Bailey,* 2012], which both validates our assessment and brings into question the need for additional field studies, at least those using single-exponent decay models fit to mass loss over a single time interval. In reality, necromass decay over time is expected to exhibit some initial lag (as substrates await decomposer colonization or fragmentation) and a decreasing proportional loss over time (as mixed substrates are reduced to their more recalcitrant fractions). By measuring mass loss across a chronosequence of dead wood, *Harmon et al.* [2000] demonstrated that dead wood decay can, in fact, exhibit such lags and tails in mass loss over time. Still, provided necromass pools are appropriately disaggregated (i.e., relatively recalcitrant and labile substrates assigned their own loss rate constants), single-exponent models like those used in this study fit empirical data just as well as multiparameter models [*Freschet,* 2012].

Given the recognized effects of moisture and temperature on decomposition, our inability to detect site effects on decomposition rate was likely a combination of measurement error (driven largely by our use of a single-species-specific green tree wood density in assessing mass loss for all wood fragments) and a wide variation in realized decay environments within the crude climate zones we recognized (Table 1). Given our samples were so widely distributed across our study area, our mean decomposition rates remain good estimates for our particular study. However, caution should be taken in applying these or any other landscape-average decomposition rates to any particular site, as decay rates of common substrates may vary across forest microenvironments by as much as 10 times, more so even than across large-scale climate gradients [*Vanderhoof*, 2013; *Bradford et al.,* 2014].

4.3. Fall Rates

The fall rates of standing necromass by fragmentation and whole-tree fall pertain to carbon emissions only to the degree that decomposition rates are different between the aerial and surface environments. It is commonly

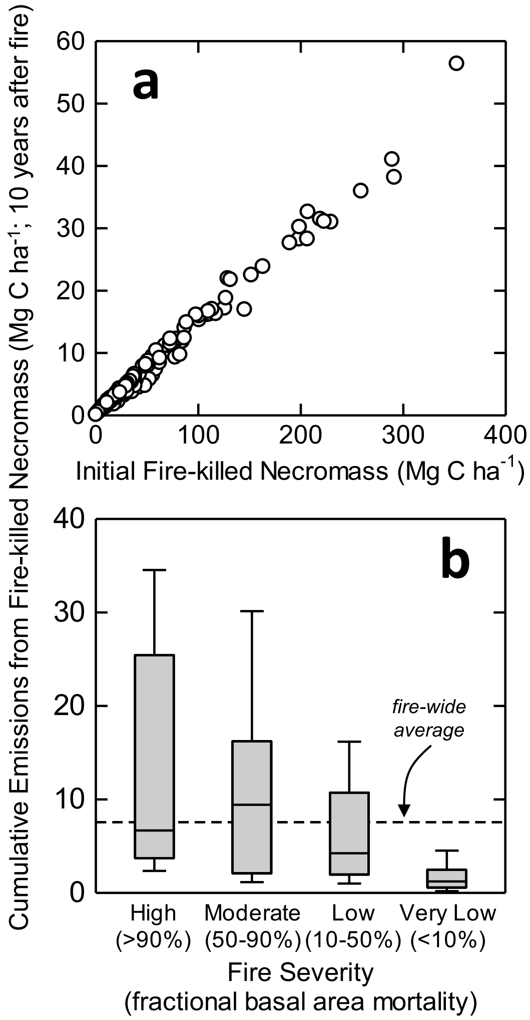

Figure 5. Carbon emissions from fire-killed necromass as a function of (a) absolute mortality and (b) fire severity among 180 inventory plots regularly stratified across the Biscuit Fire. Centerline, box, and whiskers, represent median, 25th percentiles, and range up to three-halves end quartiles (i.e., range excluding outliers), respectively. Fire severity (fractional tree basal area mortality) was directly determined for each plot (not remotely sensed).

assumed and consistently observed that decay rates of wood are slower in the drier aerial environment than in the moister surface environment [*Harmon et al.*, 2011b; *Yatskov et al.*, 2003; *Dunn and Bailey*, 2012]. Ecosystem models which apply the more commonly available surface decay rates to all fire mortality, without considering the decades many dead trees may spend in a standing condition, will inevitable overestimate initial emission rates and underestimate their duration. Similarly, models which assume negligible wood decay until a dead tree falls are prone to an inverse bias. The significance of tree fall rates in the timing of postfire carbon emissions is apparent in Figure 4a where peak emissions from branch, bark, and bole wood occur not immediately following the fire (when pool sizes are necessarily largest), but rather 10–20 years following the fire (after a requisite portion of the pool has fallen to the ground where it decays quicker). To further evaluate the relevance of tree fall on carbon emissions following the Biscuit Fire, we compared our fully parametrized model to others with alternate assumptions regarding fall rate and differential decay. As illustrated in Figure 4d, the largest bias occurred in the model which assumed wood remained undecayed until it fell to the ground. Applying a single surface decay rate to all wood did overestimate the near-term emission rates, but not as much as purported for other disturbed forests where both fall rates and the disparity between aerial and surface decay were determined to be higher than we observed in the Biscuit Fire [*Harmon et al.*, 2011b]. Moreover, once combined with the consistently attenuating emission from fire-killed roots and foliage, the fall-mediated lag in emissions from bole, branch, and bark did not produce a bimodal or "double-humped" emission pattern as it might have [*Harmon et al.*, 2011a].

Some authors have reported a brief (2 to 3 year) delay between tree mortality and the onset of measurable fall (see review by *Cluck and Smith* [2005]), suggesting that fall rates sometimes accelerate after passing some threshold in declining stability (e.g., root or basal decay). Since snag fall in this study is evaluated using stem attrition measured only at one-time point (10 years after death), we cannot resolve any early changes in fall rate. However, as a general rule, snag attrition measured over decades in prior studies conforms well to a first-order decay function as we have done here [*Everett*, 1999; *Cluck and Smith*, 2005]. Necromass decay over time is expected to exhibit some initial lag (as substrates await decomposer colonization or fragmentation) and a decreasing proportional loss over time (as mixed substrates are reduced to their more recalcitrant fractions).

4.4. Emission Rates

It is expected that dead wood dynamics operate over longer time scales in the Pacific Northwest than they do in other forests where environmental conditions or disturbance frequency prevent individual trees from growing as large. The analysis by *Spies and Franklin* [1988] suggests it would take >1000 years for woody

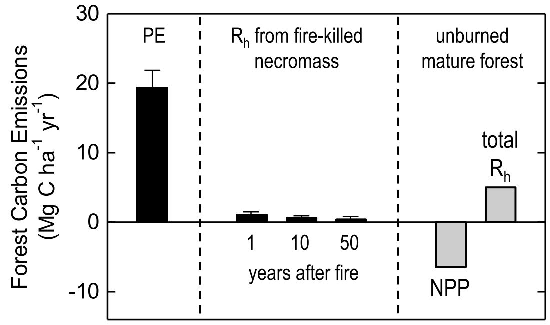

Figure 6. Forest carbon emissions from heterotrophic respiration (R_h) of necromass killed in the Biscuit fire, compared to the one-time pyrogenic emissions (PE) incurred during the fire and the biological fluxes typical of unburned mature forests of the Klamath region. Error bars on R_h are propagated 95% confidence intervals in decomposition rates. Pyrogenic emissions and uncertainty estimated by *Campbell et al.* [2007]. Net Primary Production (NPP) modeled by *Turner et al.* [2007] and consistent with empirical observations of *Hudiburg et al.* [2009]. Total R_h, which includes both the heterotrophic fraction of soil surface efflux and dead wood decay, modeled by *Turner et al.* [2007] and consistent with empirical observations of *Campbell et al.* [2004a, 2004b].

debris to reach a site-level steady state in Western Oregon, and as such, most forests in the region exist in a state of dead wood disequilibrium defined by site-specific disturbance history. In this study, the measured magnitude and modeled duration of carbon released to the atmosphere through the decomposition of fire-killed trees speaks to how disturbance-generated mortality shapes not only the amount woody debris present at any given time, but in the exchange of carbon occurring between forest and atmosphere at any given time.

As shown in Figure 6, 10 years after the Biscuit Fire the annual flux of carbon from fire-killed trees into the atmosphere is estimated to be 0.6 Mg ha^{-1} yr^{-1}, which is only 10% the total heterotrophic respiration rates to which these forests hypothetically equilibrate once mature [*Turner et al.,* 2007; *Campbell et al.,* 2004a] and only 3% the one-time pyrogenic emissions released during the fire [*Campbell et al.,* 2007]. Clearly, the capacity of this relatively modest carbon flux to shape carbon exchange between forest and atmosphere has not to do with its magnitude, but rather its duration and the fact that other ecosystem carbon fluxes such as net primary production, and potentially soil surface efflux, are greatly reduced in the initial period following wildfire.

Several studies suggest that high-severity wildfire, despite generating substantial additions to the dead wood pool, actually reduces total heterotrophic respiration by about one half [*Meigs et al.,* 2009; *Dore et al.,* 2012]. This is because wildfire typically consumes the forest floor (the substrate from which up to 30% of total heterotrophic respiration arises; *Campbell et al.* [2004b]) and temporally cuts off the supply of fine root turnover (a sizable contribution to belowground heterotrophic respiration). It was not the purpose of the paper to compute postfire NEP which would depend largely on uncertain patterns of forest regrowth and mineralization of soil carbon; however, NPP of regenerating and surviving vegetation need only reach 0.57 Mg ha^{-1} yr^{-1} by the 10 year following fire in order to compensate for the respiration from the remaining fire-killed necromass. Preliminary measurements (unpublished data) suggest that shrub production alone 10 years after the Biscuit Fire has already far exceeded this rate, consistent with other studies showing NPP over 1.5 Mg C ha^{-1} by 2 years postfire in dry forests [*Irvine et al.,* 2007].

4.5. Regional Carbon Disequilibrium

Single, large disturbances like the Biscuit Fire make for valuable examples because they provide a broad range of conditions over which to stratify measurements. The specificity with which we evaluated mortality, fall, and decay within the Biscuit Fire was limited only by resources, not by opportunity. But quantifying the impacts of single events such as the Biscuit Fire also sheds light on the unique importance of rare events in shaping regional carbon exchange and the need to accurately account for them when either upscaling terrestrial measurements or downscaling atmospheric measurements.

It is reasonable to postulate, as *Odum* [1969], that over a sufficiently large landscape, disturbance-induced disequilibrium in any one location will be balanced in other locations experiencing similar disturbances at different times, and as long as the region-wide frequency of such disturbances remains constant, this shifting mosaic will operate with mass neutrality (e.g., NEP). However, within many ecoregions forest fires may not occur at fine-enough grain and high-enough frequencies for such equilibriums to arise. In fact, the self-organizing behavior of fire across landscapes dictates that most of the area burned in any given fire regime is the result of relatively few, very large events [*Malamud et al.,* 1998; *Reed and McKelvey,* 2002]. This disproportional impact of large infrequent disturbances thwarts landscape equilibriums in two dimensions. First, it can extend the area required to balance disturbance effects at any given time beyond meaningful ecological boundaries. Second, it can extend the time horizon required for any bounded area to achieve equilibrium beyond the period we expect disturbance regimes to be reasonable stable. This second constraint on landscape equilibrium is especially relevant considering climate change may now be altering probabilistic fire regimes faster than the return interval of the most important events [*Zinck et al.,* 2011], rendering the realized impacts of fire on processes such as carbon emission wildly stochastic in space and time.

As illustrated in Figure 6, the carbon emissions attributed to the decomposition of trees killed in the Biscuit Fire documented in this study, as well as the pyrogenic emissions released by the Biscuit Fire documented in *Campbell et al.* [2007], attest to the importance single-disturbance events can have in regional carbon dynamics, especially in large biomass systems confined to relatively small ecological boundaries. Predicting the frequency of these rare events will be increasingly difficult in a changing environment, but our ability to accurately assess their impacts on regional carbon flux is slowly approaching sufficiency.

Acknowledgments
This work was supported, in part, by the Joint Fire Science Program, administered through the U.S. Bureau of Land Management in cooperation with the Department of Forest Ecosystems and Society at Oregon State University (project 11-1-1-4, cooperative agreement L11AC20276). The views and conclusions contained in this document are those of the authors and should not be interpreted as representing the opinions or policies of the U.S. Government or any other institution. We would like to extend special thanks to Melody Culp of the Rogue-Siskiyou National Forest for her invaluable assistance throughout the project. BATS IN THE BURNS
Studying the impact of wildfires and climate change

COURTESY OF ERIN SAUNDERS

by Carol Chambers and Erin Saunders

Researchers captured bats in mist nets over this pond in a severely burned area of the Apache-Sitgreaves National Forests in Arizona during their study of how bats respond to forest fires.

The Wallow Fire began with an abandoned campfire on the Apache-Sitgreaves National Forests in Arizona's White Mountains on May 29, 2011. By the time it was controlled 40 days later, it had become the largest wildfire in the state's history. Flames blazed across 538,000 acres that range from high-country grasslands to the giant pine forests favored by bats. And bats, like most other wildlife, will likely face more and more charred habitat in the years to come. Thanks to decades of fire suppression and livestock grazing, plus the stirrings of climate change, wildfires are becoming bigger and more frequent throughout the American West.

Our field crew, a half-dozen biologists – plus 50 volunteers from Virginia to California who stepped up to help for a week – spent an intense and arduous summer within the boundaries of that immense fire last summer as part of a study into how bats adapt to a burned-over landscape. We captured bats in mist nets over ponds, attached tiny radio transmitters to reproductive females and tracked them back to often-surprising maternity roosts. We call our research project, a collaboration of Northern Arizona University and the National Forests, "Bats in the Burns," and we hope to expand into other wildfire-burned forests in the Southwest.

Our preliminary evidence suggests that, not surprisingly, bats prefer unburned areas for travel, foraging and drinking. Roost selection was a different story: bats of some species chose roosts in completely charred tree trunks, including some surrounded by burned-over forests.

The forests of the White Mountains range from short-statured piñon pine and juniper woodlands around 5,000 feet (1,500 meters) elevation to subalpine meadows above 9,000 feet (2,750 meters). In between are forests of tall ponderosa pine, quaking aspen, and Douglas-fir trees. During summers, the White Mountains are green, cool and lush with scattered ponds, lakes and streams. At least 10 bat species spend their summers here, roosting in live trees and the dead trees known as snags. Many of them gather by species into maternity colonies to give birth and raise pups.

Previous research has found that bats typically use snags of more than two feet (60 centimeters) in diameter. They roost in vertical cracks in the snags, but will also wedge themselves under patches of loose bark that can house anywhere from one bat to hundreds, depending on the species of bat and the size of the sheltering bark. More than 900 Arizona myotis (*Myotis occultus*) were once counted as they emerged from a single snag.

Wildfires, meanwhile, have been part of forest ecosystems of the southwestern United States for centuries. Until the mid-1800s, lightning-caused fires burned through the ponderosa pine forests every 2 to 20 years. The low flames of those fires burned grasses and shrubs, but moved too fast to kill large pine trees with their thick, fire-resistant bark. That changed when Euro-Americans arrived. Livestock grazing eliminated much of the understory vegetation that had maintained low-intensity fires in the past. Plus, these new settlers considered such fires destructive and eventually began to extinguish them quickly.

Then, in the early twentieth century following a bumper seed crop and a wet year, millions of pine seedlings germinated and, without low-intensity fires to kill many of the tiny seedlings, tree densities increased from tens to thousands per acre. And these now-dense forests are facing yet another stressor in the form of changing climate. The unusually dry summers and winters that the Southwest is now experiencing have changed the way fires burn in forests. Tall flames now reach forest canopies and incinerate whole trees and snags. The decades of accumulated needles and forest litter smolder on the ground, killing old pine trees that would usually survive the fast-moving, pre-settlement fires. Today's forest fires can be so hot they create their own weather and wind patterns: a virtual firestorm. In addition, humans are now one of the leading causes of fires.

The Wallow Fire scorched or incinerated many existing bat-friendly snags. Although new snags were created from trees killed by fire, many were smaller than the size preferred by bats. So the question becomes: would bats accept or reject these blackened snags?

To find out, we captured bats at 20 livestock ponds. Not all the area burned, so we split our efforts among ponds in areas of high severity (at least 75 percent of surrounding landscape burned) or low (25 percent or less). Despite some rainy nights, between mid-June and the end of July, we captured more than 650 bats of 13 species, including the uncommon Allen's big-eared bat (*Idionycteris phyllotis*). The long-legged myotis (*Myotis volans*) was the most common capture, accounting for 25 percent of the total. Arizona myotis, long-eared myotis (*M. evotis*), silver-haired bats (*Lasionycteris noctivagans*) and big brown bats (*Eptesicus fuscus*) rounded out the top five, which represented 83 percent of our captures for the summer.

With long days of driving over rough, rocky and muddy roads, plus rugged hikes into forested ravines, we tracked our radiotagged females back to their roosts. We also occasionally resorted to telemetry flights to locate roosts from the air. In all, we found 19 roosts, including one snag that was shared by an Arizona myotis and a long-legged myotis colony, each of which used a different part of the snag.

More than half the roosts (58 percent) were large ponderosa pine snags, while 21 percent were Douglas-fir, 16 percent quaking aspen and 5 percent white fir. The pine snags averaged 24 inches (62 centimeters) in diameter and the Douglas-fir snags were 17 inches (43 centimeters). The average height of the roost snags was 80 feet (24 meters).

Most of the bats roosted in unburned snags, and bats were mostly captured while foraging and drinking at ponds in habitat relatively untouched by fire. The Arizona myotis and long-legged myotis roosted in unburned snags surrounded by unburned forest. However, four individuals of three species (long-eared myotis, fringed myotis [*M. thysanodes*] and Allen's big-eared bat) used snags that were completely charred – picture a huge, black toothpick. And big brown bats, long-eared myotis, fringed myotis and the single Allen's big-eared bat roosted in the midst of burned-out forest. What causes these species to choose burned or unburned areas for roosting? Perhaps thermal properties of roosts at these high elevations are important. We hope to find out more next summer, when we will be back in the White Mountains to hunt down still more roosts.

This project has been full of surprises, not the least of which is that so many people are willing to volunteer to work at night in remote and challenging terrain. And we were amazed at how bats choose and use roosts in this wildfire-burned area. We were astonished when 70 bats emerged from a completely charred pine snag. We found species segregating the use of snags based on the severity of fire damage in the surrounding landscape. That bats can bear and raise pups at elevations above 8,000 feet (2,400 meters) in such cold temperatures shows how unique and tough these little animals can be.

We will continue our investigation next summer to expand our initial results into how bats are using the Wallow Fire zone. And we hope in the future to explore the remnants of large fires in Arizona and New Mexico. Given the certainty of climate change, it is imperative that we learn how this complex assemblage of bats in the Southwest responds to this transformed habitat.

Preventing DISASTER

Home Ignitability in the Wildland–Urban Interface

Wildland-urban interface (W-UI) fires are a significant concern for federal, state, and local land management and fire agencies. Research using modeling, experiments, and W-UI case studies indicates that home ignitability during wildland fires depends on the characteristics of the home and its immediate surroundings. These findings have implications for hazard assessment and risk mapping, effective mitigations, and identification of appropriate responsibility for reducing the potential far home lass caused by W-UI fires,

By Jack D. Cohen

Once largely considered a California problem, residential fire losses associated with wildland fires gained national attention in 1985 when 1,400 homes were destroyed nationwide (Laughlin and Page 1987). The wildland fire threat to homes is increasing and is commonly referred to as the wildland—urban interface (W-UI) fire problem. Since 1990, W-UI fires have threatened and destroyed homes in Alaska, Arizona, California, Colorado, Florida, Michigan, New Mexico, New York, and Washington. Extensive or severe fires in Yellowstone in 1988, Oakland in 1991, and Florida in 1998 attracted much media coverage and focused national attention on wildland fire threats to people and property

Federal, state, and local land management and fire agencies must directly and indirectly protect homes from wildfire within and adjacent to wildlands. Davis (1990) indicated that since the mid-1940s, a major population increase has occurred in or adjacent to forests and woodland areas. Increasing residential presence near fire-prone wildlands has prompted agencies to take actions to reduce W-UI fire losses.

When an apparently all-encompassing, seemingly unstoppable W-UI fire occurs, the rapid involvement of many homes over a wide area produces a surreal impression; some homes survive amid the complete destruction of surrounding residences. After the 1993 Laguna Hills fire, some termed this seemingly inexplicable juxtaposition a “miracle.’ Miracles aside, the characteristics of the surviving home and its immediate surroundings greatly influenced its survival.

Wildland fire and home ignition research indicates that a home’s exterior and site characteristics significantly influence its ignitability and thus its chances for survival. Considering home and site characteristics when designing, building, siting, and maintaining a home can reduce W-UI fire losses.

W-UI Fire Loss Characteristics

W-UI residential fire losses differ from typical residential fire losses. Whereas residential fires usually involve one structure with a partial loss, W-UI fires can result in hundreds of totally destroyed homes. Particularly during severe W-UI fires, numerous

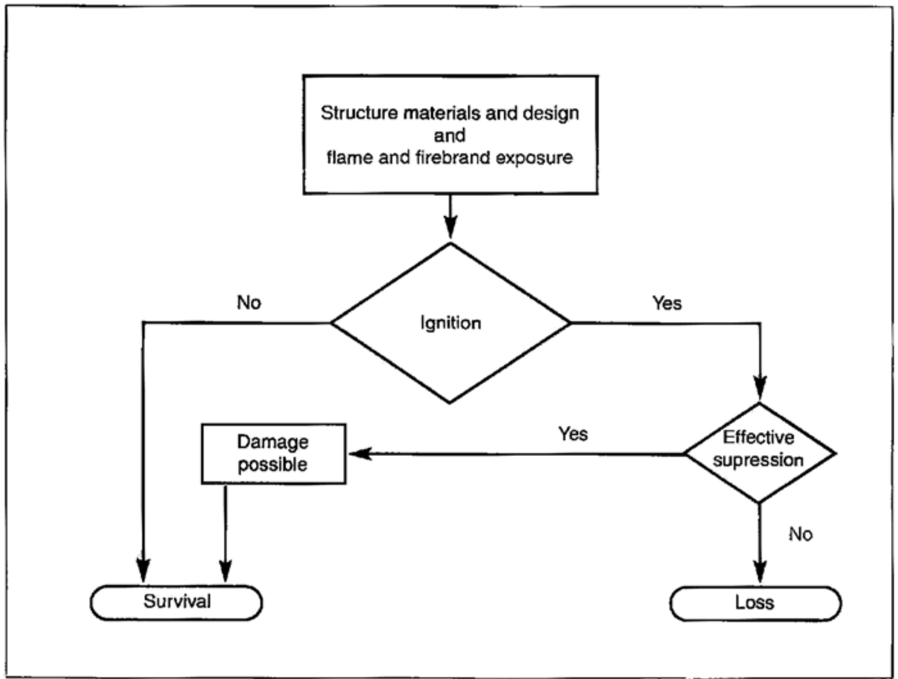

Figure 1. **The structure survival process**

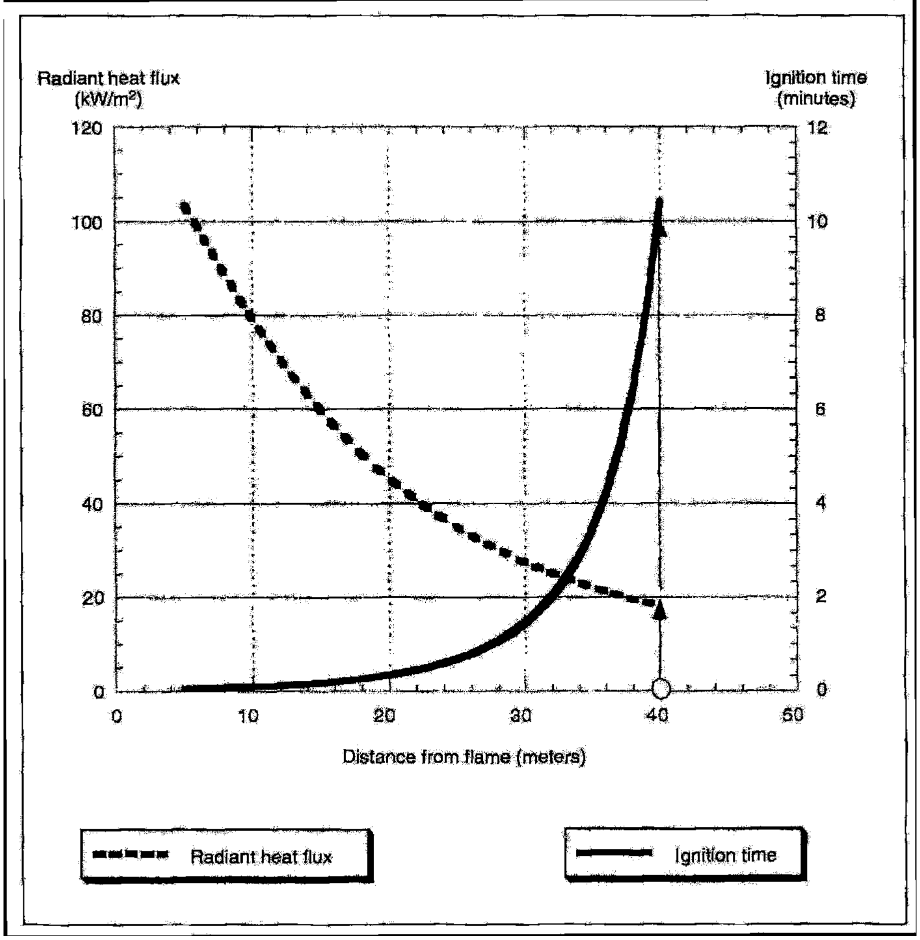

***Figure* 2.The incident radiant heat flux is shown as a function of a wall's distance from a flame 20 meters high by 50 meters wide, uniform, constant, 1,200 K, black-body. The minimum time required for a piloted wood ignition is shown given the corresponding heat flux at that distance.**

homes can ignite in a very short time. The usual result is that a home either survives or is totally destroyed; only a few structures incur partial damage (Foote 1994).

The W-UI Fire commonly originates in wildland fuels. During dry, windy conditions in areas with continuous fine fuels, a wildland fire can spread rapidly, outpacing the initial attack of firefighters. If residences arc nearby, a wildland fire can expose numerous homes to flames and lofted burning embers, or firebrands.

A rapidly spreading wildland fire coupled with highly ignitable homes can cause many homes to burn simul-taneously. This multistructure involvement can overwhelm fire protection Capabilities and, in effect, result in unprotected residences. Severe W-UI fires can destroy whole neighborhoods in a few hours—much faster than the response time and suppression capabilities of even the best—equipped and staffed firefighting agencies. For example, 479 homes were destroyed during the 1990 Painted Cave fire in Santa Barbara, most of them within two hours of the initial fire report. The 1993 Laguna Hills fire in southern California ignited and burned nearly all of the 366 homes destroyed in less than five hours.

Whether a home survives depends initially on whether it ignites; if ignitions with continued burning occur, survival then depends on effective fire suppression. *Figure 1* shows that home survival begins with attention to the factors that influence ignition. These factors determine home ignitability and include the structure's exterior materials and design combined with its exposure to flames and firebrands. The lower the home ignitability the lower the chance of incurring an effective ignition.

Ignition: A local Process

Ignition and spread of fire, whether on structures or in wildland vegetation, is a combustion process. Fire spreads as a continuing ignition process whether from the propagation of flames or from the spot ignitions of firebrands. Unlike a flash flood or an avalanche, in which a mass engulfs objects in its path, fire spreads because the requirements for combustion are satisfied at locations along the path. The basic requirements for combustion—the fire triangle—are fuel, heat, and oxygen. An insufficiency of any one of the three components, which can occur over a relatively short distance, will prevent a specific location from burning. “Green islands” that remain after the passage of a severe, stand-replacement fire demonstrate this phenomenon. Commonly one can find a green, living tree canopy very close to a completely consumed canopy.

The requirements for combustion equally apply to the W-UI fire situation. In the wildland fire context, fire managers commonly refer to vegetation as fuel. However, for the specific context of W-UI residential fire losses, a house becomes the fuel. Heat is supplied by the flames of adjacent burning materials that could include firewood piles, dead and live vegetation, and neighboring structures. Firebrands from upwind fires also supply heat when they collect on a house and adjacent flammable materials. The atmosphere amply supplies the third necessary component, oxygen.

A wildland fire cannot spread to homes unless the homes and their adjacent surroundings meet those combustion requirements. The home ignitability determines whether these requirements are met, regardless of how intensely or fast—spreading distant fires are burning. To use an extreme example, a concrete bunker would not ignite during any wildland fire situation. At the other extreme, some highly ignitable homes have ignited without flames having spread to them. These homes directly ignited from firebrands.

Firebrands are a significant ignition source during W-UI fires, particularly when flammable roofs are involved. Foote (1994) found a significant difference in home survival solely based on roof f1ammability. Homes with nonflammable roofs had a 70 percent survival rate compared with 19 percent for homes with flammable roofs. Davis (1990) reported similar results related to roof flammability.

Reducing W-UI fire losses in the context of home ignitability involves mitigating the fuel and heat components sufficiently to prevent ignitions. However, the question of sufficiency (or efficiency) remains: How much, or perhaps more appropriately, how little fuel and heat reduction must be done to effectively reduce home ignitions? To answer this question, we must first quantify the heat source in terms of the fuel’s ignition requirements; specifically, how close can flames be to a home’s wood exterior before an ignition occurs?

Research Insights

Diverse research approaches are providing clues for assessing the fuel and heat requirements for residential ignitions. Structure ignition modeling, fire experiments, and W-UI fire case studies indicate that the fuel and heat required for home ignitions only involve the structure and its immediate surroundings—the home ignitability context.

Modeling. The Structure Ignition Assessment Model (SIAM) (Cohen 1995) is currently being developed to asses the potential for structure ignitions from flame exposure and firebrands during W-UI fires. One function of SIAM is to calculate the total heat transferred, both radiation and convection, to a structure for varying flame sizes and from varying distances. From the calculated heat transfer, SIAM calculates the amount of heat over time that common exterior wood products can sustain before the occurrence of a piloted ignition (Tran et al. 1992).

Piloted ignition When wood is sufficiently heated, it decomposes to release combustible volatiles. At a sufficient volatile—air mixture, a small flame or hot spark can ignite it to produce flaming; thus, a piloted ignition.

Based on severe-case assumptions of flame radiation and exposure time, SIAM calculations indicate that wildland flame fronts comparable to crowning and torching trees (flames 20 meters high and 50 meters wide) will not ignite wood surfaces at distances greater than 40 meters (Cohen and Butler, in press). *Figure 2* shows the radiant heat a wall would receive from flames depending on its distance from the fire. The incident radiant heat flux, defined as the rate of radiant energy per unit area received at an exposed surface, decreases as the distance increases.

Figure 2 also shows that the time required for ignition depends on the distance to a flame of a given size. At 40 meters the radiant heat transfer is less than 20 kilowatts per square meter *(kW/m^2),* which translates to a minimum piloted ignition time of more than 10 minutes.

1 kW/m^2	Maximum for indefinite skin exposure.
10.4 kW/m^2	Pain after three seconds of skin exposure.
16.0 kW/m^2	Second-degree burn after five seconds of skin exposure.

Source: Drysdale 1985.

Ten minutes, however, is significantly longer than the burning time of wildland flame fronts at a location. Large flames of wildland fires typically depend on fine dead and live vegetation, which limits the intense burning duration at a specific location to less than a few minutes. Recent crown fire experiments have demonstrated a location-specific burning duration of 50 to 70 seconds.

Experiments. Field studies conducted during the International Crown Fire Modelling Experiment (Alexander et al. 1998) provide data for comparisons with SIAM model estimates. Total heat transfer (radiation and convection) and ignition data were obtained from heat flux sensors placed in wooden wall sections.

The instrumented walls were located on flat, cleared terrain at 10, 20, and 30 meters downwind from the edge of the forested plots. The wall section at 10 meters was 2.44 meters wide and 2.44 meters high with a 1.22-meter eave and roof section (*fig. 3a).* Exterior plywood (T-1-11) covered the wall with oriented-strand board covering the roof section and the eave soffit. Trim boards were solid wood with wood fiber composition board on the cave fascia. None of the materials were treated with fire retardant.

(a) 10-meter wood wall section before the crown fire. (b) Experimental crown fire.

Figure 3. International Crown Fire Modelling Experiment.

The forest was variably composed of an overstory of jack pine *(Pinus banksiana)* about 14 meters high with an understory of black spruce *(Picea mariana).* The spreading crown fire produced flames approximately 20 meters high. *Figures 3b and 3c* show examples of the experimental crown fire.

Five burns were conducted where wall sections were exposed to a spreading crown fire. As the crown fires reached the downwind edge of the plot, turbulent flames extended into the clearing beyond the forest edge. In two of the five burns, flames extended beyond 10 meters to make contact with the 10-meter wall section. When flame contact occurred, the 10-meter walls ignited; however, without flame contact, only scorch occurred, as shown in *figure 3d.* The wooden panels at 20 meters experienced light scorch when flames extended beyond 10 meters from the experimental plot, and no scorch from the other burns. The 30-meter wall section had no scorch from any of the crown fires.

Figure 4 displays the average total incident heat flux (radiation and convection combined) corresponding to the wall at 10 meters *(fig. 3d)* and the crown fire shown in figures *3b and 3c.* The average total incident heat flux is calculated from two sensors placed 1 meter apart in the wall. The amount of heat received by the wall increased as the flame front approached and decreased as the fine vegetation was consumed. The initial heat flux "spike" was caused by a nonuniform crowning flame front.

The flux-time integral shown in *figure 4* indicates whether sufficient heating has occurred to pilot-ignite wood (Tran et al. 992). SIAM uses the flux-time integral for calculating ignition potential, a correlation of the incident heat flux and the time required for piloted wood ignition.

The flux-time correlation identifies two principal ignition criteria: (1) A minimum heat flux of 13 kW/m^2 must occur before a piloted ignition can occur for any exposure time, and (2) piloted ignition depends on attaining a critical heating dosage level (heat transfer and its duration). These criteria are graphed in *figure 4.* The flux-time integral only increases for incident heat fluxes greater than the minimum of 13 kW/m^2, and the flux-time integral threshold value of 11,500 is shown as the ignition threshold. As seen in the figure, the flux-time integral does not reach the ignition threshold, indicating an exposure insufficient for ignition and corresponding to no actual occurrence of a wall ignition. Therefore, a home at some distance from a large flame front, such as a crown fire, may not receive sufficient energy to meet the minimum for ignition over any time period. In addition, a home closer to a large flame front can receive a high heat flux (for example, 46 kW/m^2 as shown in *figure 4*), but without the necessary duration to meet the threshold for ignition.

The flux-time integral plot indicates the duration of the heat transfer relevant to ignition. The heat transfer duration relevant to ignition combines the heat transfer from the approaching crown fire plus the burning time of the fire after it has reached the end of the plot. The observed time required for the flux-time integral to increase from zero to its maximum value corresponds to the heat transfer duration significant for ignition. *Figure 4* indicates a duration of 65 seconds (flux-time plot from 75 seconds to 140 seconds).

Case studies. Case studies of actual W-UI fires provide an independent comparison with SIAM and the crown

(c) Experimental crown fire.

(d) After crown fire exposure the wall scorched but did not ignite. Note the lack of wall scorch under the eave because of the radiation "shading" from the eave.

fire experiments. The actual fires incorporate a wide range of fire exposures. The case studies chosen examine significant factors related to home survival for two fires that destroyed hundreds of structures. The Bel Air fire resulted in 484 homes destroyed (Howard et al. 1973) and the Painted Cave fire destroyed 479 homes (Foote 1994).

Analyses of both fires indicate that home ignitions depend on the characteristics of a structure and its immediate surroundings. Howard et al. (1973) observed 86 percent survival for homes with nonflammable roofs and a clearance of 10 meters or more.

Dicussion

A comparison of the SIAM model calculations in *figure 2* with the observed heat flux from the experimental crown fire in *figure 4* indicated that the model overestimates the heat flux. The model calculation at 10 meters reveals a radiant heat flux of 70 kW/m^2, which exceeds the highest total heat flux of 46 kW/m^2 observed

At the 10-meter wall section in *figure 4*. SIAM calculations

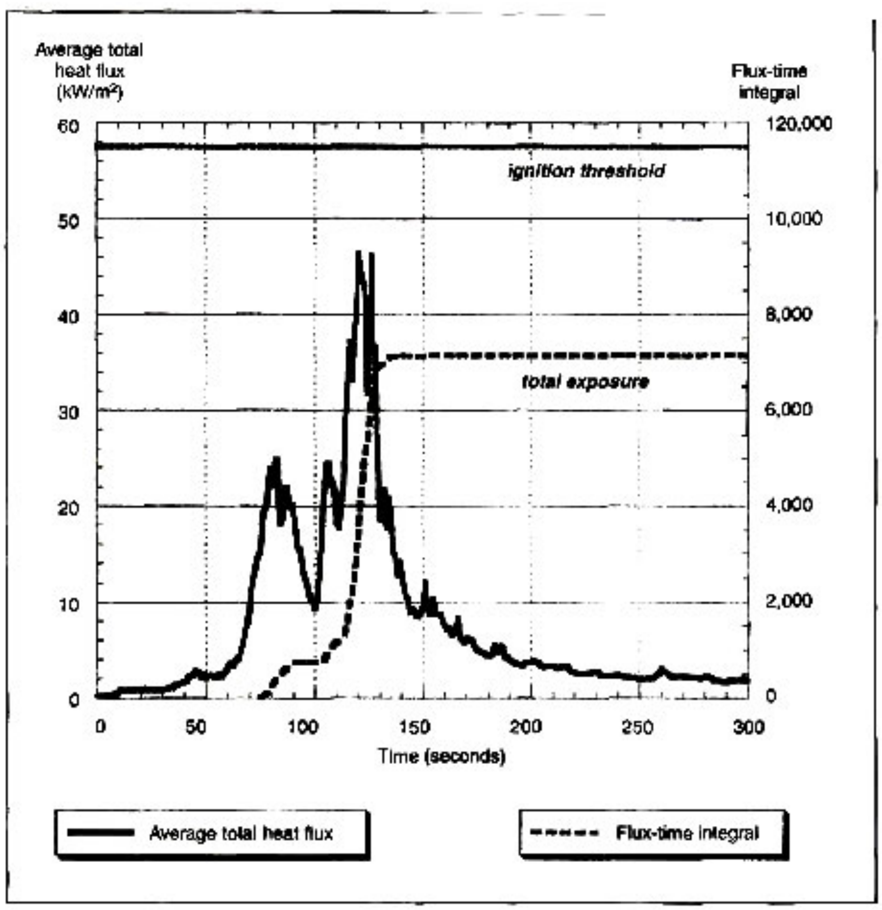

Figure 4. Actual average total incident heat flux and flux-time integral for the crown fire and 10-meter wall section shown in figure 3.

overestimate the heat transfer because the severe-case assumptions designate a homogeneous, black-body radiating flame front. Real flame fronts do not meet these assumptions and produce a significantly smaller radiant heat flux by comparison. For a given flame front, the SIAM calculations represent an extreme-case estimate of radiant heat transfer, and thus an extreme-case estimate of ignition potential.

Given the duration of the experimental heat flux (65 seconds), we can calculate the heat flux and corresponding distance required for ignition. At 65 seconds, the ignition time graph (*fig. 2)* indicates ignition at a flame distance of less than 30 meters. If the heat flux duration is extended by a factor of five to 325 seconds, the flame distance for ignition is less than 40 meters. By comparison, the 10-meter wall sections in the crown fire experiment did not ignite without flame contact and all burns produced little or no scorch to wall sections at 20 and 30 meters. The W-UI fire case studies indicated approximately 90 percent survival with a vegetation clearance on the order of 10 to 20 meters for homes with nonflammable roofs. Thus, the case studies support the general flame-to-structure distance range of 10 to 40 meters as found through modeling and experiments.

However, firebrands can also cause homes to ignite during wildland fires. Although firebrands capable of ignition can originate from a fire several kilometers away, homes can only be threatened if the firebrands ignite the home directly or ignite adjacent flammable materials that then ignite the home.

Analyses of potential home ignitions using modeling, experiments, and case studies did not explicitly address firebrand ignitions. However, firebrand ignitions were implicitly considered because of the firebrand exposures that occurred during the crown fire experiments and the case studies. The experimental crown fires provided a firebrand exposure that resulted in spot ignitions in the dead wood and duff around the wall sections hut not directly on the walls. In the case studies, firebrand ignitions occurred throughout the areas affected by the Bel Air and Painted Cave fires. The high survival rate for homes with nonflammable roofs and 10- to 20-meter vegetation clearances included fire-brands as an ignition factor, thus indicating that firebrand ignitions also depend on the ignition characteristics of the home and the adjacent flammable materials.

Conclusions

The key to reducing W-UI home fire losses is to reduce home ignitability. SIAM modeling, crown fire experiments, and case studies indicate that a home's structural characteristics and its immediate surroundings determine a home's ignition potential in a W-UI fire. Using the model results as guidance with the concurrence of experiments and case studies, we can conclude that home ignitions are nor likely unless flames and firebrand ignitions occur within 40 meters of the structure. This finding indicates that the spatial scale determining home ignitions corresponds more to specific home and community sites than to the landscape scales of wildland fire management. Thus, the W-UI fire loss problem primarily depends on the home and its immediate site.

Consequently if the community or borne site is not considered in reducing W-UI fire losses, extensive wildland fuel reduction will be required. For highly ignitable homes, effective wildland fire actions must riot only prevent fires from burning to home sites, but also eliminate firebrands that would ignite the home and adjacent flammable materials. To eliminate firebrands, wildland fuel reductions would have to prevent firebrand production from wildland fires for a distance of several kilometers away from homes.

Management Implications

Because home ignitability is limited to a home and its immediate surroundings, fire managers can separate the W-UI structure fire loss problem from other landscape-scale fire management issues. The home and its surrounding 40 meters determine home ignitability, home ignitions depend on home ignitability, and fire losses depend on home ignitions. Thus, the W-UI fire loss problem can be defined as a home ignitability issue largely independent of wildland fuel management issues. This conclusion has significant implications for the actions and responsibilities of homeowners and fire agencies, such as defining and locating potential W-UI fire problems (for example, hazard assessment and mapping), identifying appropriate mitigating actions, and determining who must take responsibility for home ignitability

W-UI fire loss potential. Because home ignitions depend on home ignitability, the behavior of wildland fires beyond the home or community site does not necessarily correspond to W-UI home fire loss potential. Homes with low ignitability can survive high-intensity wildland fires, whereas highly ignitable homes can be destroyed during lower-intensity fires.

This conclusion has implications for identifying and mapping W-UI fire problem areas. Applying the term wildland-urban interface to fire losses might suggest that residential fire threat occurs according to a geographic location. In fact, the wildland fire threat to homes is not a function of *where* it happens related to wildlands, but rather to *how* it happens in terms of home ignitability. Therefore, to reliably map the potential for home losses during wildland fires, home ignitability must be the principal mapping characteristic. The home threat information must correspond to the home ignitability spatial scale, that is, those characteristics of a home and its adjacent she within 40 meters.

Home fire loss mitigation. W-UI home losses can be reduced by focusing efforts on homes and their immediate surroundings. At higher densities where neighboring homes may occupy the immediate surroundings, loss reductions may necessarily involve a community. If homes have a sufficiently low home ignitability, a community exposed to a severe wildfire can survive without major fire destruction. Thus, there is a need to examine the reduction of wildland fuel hazard for the specific objective of home protection. There are various land management reasons for conducting wildland vegetation management. However, when considering the use of wildland fuel hazard reduction specifically for protecting homes, an analysis specific to home ignitability should determine the treatment effectiveness.

Responsibility for home ignitability. If no wildfires or prescribed fires occurred, the wildland fire threat to residential development would not exist. However, our understanding of the fire ecology for most of North America indicates that fire exclusion is neither possible nor desirable. Therefore, homeowners who live in and adjacent to the wildland fire environment most take primary responsibility for ensuring that their homes have sufficiently low home ignitability. Homes should not be considered simply as potential victims of wildland fire, but also as potential participants in the continuation of the fire at their location.

A change needs to take place in the relationship between homeowners and the fire services. Instead of home-related presuppression and fire protection responsibilities residing solely with fire agencies, homeowners must take the principal responsibility for ensuring adequately low home ignitability.

The fire services should become a community partner providing homeowners with technical assistance as well as fire response in a strategy of assisted and managed community self-sufficiency (Cohen and Saveland 1997). For this approach to succeed, it must be shared and implemented equally by homeowners and the fire services.

Assessing the value of roadless areas in a conservation reserve strategy: biodiversity and landscape connectivity in the northern Rockies

MICHELE R. CRIST,* BO WILMER† and GREGORY H. APLET‡

**Ecology and Economics Research Department, The Wilderness Society, 350 N 9th Street, Suite 302, Boise, ID 83702, USA; †Center for Landscape Analysis, The Wilderness Society, 1424 Fourth Ave, Ste 816, Seattle, WA 98101, USA; and ‡Ecology and Economics Research Department, The Wilderness Society, 7475 Dakin Street, Ste 410, Denver, CO 80221, USA*

Summary

1. Roadless areas on United States Department of Agriculture (USDA) Forest Service lands hold significant potential for the conservation of native biodiversity and ecosystem processes, primarily because of their size and location. We examined the potential increase in land-cover types, elevation representation and landscape connectivity that inventoried roadless areas would provide in a northern Rockies (USA) conservation reserve strategy, if these roadless areas received full protection.
2. For the northern Rocky Mountain states of Montana, Wyoming and Idaho, USA, we obtained GIS data on land-cover types and a digital elevation model. We calculated the percentage of land-cover types and elevation ranges of current protected areas (wilderness, national parks and national wildlife refuges) and compared these with the percentages calculated for roadless and protected areas combined. Using five landscape metrics and corresponding statistics, we quantified how roadless areas, when assessed with current protected areas, affect three elements of landscape connectivity: area, isolation and aggregation.
3. Roadless areas, when added to existing federal-protected areas in the northern Rockies, increase the representation of virtually all land-cover types, some by more than 100%, and increase the protection of relatively undisturbed lower elevation lands, which are exceedingly rare in the northern Rockies. In fact, roadless areas protect more rare and declining land-cover types, such as aspen, whitebark pine, sagebrush and grassland communities, than existing protected areas.
4. *Synthesis and applications*. Landscape metric results for the three elements of landscape connectivity (area, isolation and aggregation) demonstrate how roadless areas adjacent to protected areas increase connectivity by creating larger and more cohesive protected area 'patches.' Roadless areas enhance overall landscape connectivity by reducing isolation among protected areas and creating a more dispersed conservation reserve network, important for maintaining wide-ranging species movements. We advocate that the USDA Forest Service should retain the Roadless Area Conservation Rule and manage roadless areas as an integral part of the conservation reserve network for the northern Rockies.

Key-words: conservation, elevation zones, land-cover types, landscape metrics, national forests, reserve design

Introduction

A growing body of scientific evidence indicates that the current USA system of federal protected areas (designated wilderness areas, national parks and national wildlife refuges) may be too small and disconnected to protect against the decline and loss of native species diversity or to accommodate large natural ecosystem processes (Wright, Dixon & Thompson 1933; MacArthur & Wilson 1967; White 1987; Wilcove 1989; Baker 1992; Turner *et al*. 1993; Noss & Cooperrider 1994; Reice 1994; Newmark 1995; Sinclair *et al*. 1995; Soule & Terborgh 1999). Expanding road networks, human settlements, resource extraction and other encroachments on the landscape have increased the fragmentation and loss of natural areas. Such disturbances have isolated many protected areas, causing them to function as terrestrial 'islands' surrounded by a matrix of lower quality altered lands (Harris 1984; Pickett & White 1985; Wiens, Crawford & Gosz 1985; Turner 1989; Saunders, Hobbs & Margules 1991). The long-term persistence of many species within protected areas is dependent on the degree of human activities and land-use practices on lands adjacent to and near protected areas. There is a need to identify relatively undisturbed lands located outside protected areas that may increase the potential of protected areas in maintaining native biodiversity and certain ecological processes, and to include these lands within the conservation reserve system before they are lost or altered.

Inventoried roadless areas, large tracts of relatively undisturbed land on USA Forest Service lands, are often left out of landscape assessments for identifying functional conservation reserves. Only two studies (DeVelice & Martin 2001; Strittholt & DellaSala 2001) have analysed the contribution that roadless areas make to the current protected areas reserve network. However, more than one-third of inventoried roadless areas on national forests are adjacent to protected areas (DeVelice & Martin 2001). They hold the potential to increase the size and connectivity of designated wilderness areas, national parks and national wildlife refuges, thus increasing the ability of protected areas to maintain natural landscape dynamics and native species population viability over the long term. Smaller, isolated roadless areas are also important because they may contain rare species, capture more habitat variation, including underrepresented habitat types, and may function as 'stepping stones' that connect current protected areas across a landscape (Shafer 1995; Strittholt & DellaSala 2001).

There is a precedent for the protection of national forest roadless areas. The USA Congress has designated as wilderness more than half, 6 million ha, of roadless areas that the Forest Service inventoried in national forests in the 1970s. In 1998, the Forest Service began to devise regulations aimed at protection of roadless area characteristics in national forests. In May 2000, the agency released its proposed rule, familiarly known as the Roadless Rule, and draft environmental impact statement. Eight months later, the Forest Service adopted the rule. In July 2004, the Forest Service proposed to repeal the Roadless Rule and replace it with a state petition and rule-making process, which would offer less protection by presumably opening national roadless areas to all forest service activities and requiring state governors to 'opt in' Roadless Rule protections affirmatively for any roadless area.

Included in the Roadless Rule environmental impact statement was an evaluation of the potential contribution that protection of roadless areas could make to the conservation of biodiversity at a national scale (USDA Forest Service 2000b). In that evaluation, DeVelice & Martin (2001) found that the inclusion of roadless areas in the network of federal protected areas would expand representation of ecoregions in protected areas, increase the acreage of reserved areas at lower elevations, and increase the number of areas large enough to provide refuge for wide-ranging species.

Strittholt & DellaSala (2001) focused on similar questions at a regional scale for the Klamath-Sikiyou area in southern Oregon and northern California, USA. They found that roadless areas protect a wide range of ecological attributes, especially at mid- to lower elevations, important in this region. They also concluded that roadless areas increase the connectivity among ecoregions.

The northern Rocky Mountain states of Montana, Wyoming and Idaho comprise a region particularly rich in roadless areas, roughly 2·6 million ha, providing a unique opportunity to create a relatively intact reserve design that captures important elements of conservation for the northern Rockies. Using two key concepts in conservation biology, biodiversity representation and landscape connectivity, we investigated the potential contributions of national forest roadless areas to the protected areas reserve network across the northern Rocky Mountain region.

DIVERSITY REPRESENTATION

An important goal in the design and establishment of conservation reserves is to represent a full range of native biodiversity (Shelford 1926; Margules, Nicholls & Pressey 1988; Church, Stoms & Davis 1996; Possingham, Ball & Andelman 2000). Even though this goal has been articulated for some time, most protected areas are demarcated around areas with high scenic and recreational attributes (Davis *et al*. 1996). As a result, existing protected areas in the northern Rockies are, for the most part, concentrated at higher elevations, where other important elements of biodiversity are most likely to be poorly represented (Scott *et al*. 2001).

Representation of a full range of biodiversity in reserves requires an understanding of all species and ecosystem processes operating within a given landscape. However, many researchers have used ecological communities and elevation ranges as coarse-scale surrogates for native biodiversity in the design of conservation reserves (Scott *et al*. 1993; Host *et al*. 1996). This concept is based on the idea that if a full range of ecological communities and elevation ranges is protected, it is more likely that many ecological communities, wide-ranging species and ecosystem processes will be maintained in the reserves. In the northern Rockies, ecological communities are often associated with elevation gradients (Hansen & Rotella 1999). Hence, roadless areas situated at middle and lower elevations may make valuable contributions in protecting many elements of biodiversity that are currently not well represented in protected areas (DeVelice & Martin 2001).

LANDSCAPE CONNECTIVITY

Connectivity refers to the degree to which the structure of a landscape helps or hinders the movement of wildlife species or natural processes such as fire (Wiens, Crawford & Gosz 1985; Turner *et al*. 1993; Noss & Cooperrider 1994; Bascompte & Solé 1996; With 1999). A 'well-connected' area can sustain important elements of ecosystem integrity, namely the ability of species to move and natural processes to function, and is more likely to maintain its overall integrity compared with a highly fragmented area.

Roads are highlighted in the scientific literature as major causes of landscape fragmentation, and function as barriers to organism movements, resulting in a reduction of overall landscape connectivity for many native species. The effects of roads are broad and include mortality from collisions, modification of animal behaviour, disruption of the physical environment, alteration of chemical environments, spread of exotic and invasive species, habitat loss, increase in edge effects, interference with wildlife life-history functions and degradation of aquatic habitats through alteration of stream banks and increased sediment loads (Franklin & Forman 1987; Andrews 1990; Noss & Cooperrider 1994; Reice 1994; Reed, Johnson-Barnard & Baker 1996; Trombulak & Frissell 2000; McGarigal *et al*. 2001). Thus, the addition of roadless areas to existing protected areas reserve is likely to maintain or increase landscape connectivity, as well as increase the integrity of protected areas.

With the advent of landscape metrics, it is now possible to quantify connectivity for landscapes, land-cover types, species' habitats, species' movements and ecosystem processes across a given region (O'Neill *et al*. 1988; McGarigal & Marks 1995; Gustafson 1998; With 1999). Many different metrics that quantify spatial characteristics of patches or entire landscape mosaics have been described (Turner & Gardner 1991; McGarigal & Marks 1995; Ritters *et al*. 1995; Hargis, Bisonette & David 1998; Dale 2000; Jaeger 2000; McGarigal & Holmes 2002). We chose metrics that measure three elements of landscape connectivity: area, isolation and aggregation.

Area

It is known that larger areas (patches) generally contain more species, more individuals, more species with large home ranges and/or sensitive to human activity, and more intact ecosystem processes than smaller areas (Robbins, Dawson & Dowell 1989; Turner *et al*. 1993; Newmark 1995; Shafer 1995). Higher numbers of patches will usually contribute to greater resilience of populations and may also increase the utility of patches that act as 'stepping stones' or connectors across a landscape (Buechner 1989; Lamberson *et al*. 1992).

Isolation

The distance between patches plays an important role in many ecological processes. Studies have shown that patch isolation is the reason that fragmented habitats often contain fewer bird and mammal species than contiguous habitats (Murphy & Noon 1992; Reed, Johnson-Barnard & Baker 1996; Beauvais 2000; Hansen & Rotella 2000). As habitat is lost or fragmented, residual habitat patches become smaller and more isolated from each other, species movement is disrupted, and individual species and local populations become isolated (Shinneman & Baker 2000).

Aggregation

The spatial arrangement of patches may help to explain how certain species are found in patches located close together and are not found in patches that are more isolated, or vice versa (Ritters *et al*. 1995; He, DeZonia, & Mladenoff 2000). This concept generally follows the ideas developed in island biogeography theory (MacArthur & Wilson 1967) and metapopulation theory (Levins 1969, 1970).

For some species or natural processes, the isolation or aggregation of patches across the landscape may be more important, for others, area may be the key element. Together, these three elements offer a comprehensive assessment of the importance of roadless areas to the maintenance of overall landscape connectivity and ecosystem integrity of current protected areas in the northern Rockies.

In this study, we aimed to assess the extent to which roadless areas increase biodiversity representation and landscape connectivity when they are included in the protected areas reserve network for the northern Rockies.

Methods

STUDY AREA

Of the 84 million ha of land that stretch across Montana, Wyoming and Idaho in the USA, roadless areas cover 2·6 million ha and existing federal protected areas (wilderness areas, national parks, special management areas and national wildlife refuges) protect almost 8·7 million ha. Within this region, three large, relatively

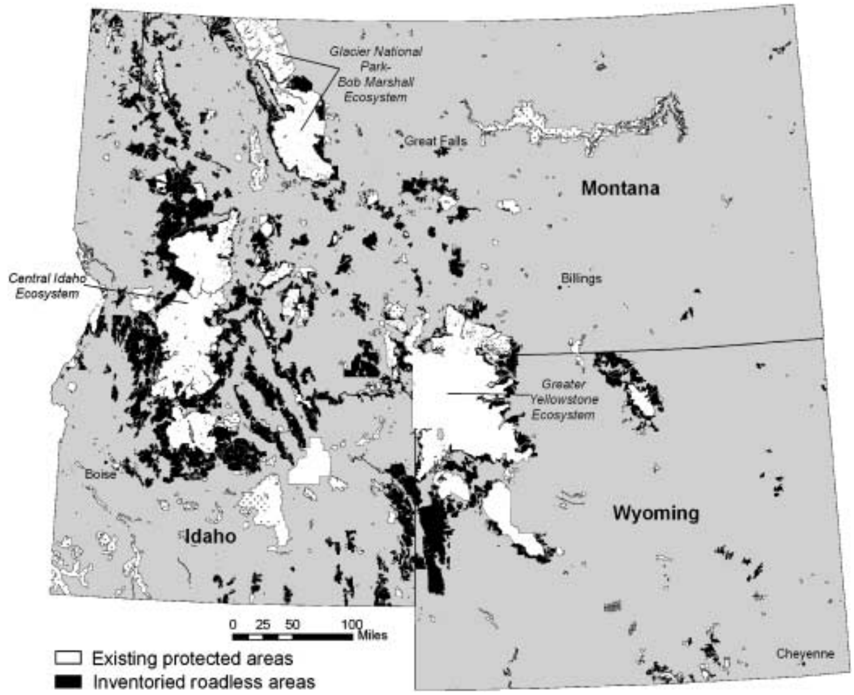

Fig. 1. Roadless areas and protected areas across the states of Idaho, Montana and Wyoming, USA.

undisturbed, mountain ecosystems are delineated around national parks and/or wilderness complexes. These are the Greater Yellowstone Ecosystem, Glacier National Park–Bob Marshall Ecosystem, and the Central Idaho Ecosystem (Fig. 1).

The topography of the northern Rocky Mountain states spans steep physical gradients in elevation, slope, aspect, temperature and precipitation that give rise to diverse vegetation types. Elevations range from 150 m to 4200 m. Average precipitation ranges from 28 cm to 51 cm (Franklin 1983). The northern Rockies comprise a variety of non-forested and coniferous forest types. Low-lying valleys are characterized by grasslands, sagebrush (*Artemisia* spp.) and desert shrublands, interspersed with juniper (*Juniperus* spp.) and riparian woodlands. Ponderosa pine *Pinus ponderosa* dominates lower elevation montane forests, while xeric coniferous forests of mainly Douglas fir *Psuedotsuga mensiezia*, ponderosa pine, grand fir *Abies grandis*, lodgepole pine *Pinus contorta* and aspen *Populus tremuloides* occur at mid-elevations. Mesic forests in the north and west largely contain western larch *Larix occidentalis*, grand fir, western red cedar *Thuja plicata* and mountain hemlock *Tsuga mertensiana*. Higher elevations are composed of Engelmann spruce *Picea engelmannii*, subalpine fir *Abies lasiocarpa*, alpine larch *Larix lyalli* and whitebark pine *Pinus albicaulis* intermixed with subalpine meadows. Herb lands, rock, alder *Alnus sinuata* shrubfields and snowfields/ice occur at the highest elevations.

DATA COLLECTION

We used a land management status GIS coverage and classification system developed by the USA Geological Survey's Biological Resources Division in its nationwide GAP Analysis Programme (Scott, Tear & Davis 1996) to delineate 'protected areas'. This programme devised a ranking scheme to represent various levels of protection, ranging from the least protected lands (category 4, e.g. private lands) to those with the highest level of protection (category 1, e.g. wilderness areas) for all public lands in the GIS spatial database. For this study, we assumed that categories 1 and 2 represent adequate protection as their primary management objective is conservation (Scott, Tear & Davis 1996), and selected these categories as our protected areas on all forest service lands located in the three states.

We used the federal inventoried roadless areas GIS database (USDA Forest Service 2000a). This includes areas that are greater than 2000 ha in size, where road building is prohibited under current National Forest Plan decisions and where road building is presently allowed. We recognize that our decision leaves out smaller roadless areas that were not considered during the inventory of federal roadless areas and that these areas serve important conservation goals (Strittholt & DellaSala 2001). For this study, the term 'roadless areas' refers to inventoried roadless areas.

We used three independently derived land cover maps for Montana, Wyoming and Idaho from the GAP Analysis Programme (Scott, Tear & Davis 1996). The Montana and Idaho GAP products were produced based on classification techniques by Redmond *et al.* (1998) for raw Landsat Thematic Mapper (TM) satellite imagery. Spatial resolution of the grid was 90 m for Montana and 30 m for Idaho. The Wyoming GAP Analysis Programme digitized land cover data in a vector format from Landsat TM satellite imagery at a scale of 1 : 100 000 (Gap Analysis Wyoming 1996). We converted Wyoming's vector map into a grid format and resampled the three data sets to 90-m resolution. Then we merged the three land cover maps into a single image and a common land cover classification scheme (Appendix 1).

Similar to most GIS databases, errors are associated with the land management status, inventoried roadless areas and land-cover grids. These grids represent a composite of data from many sources and include variations in mapping procedures and possible misclassifications that could potentially cause inconsistencies that are difficult to detect. However, we believe, based on professional judgement, that the error rate is not large enough to affect conclusions drawn from this large regional-scale analysis.

To investigate the representation of roadless areas at various elevation classes, we downloaded a digital elevation model from the 30-m National Elevation Dataset produced by the USA Geological Survey's EROS Data Center (Sioux Falls, SD). We reclassified the elevation range into 21 equal-interval classes ranging in 200-m increments from approximately 150 m to 4200 m.

DATA ANALYSIS

All data analyses were conducted in ARC/INFO and ArcView GIS software from Environmental Systems Research Institute (Redlands, CA).

Land cover representation

Using ARC/INFO, we combined the protected areas database with the land cover map. To calculate the percentage representation of each land-cover type, we divided the protected portion of each land-cover type by the total area of each land-cover type across the study area. Next, we appended the national forest inventoried roadless areas to the existing protected areas and repeated the same calculation described above to measure the additional representation of each land-cover type because of the inclusion of roadless areas. In addition, we calculated the percentage increase between each land cover percentage representation for protected areas alone and protected areas and roadless areas combined. This measure quantified the 'relative' ecological contribution from roadless areas for each land-cover type. We then ranked these land-cover types according to the level of representation within the existing protected areas.

Elevation representation

Using ARC/INFO, we combined the protected areas database with the 30-m digital elevation model. Similar to the procedure for land-cover types described above, we added the roadless areas to the existing protected areas, intersected this image with the elevation data, and calculated the change in representation for each elevation class provided by protection of roadless areas.

To examine the potential increase of landscape connectivity caused by roadless areas, we used ARC/INFO and FRAGSTATS (McGarigal & Marks 1995; McGarigal & Holmes 2002), a computer program developed to quantify heterogeneity of the landscape. We identified five landscape metrics available in FRAGSTATS to assess our three elements of landscape connectivity (McGarigal & Holmes 2002). To assess area, we used the metrics percentage land (PLAND), number of patches (NP) and patch size (AREA). We included the metrics NP and AREA to help explain the context of an increase in PLAND. For example, an increase in PLAND and AREA and a decrease in NP would indicate that the added roadless patches were located next to existing conservation patches, resulting in an increase in the size of patches and a decrease in the number of patches across the landscape. Conversely, a decrease in AREA and an increase in NP would indicate that the added patches were generally smaller and did not combine with existing patches.

To assess isolation we used nearest neighbour distance (ENN). A decrease or increase in ENN would indicate that patches are either located closer together or farther apart, respectively, across the landscape.

To assess aggregation, we used contagion (CONTAG). An increase in CONTAG would indicate that patches are, to a certain extent, aggregated together across the landscape.

Using FRAGSTATS, we selected and ran our five landscape metrics on the two grids described above (current protected areas only, and roadless areas and current protected areas combined). Each grid was a binary map where all grid cells that comprised the 'protected' and 'roadless' patches were classified as 1 and all other 'non-protected' grid cells were masked out as background (–99). For each landscape metric, we computed the mean, area-weighted mean and coefficient of variation where applicable. We then compared the differences in metrics between the two grids. In addition, differences in the mean, area-weighted mean and coefficient of variation helped to explain how the range of values for each metric were distributed when existing protected areas were compared with the conservation system including roadless areas.

Results

LAND COVER REPRESENTATION

In existing protected areas, burned forest and snowfields/ice had the highest land cover representation, 88% and 86%, respectively. Representation of other land-cover types, such as alpine meadows, whitebark pine, exposed rock/soil, subalpine meadows, wetlands, mixed subalpine forest and lodgepole pine, ranged from 31% to 71%.

The inclusion of roadless areas increased the representation of all land-cover types except for one, sand dunes (Table 1). Relative percentage increases ranged

Table 1. Additional representation and percentage increase in representation of each land-cover type across the northern Rockies when national forest roadless areas are added to existing protected areas

Land-cover type	Existing level of representation (%)	Potential level of representation including roadless areas (%)	Percentage increase including roadless areas
Burned forest	88·12	93·09	5·65
Snowfields/ice	86·12	97·48	13·19
Alpine meadow	71·51	94·18	31·70
Mixed whitebark pine	59·62	84·94	42·46
Exposed rock/soil	44·67	59·92	34·12

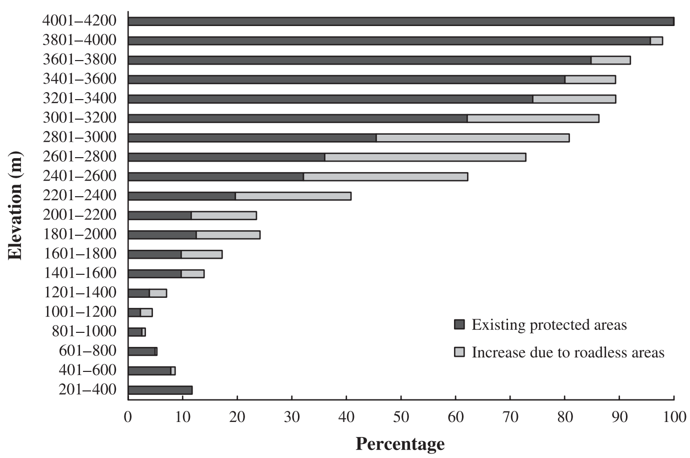

Fig. 2. Additional representation of elevation ranges resulting from the inclusion of roadless areas with protected areas for the northern Rockies. The *x*-axis represents elevation in 200-m increments and the *y*-axis shows absolute increase in percentage representation when roadless areas are added to protected areas. Black bars represent protected areas and grey bars represent roadless areas.

from 5% to 600%. Fifteen land-cover types increased by more than 40%, among them important ecological communities, western hemlock, aspen, ponderosa pine, western red cedar and sagebrush, each of which has less than 10% representation in current protected areas. Moreover, the addition of roadless areas represented one land-cover type, bur oak *Quercus macrocarpa* woodland, not present in protected areas.

ELEVATION REPRESENTATION

Our elevation analyses showed that elevations in the range of 2200–4200 m were well represented in protected areas (Fig. 2). The addition of roadless areas resulted in a large increase in representation of lands at elevations ranging from 1000 m to approximately 3400 m. For elevation ranges below 1000 m and above 3400 m, the

Table 2. Landscape metrics comparing the spatial pattern of protected areas alone with a scenario that includes protected areas and national forest roadless areas combined for the northern Rockies. + and – indicate an increase or decrease, respectively, in the metric value caused by the addition of roadless areas

Landscape Metrics	Protected areas	Protected and roadless areas	+/ –
Area			
Class area (ha)	8 814 900	15 673 600	+
Percentage land	9	16	+
Number of patches	770	722	–
Patch size (mean, ha)	11 447·92	21 708·59	+
Patch size (area-weighted mean)	1 105 055·78	2 505 909·11	+
Patch size (coefficient of variation)	977·39	1 069·74	+
Isolation			
Nearest neighbour (m)	7 013·72	5 353·11	–
Nearest neighbour (area-weighted mean)	3 153·73	2 518·75	–
Nearest neighbour (coefficient of variation)	122·47	134·16	+
Aggregation			
Contagion index	72·56	58·64	–

contribution of roadless areas was small. However, the proportion of area represented at lower elevations increased when we included roadless areas with protected areas.

CONNECTIVITY

Results from the landscape metrics showed that the addition of roadless areas increased regional connectivity for all three connectivity elements (Table 2). Area metrics demonstrated that the addition of roadless areas almost doubled the amount of area protected, rising from 9% to 16%, and the mean patch size in protected areas changed from 11448 ha to 21709 ha. The number of patches decreased from 770 to 722. Area-weighted mean patch size increases and the patch size coefficient of variation increased from 977 to 1070. Isolation metrics showed a decrease in the mean and area-weighted mean nearest-neighbour metrics when roadless areas were added. The mean distance between nearest protected patches decreased from 7014 m to 5353 m. The decrease in the area-weighted mean was less than the overall mean when patches of all sizes were considered. The coefficient of variation also increased for this metric. The aggregation metric (contagion) decreased from 72·56 to 58·64 when roadless areas were included, signifying more dispersion of patches across the landscape.

Discussion

BIODIVERSITY REPRESENTATION

A review of the literature suggests that a given vegetation community is adequately represented when 12–25% of it is included in a conservation area (World Commission on Environment & Development 1987; Noss & Cooperrider 1994), although it is not certain that these thresholds are truly adequate to protect vegetation communities. Based on this range, we define land-cover types above 25% as adequately protected, land-cover types within the range of 12–25% as minimally protected, and those below 12% as underrepresented, similar to DeVelice & Martin (2001).

Our results show that roadless areas make a substantial contribution in maintaining regional biodiversity. One of our most important findings is that roadless areas would protect a wider range of land-cover types and elevation ranges than protected areas alone, especially those characteristic of mid- to low elevations that are underrepresented in protected areas. These lands are among the last remnants of biologically productive lands that have not been significantly altered through human settlements, resource extraction and road construction (Scott *et al*. 2001; Strittholt & DellaSala 2001). We also found that protected areas adequately represent land-cover types that are characteristic of higher elevations. This finding supports the generally accepted notion that wilderness areas and national parks mainly protect higher elevation ecological communities (Davis *et al*. 1996; Possingham, Ball & Andelman 2000). Contrary to DeVelice & Martin (2001), whose study found that roadless areas mainly occurred at mid- to lower elevations, but similar to Strittholt & DellaSala (2001), we found that roadless areas considerably increase the protection of higher elevations and corresponding cover types as well. The different results are probably because of the scale at which the studies were implemented. DeVelice & Martin's (2001) study included all roadless areas across the nation, incorporating a wide range of elevations from sea level to the highest peaks. Our study, and that of Strittholt & DellaSala (2001), focused on smaller regions at higher elevations.

Across the northern Rockies region (Montana, Wyoming and Idaho), protected areas adequately represent nine land-cover types, whereas five biologically important land-cover types, western hemlock, aspen, ponderosa pine, western red cedar and mesic upland shrub, are underrepresented in protected areas. However, the addition of roadless areas increases representation of two cover types (western hemlock and western red cedar) to the minimally protected threshold and two cover types (aspen and mesic upland shrub) to the adequately represented threshold (greater than 25%). Ponderosa pine, even though it increases by nearly 100%, remains underrepresented. Overall, the magnitude of the increased representation, from 100% to 600%, indicates that roadless areas can make substantial contributions to the protection of land-cover types that are not well represented in protected areas.

Increased representation of certain rare ecological communities is particularly important in a northern Rockies conservation strategy. Aspen, for example, is thought to be declining in the northern Rockies (Gallent *et al*. 1998). When roadless areas are added to protected areas, aspen moves up two full categories: from underrepresented to adequately represented, a 480% increase in representation for this forest type, on which many avian species depend upon (Hansen & Rotella 2000). Representation of whitebark pine changes from 60% to 85% when roadless areas are added. Whitebark pine is declining throughout North America due to blister rust *Cronartium ribicola*, an introduced disease, and is a 'keystone species' important for many higher elevation species (Keane, Morgan & Menakis 1994).

Elevation representation results demonstrate that protected areas are mainly located at higher elevations. We also found that roadless areas are generally concentrated at mid- to high elevations and represent a wider range of elevations, especially low- to mid elevations, than protected areas. However, our results show that protected areas encompass more lower elevation lands than roadless areas. This situation is somewhat deceiving. Representation of lower elevations in protected areas is largely a result of two well-placed low-elevation conservation areas: Hell's Canyon National Recreation Area and Missouri Breaks National Monument. In fact, low-elevation lands below 1000 m are not well represented in either protected areas or roadless areas. As a majority of lower elevation lands in the northern Rockies have been converted to other uses, it is of utmost importance to increase representation of lower elevation sites in protected areas (Strittholt & DellaSala 2001). Protection of these lower elevation roadless areas would contribute greatly to the conservation of lower elevation species and ecological communities that are poorly represented in protected areas.

Landscape connectivity

Our analyses of three elements of connectivity show that roadless areas increase connectivity across the northern Rockies, and increase both the area and size of protected area patches. In addition, the number of protected area patches decreases with the addition of roadless areas because they combine with protected areas to form one larger patch. Larger patches will protect more species and more individuals, species with large home ranges, species sensitive to human activity, and more intact ecosystem processes than smaller areas (Askins, Philbrick & Sugeno 1987; Robbins, Dawson & Dowell 1989; Turner *et al*. 1993; Newmark 1995; Shafer 1995). Roadless areas also reduce the distance between protected areas and create a more evenly dispersed reserve system, critical for maintaining many species' movements and a large distribution of local populations (MacArthur & Wilson 1967; Murphy & Noon 1992; Reed, Johnson-Barnard & Baker 1996; Ritters *et al*. 1996; Beauvais 2000; Hansen & Rotella 2000; He, DeZonia, & Mladenoff 2000; Shinneman & Baker 2000).

Our results show an increase in the coefficient of variation for patch size and isolation metrics, which may be an important consideration in delineating conservation reserve systems capable of maintaining movements of various species and ecological processes (Wiens & Milne 1989; Wilcove & Murphy 1991; Noss 1992; Noss *et al*. 1996; O'Neill *et al*. 1996). Smaller patches may supplement larger reserves by protecting rare species that occur only in certain areas (Franklin & Forman 1987; Hansen *et al*. 1991; Shafer 1995). The dispersion of roadless areas may also contribute to greater resilience or survival of island populations by allowing a greater chance for species exchange, essentially maintaining a metapopulation or source–sink population structure (Wiens, Crawford & Gosz 1985; Pullium 1988; Gilpin & Hanski 1991; Murphy & Noon 1992). Many studies are investigating how species move through landscapes and their use of stepping-stone habitats, especially in fragmented landscapes (Freemark *et al*. 1993; With 1999; Beauvais 2000; Hansen & Rotella 2000; Holloway, Griffiths & Richardson 2003; Johnson, Seip & Boyce 2004). Being relatively undisturbed and well-distributed among protected areas, roadless areas are top candidates for the delineation of high-quality 'habitat connections' across the northern Rockies, particularly those that target rare or declining species. The loss or alteration of roadless areas may further reduce the movement of species among interdependent island populations located in protected areas and roadless areas, resulting in greater isolation.

Moreover, the addition of roadless areas increases the effective size of the three largest wilderness and national park complexes in the northern Rockies: the Greater Yellowstone Ecosystem, the Glacier National Park–Bob Marshall Ecosystem and the Central Idaho Ecosystem, where management challenges include maintaining large-scale ecological processes such as species' movements and natural fire across jurisdictional boundaries (Pickett & White 1985; Turner *et al*. 1993). Roadless areas not immediately adjacent to these complexes are dispersed in the surrounding landscape, which helps to decrease the degree of isolation between the complexes and possibly allows for species movement among these ecosystems.

Management implications

Using research to guide reserve design and develop land protection policies is the strongest approach in conservation. The importance of intact, functioning natural ecosystems to the maintenance of native biodiversity and ecological processes is unquestioned (Wright, Dixon & Thompson 1933; MacArthur & Wilson 1967; Usher 1987; White 1987; Shafer 1995; Noss, O'Connell & Murphy 1997). The negative impacts of roads in natural areas are well known (Andrews 1990; Foreman & Wolke 1992; Reed, Johnson-Barnard & Baker 1996; Spellerberg 1998; Trombulak & Frissell 2000; McGarigal *et al*. 2001). Our landscape assessment demonstrates how roadless areas, the remaining relatively undisturbed forested lands in the northern Rockies, are essential for maintaining biodiversity and landscape connectivity in a conservation reserve strategy for this area. This has direct bearing on management decisions regarding the protection of roadless areas in this region. Our results, along with the findings of DeVelice & Martin (2001) and Strittholt & DellaSala (2001), highlight the important role of roadless areas in USA conservation efforts and contribute to the larger policy dialogue surrounding roadless areas.

The methods used in this study can help land managers determine appropriate guidelines to identify and assess roadless areas that are critical in maintaining regional biodiversity, ecosystem processes, landscape connectivity and overall intact ecosystem integrity. Land managers should avoid activities such as road building, logging, spread of exotic species, off-road vehicle use and exurban development in roadless areas that would result in their degradation or loss. If roadless areas are not protected from these activities as a matter of priority, it is possible that their potential contribution to conservation effort in the future will be diminished and existing protected areas surrounded by or in close proximity to roadless areas will be negatively affected as well. We recommend that roadless areas receive full protection and are managed responsibly, so that they can function as an important part of the current conservation reserve system in the USA.

Acknowledgements

We thank The Aspenwood Foundation for the support of this project. We also thank ESRI Conservation Program for donations of GIS software. We acknowledge use of FRAGSTATS, a spatial computer program in the public domain developed by K. McGarigal and C. Holmes at the University of Massachusetts, Amherst. We thank Deanne Kloepfer and Dominik Kulakowski for edits and suggestions on earlier drafts. We also thank three anonymous referees for their edits and suggestions that improved the final draft.

ERRATA

The preceding paper unfortunately was published with several minor errors that are corrected below:

Page 181: Gregory H. Aplet's address is The Wilderness Society, 1660 Wynkoop Street, Ste. 850, Denver, CO 80202, USA.

"Forest Service" should be capitalized throughout.

Page 183, col. 2: The first sentence of the Study Area section should read: Of the 84 million ha of land that stretch across Montana, Wyoming and Idaho in the USA, roadless areas cover 6.8 million ha, and existing federal protected areas (wilderness areas, national parks, special management areas and national wildlife refuges) protect 8.8 million ha.

Page 184, par. 1, line 13: The correct spelling is: Douglas-fir *Pseudotsuga menziesii*.

Page 185, col. 2: The top of the column should begin with the heading *Landscape connectivity.*

Page 187, col. 2, par. 1.: The last sentence should read: Our study, and that of Strittholt and DellaSala (2001), focused on smaller regions, where national forests are concentrated at higher elevations.

Page 188, col. 1, par. 1: The third sentence should read: When roadless areas are added to protected areas, aspen moves up two full categories: from underrepresented to adequately represented, a 480% increase in representation for the forest type, upon which many avian species depend (Hansen and Rotella 2000).

Page 188, col. 1, par. 2: The first two sentences should read: Elevation representation results demonstrate that higher elevations are well represented in existing protected areas. We also found that roadless areas would add substantially to protected areas at mid- to high elevations.

Page 189, col. 2: The reference to Beauvais (2000) should refer to F.W. Smith.

Page 191, col. 2, last line: The manuscript was received 30 December 2003.

Abstract. To control and use wildland fires safely and effectively depends on creditable assessments of fire potential, including the propensity for crowning in conifer forests. Simulation studies that use certain fire modelling systems (i.e. NEXUS, FlamMap, FARSITE, FFE-FVS (Fire and Fuels Extension to the Forest Vegetation Simulator), Fuel Management Analyst (FMAPlus®), BehavePlus) based on separate implementations or direct integration of Rothermel's surface and crown rate of fire spread models with Van Wagner's crown fire transition and propagation models are shown to have a significant underprediction bias when used in assessing potential crown fire behaviour in conifer forests of western North America. The principal sources of this underprediction bias are shown to include: (i) incompatible model linkages; (ii) use of surface and crown fire rate of spread models that have an inherent underprediction bias; and (iii) reduction in crown fire rate of spread based on the use of unsubstantiated crown fraction burned functions. The use of uncalibrated custom fuel models to represent surface fuelbeds is a fourth potential source of bias. These sources are described and documented in detail based on comparisons with experimental fire and wildfire observations and on separate analyses of model components. The manner in which the two primary canopy fuel inputs influencing crown fire initiation (i.e. foliar moisture content and canopy base height) is handled in these simulation studies and the meaning of Scott and Reinhardt's two crown fire hazard indices are also critically examined.

Introduction

Crowning forest fires are exceedingly exciting to observe but like most natural phenomena, are dangerous as well. The safe and effective management of fire in most coniferous forest ecosystems is thus dependent to a very large extent on the ability to reliably assess or forecast crown fire potential based on predictive aids produced by research coupled with the skill and knowledge of the user.

Many advances have been made in crown fire behaviour research in recent years, including more intensively monitored experimental crown fires (Stocks *et al.* 2004) and physical-based modelling (Butler *et al.* 2004; Cruz *et al.* 2006*a*, 2006*b*). Nevertheless, crown fire behaviour is sometimes portrayed as a complex phenomenon for which we possess very limited knowledge and understanding of the exact physical processes involved (Cohen *et al.* 2006). Although this may very well be true, a substantial number of observations garnered from conducting outdoor experimental fires (Alexander and Quintilio 1990) and monitoring wildfires coupled with case study documentation (Cruz and Plucinski 2007) over the years have provided a solid foundation on several aspects of crown fire phenomenology as well as benchmark data on expected fire characteristics under certain environmental conditions, at least on an empirical basis.

Understanding the environmental conditions required for the onset or initiation and sustained propagation of crown fires is necessary to implement fuel management programs aimed at mitigating the likelihood of large, high-intensity crowning wildfires in the conifer-dominated forests found in western North America. Keyes and Varner (2006) have recently outlined just how complicated the processes involved are in using silvicultural methods to treat forest fuels in order to modify potential crown fire

10.1071/WF08132 1049-8001/10/040377

behaviour. The need for research into the effectiveness of fuel treatments in reducing crown fire potential has received considerable attention in recent years (Graham *et al.* 2004; Agee and Skinner 2005; Peterson *et al.* 2005). Roccaforte *et al.* (2008) classified research of this type into three categories: experimental, observational and simulation modelling.

Martinson and Omi (2008) have recently reported that more than half of the published studies aimed at quantifying fuel treatment effectiveness rely solely on modelling simulations. Commonly, these simulation studies characterise the fuel structure of distinct forest stands and through the use of fire modelling systems, coupled with specified fire weather, fuel moisture and slope conditions, attempt to integrate this information into a few fire behaviour descriptors in order to assess the relative 'flammability' of the fuel complex (McHugh 2006), and in turn, are able to gauge the effectiveness of fuel management strategies to mitigate the possibility of crown fires occurring (Graham *et al.* 1999; Keyes and O'Hara 2002).

Various fire modelling systems, such as NEXUS (Scott and Reinhardt 2001), Fire and Fuels Extension to the Forest Vegetation Simulator (FFE-FVS) (Reinhardt and Crookston 2003), FARSITE (Finney 2004), Fuel Management Analyst (FMAPlus®) (Carlton 2005), FlamMap (Finney 2006) and BehavePlus (Andrews *et al.* 2008), are extensively used in these simulation studies to assess potential crown fire behaviour in the western US (Keyes and Varner 2006; McHugh 2006; Varner and Keyes 2009) and to a lesser extent to date in western Canada (e.g. Bessie and Johnson 1995; Feller and Pollock 2006). The technical basis and intended uses of these modelling systems are contrasted elsewhere (McHugh 2006; Andrews 2007; Peterson *et al.* 2007).

All of the fire modelling systems referred to previously implement, link or integrate (or both) Rothermel's (1972, 1991) models for predicting surface and crown fire rates of spread with Van Wagner's (1977, 1993) crown fire transition and propagation models in various ways, and provide an output of several fire behaviour characteristics (e.g. rate of fire spread, fireline intensity, type of fire, crown fraction burned). Some of the systems also output two crown fire hazard indices – the Torching index (TI) and the Crowning Index (CI) as per Scott and Reinhardt (2001). The TI and CI represent the threshold wind speeds required for the onset of crowning and active crown fire propagation in coniferous forests respectively. Each TI and CI value is tied to a unique set of surface fuelbed characteristics (expressed in terms of a stylised or custom fuel model), dead and live moisture contents of surface fuels, crown fuel properties (canopy base height and bulk density, foliar moisture content), and slope steepness. This approach of using fire modelling systems to assess potential crown fire behaviour has gained widespread popularity within the US wildland fire research community, as evident by the number of published simulation studies over the past 10 years or so (e.g. Scott 1998*a*; Stephens 1998; Raymond and Peterson 2005; Harrington *et al.* 2006; Graetz *et al.* 2007; Mason *et al.* 2007; Battaglia *et al.* 2008). Scott and Reinhardt's (2001) two crown fire hazard indices are now being recommended for use in Canada (Gray and Blackwell 2008).

Our cursory critique of these simulation studies has revealed that many of them have produced unrealistic outcomes in terms of crowning potential, as evident by the resulting TI and CI values, given the specified environmental conditions and fuel characteristics. Quite often, critically dry fuel moisture levels are specified along with very low canopy base heights and relatively high canopy bulk densities and yet the simulations suggest that exceedingly strong winds are commonly required to initiate crowning and for fully developed or active crown fires to occur.

We have subsequently discovered that the fire modelling systems used in assessing crown fire potential in these simulation studies have an inherent underprediction bias associated with them as a result of the underlying models or the manner in which they have been implemented (Cruz *et al.* 2003*a*). The primary purpose of the present paper is to accordingly document the unrealistic nature of the outputs from these simulation studies and the level of underprediction bias involved in the models or modelling systems (or both), and then to explain the reasons for such results. Finally, comments are made on the manner in which two of the canopy fuel characteristics (i.e. foliar moisture content and canopy base height) involved in these simulation modelling studies are handled as well the interpretation of the two crown fire hazard indices.

Wind speeds quoted in this article are in terms of the international 10-m open standard (Lawson and Armitage 2008) unless otherwise stated. For the convenience of the reader, a summary list of the variables, including their symbols and units, referred to in the equations and text is given at the end of this article.

Evidence for underprediction of crowning potential in relation to environmental conditions

The notion of an underprediction trend associated with the modelling systems used in various simulation studies has also been hinted at by others. Hall and Burke (2006) found in applying the NEXUS modelling system to prefire fuel complex data collected in the area burned by the 2002 Hayman Fire in north-central Colorado (Graham 2003) that the system failed to simulate the crowning activity actually observed under the weather and fuel moisture conditions that prevailed. Similarly, Agee and Lolley (2006) noted that the low torching potential found in their simulations was 'contradictory to local and regional experience on recent wildfires'. Fulé *et al.* (2001*a*) also recognised that simulation outputs from the NEXUS modelling system appeared contradictory to actual wildfire experience, noting that 'simulated fires using our fuel and weather conditions proved nearly impossible to crown using realistic data, even though real fires had crowned under similar or even less severe conditions'. Here, we specifically discuss and provide evidence for the underprediction bias in terms of wind speed and dead fuel moisture content.

Wind speed and dead fuel moisture combinations

The simulations produced in several studies examining fuel treatment effectiveness reveal a rather low potential for crown fire behaviour relative to the specified environmental conditions (e.g. Scott 1998*a*; Graves and Neuenschwander 2001; Fulé *et al.* 2002; Perry *et al.* 2004; Raymond and Peterson 2005; Agee and Lolley 2006; Hall and Burke 2006; Harrington *et al.* 2006; Page and Jenkins 2007; Roccaforte *et al.* 2008). This is reflected in the threshold wind speeds required for the onset of crowning as represented by the TI and for active crown fire spread as represented by the CI. Both values are generally quite high considering that the simulations are generally based on extremely dry fuel moisture conditions. In many cases, these simulation studies have reported TI and CI values associated with gale-force winds (i.e. sustained winds greater than $\sim$100 km h^{-1}). Such winds seldom occur inland, but when they do, they generally result in trees and whole forest stands being blown down over large areas (List 1951). Scott (2006) has indicated that these very high wind velocities simply indicate 'a very low potential for initiating a crown fire' and that wind speeds at or in excess of 100 km h^{-1} 'occur so rarely that crown fire can be considered nearly impossible to initiate'. Stephens *et al.* (2009) suggest that such levels of wind strength should be 'interpreted as a characteristic of a forest structure that is extremely resistant to passive crown fire'. Although these are possible explanations, they aren't the only ones.

It can be argued that the outcomes of these simulation studies are realistic in that they simply reflect the fact that both strong winds and dry fuels are required to achieve any sort of torching or crowning activity. Although this may be intuitively true for areas that have undergone some form of fuel treatment, for control or untreated areas, the simulation results do not appear realistic based on general observation and experience (Fig. 1 and Table 1), thereby suggesting that the authors of these simulation studies have failed to compare their simulation outputs with empirical observation in order to gauge that their results are realistic (Alexander 2006). Empirical evidence from outdoor experimental crown fires (Stocks *et al.* 2004; Cruz *et al.* 2005) and from wildfire case study documentation (Alexander and Cruz 2006) provides a ready test of this assertion. Fig. 1*a* is a plot of the range in the fine dead fuel moisture (FDFM, %) as per Rothermel (1983) and 10-m open wind speed (U_{10}, km h^{-1}) associated with a dataset of 54 documented crowning wildfires from across North America as taken from a summary given in Alexander and Cruz (2006). FDFM is referred to as the 'estimated fine fuel moisture' in Cruz *et al.* (2004, 2005), Alexander and Cruz (2006), and Alexander *et al.* (2006).

Also plotted in Fig. 1*a* is the 1-h time-lag fuel moisture content (Fosberg and Deeming 1971; Deeming *et al.* 1977) – in lieu of the FDFM – and U_{10} pairs used in the control or no-treatment fuel complexes for a selected set of fuel treatment effectiveness simulation studies. It is apparent from Fig. 1*a* that the conditions used in these simulation studies are extremely severe and not representative of the conditions commonly encountered in large, high-intensity wildfire incidents that involve extensive crowning activity.

Fig. 1*b* illustrates the level of underprediction bias associated with crown fire rate of spread for nine simulation studies by comparing the resultant outputs with observed wildfire rates of spread in relation to U_{10}; some additional observations are given in Table 1. As a general trend, the simulation studies, even though they are relying on extremely dry fuel moisture conditions, require almost a doubling in the U_{10} to attain the level of fire spread rates contained within the wildfire dataset. It is evident from the plots of the TI and CI values (Fig. 1*c*) – the outputs sought by these studies in order to quantify stand or landscape 'flammability' – that the simulation results constitute a distinctly different population from the dataset compiled by Alexander and Cruz (2006) that is based largely, but not exclusively, on wildfires in the western and northern North American coniferous forests. The TI and CI values presented in Fig. 1*c* are applicable to stands with mostly low (i.e. $<$3 m) to moderately high (i.e. 3–8 m) canopy base heights. The various simulation studies generally indicate that exceptionally dry fuel conditions and very strong winds are required for passive and active crowning activity compared with the conditions associated with the documented wildfires.

Wind speed limits

Also noteworthy in Fig. 1*c* is the magnitude of simulated wind speeds, especially in respect to the TI, in several cases in excess of 100 km h^{-1}, given in some of these and other studies (e.g. Scott 1998*a*; Fiedler and Keegan 2003; Monleon *et al.* 2004; Perry *et al.* 2004; Fried *et al.* 2005; Ager *et al.* 2007; Moghaddas and Stephens 2007; Stephens *et al.* 2009). This is consentaneous with other studies aimed at quantifying the potential crown fire behaviour associated with specific fuel complex structures that have reported winds close to or in excess of 1000 km h^{-1} (e.g. Raymond and Peterson 2005; Hall and Burke 2006; Johnson 2008; Stephens *et al.* 2009; Vaillant *et al.* 2009*a*). Some authors have chosen to simply express their TI and CI (6.1-m open wind speeds) values as $\geq$40.2 km h^{-1} or the CI separately as $\geq$64.4 km h^{-1} (e.g. Skog *et al.* 2006; Huggett *et al.* 2008), thereby masking the possibility of very high speeds presumably required for crowning; $\geq$85 km h^{-1} has also recently appeared (Battaglia *et al.* 2008) and $>$145 km h^{-1} (Fiedler *et al.* 2010) have also recently appeared. More recently, some authors have elected to cite only the CI values (e.g. Ager *et al.* 2007; Brown *et al.* 2008; Finkral and Evans 2008).

In contrast to the winds reported in Fig. 1*c*, the 10-m open winds associated with the eight crown fire rate of spread observations used in the formulation of the Rothermel (1991) crown fire rate of spread model averaged 38 km h^{-1} and ranged from 20 to 83 km h^{-1}. The highest wind speed (i.e. 83 km h^{-1}) was associated with the later stages of the major run of the 1967 Sundance Fire in complex mountainous terrain in northern Idaho (Anderson 1968). If this one observation was removed, the winds would have averaged 32 km h^{-1}. Thus, based on all of the available evidence (i.e. Rothermel 1991; Alexander and Cruz 2006; Table 1), one can say with some degree of confidence that there has been no documented active crown fire of any size associated with sustained winds greater than $\sim$80 km h^{-1} reported to date.

Dead fuel moisture levels

In the development of his crown fire rate of spread model, Rothermel (1991) equated the FDFM of Rothermel (1983) to the 1-h time-lag fuel moisture content; this lack of distinction has undoubtedly led to some of the confusion now seen in several simulation studies. He then estimated the 10- and 100-h time-lag values by adding 1.0 and 2.0% to the FDFM value respectively. Some simulation studies (e.g. Cram *et al.* 2006), including many of those identified in Fig. 1*a* and 1*b*, have chosen to use the dead fuel moisture time-lags generated by the US National Fire Danger Rating System (NFDRS) (Deeming *et al.* 1977) rather than estimating the 1-h time-lag fuel moisture content from the FDFM or using the seasonal moisture condition scenarios (or both) presented in Rothermel (1991).

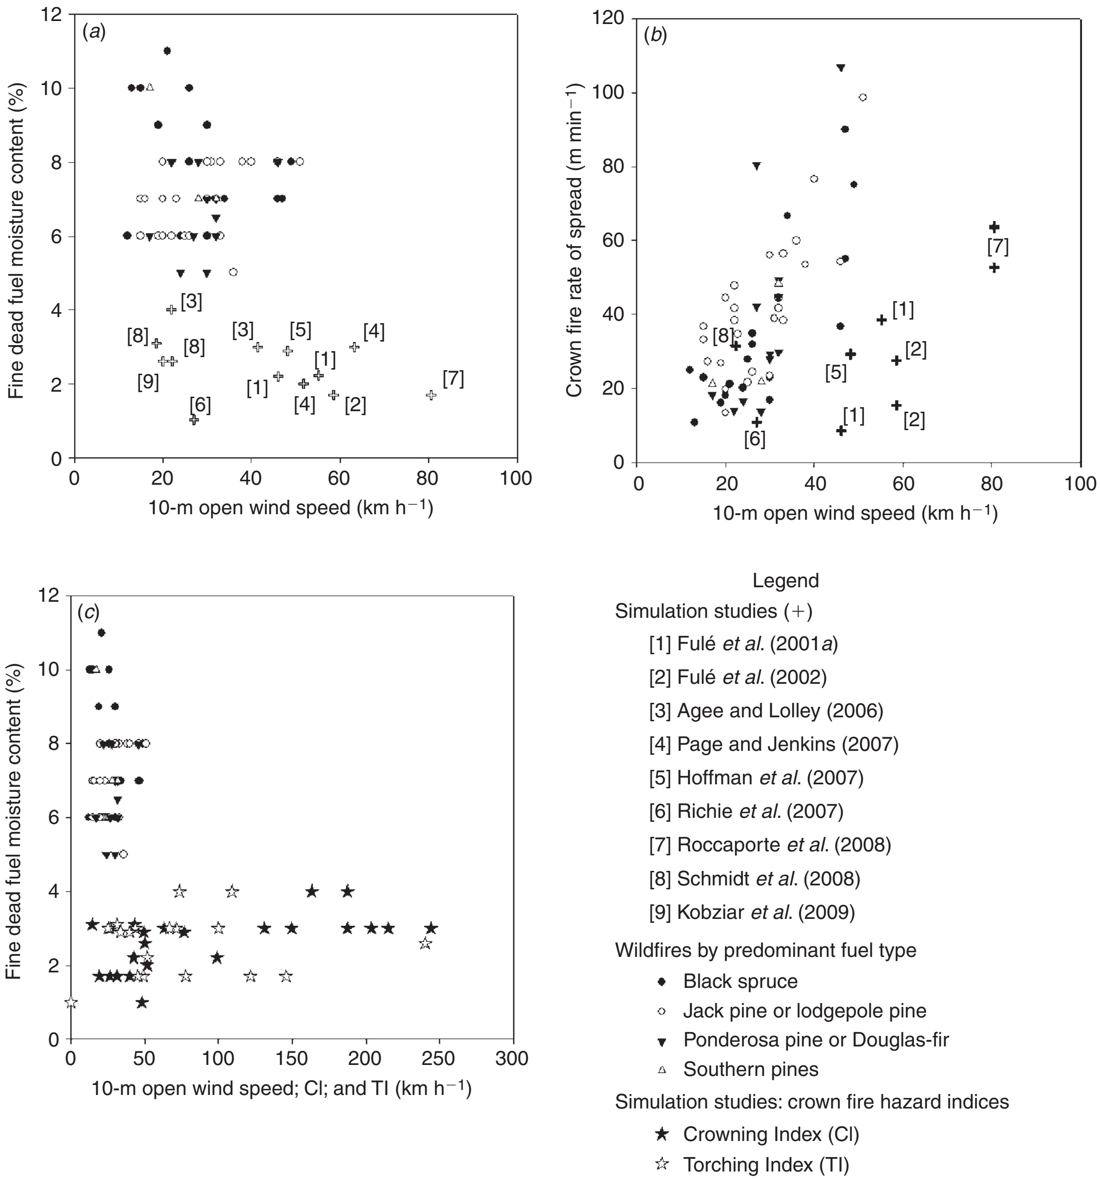

Fig. 1. Environmental conditions and associated crown fire rates of spread and indices of crown fire hazard for a dataset of actively crowning wildfires assembled by Alexander and Cruz (2006) and for a sample of selected simulation studies that have appeared in the scientific peer-reviewed literature: (*a*) fine dead fuel moisture *v.* 10-m open wind speed; (*b*) crown fire rate of spread *v.* 10-m open wind speed; and (*c*) fine dead fuel moisture *v.* 10-m open wind and Scott and Reinhardt's (2001) two crown fire hazard indices. Level terrain is assumed in all cases.

For the purpose of their simulations, Roccaforte *et al.* (2008) assumed 1-, 10- and 100-h time-lag fuel moisture contents of 1.7, 3.0 and 4.5% respectively, representing the 97th percentile level of fire weather severity based on 34 years of archived NFDRS calculations. DeRose and Long (2009) similarly applied values of 1.9, 2.1 and 3.2% respectively in their simulations. In calculating TI and CI values at the time that the 2002 Cone Fire in north-eastern California burned into their experimental fuel treatment plots, Ritchie *et al.* (2007) applied the NFDRS 1-h time-lag fuel moisture content of 1.0% as computed at a nearby fire weather station. The 10- and 100-h values both registered 2.0%. These three situations represent extremely low fuel moisture conditions for coniferous forests in all three categories.

Rothermel (1991) reported value ranges of 3–8, 4–9 and 5–9% respectively for the 1-h (i.e. FDFM was regarded as a surrogate), 10-h and 100-h time-lag fuel moisture contents associated with the wildfires used in the development of his crown fire rate of spread model. Even for his worst case 'late summer, severe drought' scenario, Rothermel (1991) only used 1-h (i.e. FDFM), 10-h and 100-h time-lag fuel moisture contents of 3.0, 4.0 and 6.0% respectively.

Table 1. Characteristics of some of the best-known or well documented (or both) crowning wildfires in conifer forests of North America and Australasia associated with exceptionally strong winds on level to gently undulating terrain not included in Fig. 1

Predominant fuel types are sand pine (*Pinus clausa*) and radiata pine (*P. radiata*). FDFM, fine dead fuel moisture; ROS, rate of spread; U_{10}, 10-m open wind speed. For U_{10}, the World Meteorological Organization standard to express wind speed at a height of 10 m in the open was followed here (Lawson and Armitage 2008). Winds measured at a height of 6.1 m in the open, as per the standard for fire danger rating and fire behaviour prediction used in the United States (Deeming *et al.* 1977; Rothermel 1983), were increased by 15% to approximate the U_{10} standard (Lawson and Armitage 2008)

Reference	Name of fire	Geographical location	Date (dd/mm/yy)	Predominant fuel type(s)	FDFM (%)	ROS ($m\,min^{-1}$)	U_{10} ($km\,h^{-1}$)	Type of crown fire
Stocks and Walker (1973)	Garden Lake	Ontario, CAN	02/06/30	Black spruce–jack pine–balsam fir	11	–[A]	48	Active
Folweiler (1937)	Big Henry	Florida, USA	12/03/35	Sand pine	–[B]	135–150	68	Active
Prior (1958)	Balmoral	New Zealand	26/11/55	Radiata pine	8	28	60	Passive and active
Schaefer (1957)	Dudley Lake	Arizona, USA	14/06/56	Ponderosa pine	6	–[C]	64	Active
Dieterich (1979)	Burnt	Arizona, USA	02/11/73	Ponderosa pine	9	30	74	Passive[D]
Geddes and Pfeiffer (1981)	Caroline	South Australia	02/02/79	Radiata pine	5	67	45	Active
Keeves and Douglas (1983)	Mount Muirhead	South Australia	16/02/83	Radiata pine	4	207	80	Active
NFPA (1992)	Spokane area	Washington, USA	16/10/91	Ponderosa pine	10[E]	30	66[E]	Passive and active[F]

[A]According to Stocks and Walker (1973), the extremely strong winds caused 'crowning and contributed greatly to the very fast spread of the fire' that saw two sustained runs of 24 and 64 km take place over a 26-h period on 1–2 June.
[B]According to Folweiler (1937), no measurements of relative humidity were available but it was 'probably low'.
[C]According to Schaefer (1957), the fire made a sustained run of 16 km. Dieterich (1976) estimated Byram's (1959) fireline intensity to have been 52 925 $kW\,m^{-1}$.
[D]According to Dieterich (1979), 'Damage from this fast-spreading fire was extremely variable ranging from complete destruction of crown material in patches of saplings and pole timber and an occasional mature tree, to large areas where the only evidence of fire was a blackened litter layer and slight scorch on the lowest portions of the crowns', and that much of the ponderosa pine was 'open grown, and tree crowns extended to within 4–5 feet [1.2–1.5 m] of the ground'. Alexander (1998) computed the fireline intensity at the head of the fire to be 5251 $kW\,m^{-1}$ using Eqn 4 and the critical surface fire intensity for initial crown combustion to be just 343 $kW\,m^{-1}$ using Eqn 1.
[E]Based on Alexander and Pearce (1992).
[F]According to the NFPA (1992) case study report, it was observed that: typically stands of ponderosa pine contain dead branches extending to the ground. In some cases, these 'ladder fuels' enabled the fire to reach the crowns of the 30- to 100-foot pine trees and would result in the fire spreading at extremely high rates. Unlike other severe wildland fires, however, this 'crowning' was fairly limited.

As illustrated in Fig. 1*a*, Alexander and Cruz (2006) found for a large database composed mainly of western and northern North American wildfires that the FDFM commonly varied between 6 and 10%. The moisture content of shaded needle litter in conifer forest stands very seldom is less than 2.5–3.0% (Countryman 1977; Harrington 1982; Rothermel *et al.* 1986; Hartford and Rothermel 1991; Wotton and Beverly 2007). The 1-h time-lag NFDRS fuel moisture content can easily be ~2.0% less than the shaded condition represented by the FDFM owing to the effects of solar radiation on fully exposed fuels. This is the reason for the very low fuel moisture conditions commonly associated with the simulation studies on fuel treatment effectiveness (Fig. 1*a*). Considering that the fine, dead fuels represented by the 1-h time-lag fuels are the principal carrier for surface fire spread, the use of the NFDRS computation in lieu of the FDFM represents a significant departure in the application of Rothermel's (1991) crown fire rate of spread model.

Reasons for underprediction of potential crown fire behaviour

The comparison of simulation results with actual observed data presented in Fig. 1 suggests there is a problem in the fundamental underlying models or the manner (or both) in which the models were implemented in the modelling systems. An in-depth analysis of the modelling system framework as dictated by the linkages between the Rothermel (1972, 1991) and Van Wagner (1977, 1993) models reveals that the underprediction bias in the assessment of potential crown fire behaviour arises from three principal sources: (1) incompatible model linkages; (2) use of surface and crown fire rate of spread models that have an inherent underprediction bias; and (3) the reduction in crown fire rate of spread based on the use of crown fraction burned functions. A further potential source of bias is the use of uncalibrated custom fuel models. All but one of these bias sources (i.e. the second one) arise from what we believe is unsubstantiated use of the cited models.

Rothermel (1972) surface fire–Van Wagner (1977) crown fire initiation model linkages

The implemented linkage between the outputs of the Rothermel (1972) surface fire model (i.e. rate of spread and intensity) and the Van Wagner (1977) crown fire initiation model overlooks an important assumption of the latter model. Through a combination of physical reasoning and empirical observation, Van Wagner (1977) defined quantitative criteria to predict the onset of crowning. He defined the critical surface fire intensity for initial crown combustion (I_o, kW m^{-1}) as a function of the canopy base height (CBH, m), and heat of ignition (h, kJ kg^{-1}):

$$I_o = (C \cdot \mathrm{CBH} \cdot h)^{1.5} \tag{1}$$

where h is in turn determined by the foliar moisture content (FMC, %) (Van Wagner 1989, 1993):

$$h = 460 + 25.9 \cdot \mathrm{FMC} \tag{2}$$

Van Wagner (1977) considered the quantity C in Eqn 1, the criterion for initial crown combustion, 'is best regarded as an empirical constant of complex dimensions whose value is to be found from field observations'. Van Wagner (1977) derived a value for the proportionality constant C using the following transformation of Eqn 1 on the basis of a blend of three experimental crown fires carried out in a red pine (*Pinus resinosa*) plantation:

$$C = \frac{I_o^{0.667}}{(\mathrm{CBH} \cdot h)} \tag{3}$$

The surface fire intensity at the onset of crowning was estimated to be ~2500 kW m^{-1} (Van Wagner 1968). Thus, for a CBH of 6.0 m and FMC of 100%, $C = 0.010$ (kW$^{2/3}$ kJ^{-1} kg m$^{-5/3}$).

Van Wagner (1977) equated I_o to Byram's (1959) fireline intensity (I_B, kW m^{-1}), which he calculated from measurements of fire spread rate and fuel consumption:

$$I_B = H \cdot w_a \cdot r \tag{4}$$

where H is the low heat of combustion (kJ kg^{-1}), w_a is the fuel consumed in the active flaming front (kg m^{-2}), and r is the rate of fire spread (m s^{-1}) (Alexander 1982). It is possible to express the requirements for the onset of crowning in terms of the surface fire spread rate by replacing I_o for I_B in Eqn 4 and working backwards (Van Wagner 1989, 1993; Forestry Canada Fire Danger Group 1992), giving the following result:

$$R_i = \frac{60 \cdot I_o}{H \cdot w_a} \tag{5}$$

where R_i is the critical surface fire rate of spread for crown fire initiation (m min^{-1}).

Modelling systems such as NEXUS, FlamMap, BehavePlus, FARSITE, FFE-FVS, and FMAPlus calculate fireline intensity from Rothermel's (1972) reaction intensity (I_R, kW m^{-2}) (Albini 1976):

$$I_B = I_R \cdot t_r \cdot r \tag{6}$$

where t_r is the flame-front residence time (s). Fireline intensities calculated in this manner are consistently lower than per the original Byram (1959) formulation (Cruz *et al.* 2003*a*, 2004). The extent of the differences is a function of the fuelbed characteristics. For the original 13 standard US fire behaviour fuel models as described by Anderson (1982), Byram's (1959) fireline intensity (Eqn 4) is larger than the Rothermel (1972) I_R-derived fireline intensity by a factor of 2 to 3 (Cruz *et al.* 2004).

The implication of these differences within a modelling system such as NEXUS is that higher simulated surface fire rates of spread, and consequently stronger wind speeds and hence larger TI values, are necessary to induce crowning than if the model linkages were to follow the original model assumptions. The end result is increasingly large TI values. Fig. 2 presents a graphical representation of the magnitude of this error for the Anderson (1982) Fuel Model 2 – Timber (grass and understorey) and Fuel Model 10 – Timber (litter and understorey) considering an I_o of 2935 kW m^{-1} per Eqns 1 and 2 based on a CBH of 5.0 m and an FMC of 140%; the output of Fuel Model 9 – Hardwood litter would be very similar to that of Fuel Model 10. The increase in mid-flame wind speed required for the onset of crowning is 72% (i.e. from 6.5 to 10.9 km h^{-1}) for Fuel Model 2 and 48% (i.e. from 8.2 to 12.1 km h^{-1}) for Fuel Model 10. The differences observed in this modelling exercise are considered as conservative in nature. The calculations of Byram's (1959) fireline intensity undertaken here assume that the fuels consumed in the flame front and thus contributing to the upward heat fluxes are the fine, dead and live fuels plus the 10-h time-lag fuels, whereas Van Wagner (1977) in his original formulation did not specifically differentiate between the fuels consumed during flaming as opposed to flaming and smouldering or glowing combustion. In other words, he assumed w_a was equivalent to the difference he obtained from pre- and post-burn fuel sampling – i.e. the fuel consumed in the active flaming front and by glowing or smouldering combustion following passage of the front (w, kg m^{-2}).

Conceptually, the two methods of computing Byram's (1959) fireline intensity should, in theory, yield nearly identical results. The main differences between these two arise from the use of the I_R and t_r models in the Rothermel (1972) model to calculate Byram's (1959) fireline intensity. I_R is estimated from an empirical model developed for homogeneous fuelbeds under no-wind/no-slope conditions in a laboratory setting. How well these assumptions hold for natural surface fuelbeds, with heterogeneous fuel particle and moisture content distributions is unknown, as the model has never been evaluated against field data to our knowledge other than the attempt by Brown (1972) involving simulated slash fuelbeds.

The use of Anderson's (1969) model to estimate t_r in Eqn 6 is the most likely source for the differences between the two methods of determining Byram's (1959) fireline intensity. Research on t_r in natural fuelbeds has identified fuel load, compactness, particle size and moisture as well as wind speed as the most influential variables (Cheney 1981; Nelson 2003). Anderson's (1969) model predicts t_r solely from the characteristic or average weighted size of individual fuel particles.

Nelson (2003) developed and evaluated a semi-physically based model to predict t_r that takes into account fuelbed structure and combustion zone properties. A comparison between the Anderson (1969) and Nelson (2003) t_r models reveals that the former model consistently yields lower t_r values when w_a exceeds ~0.5 kg m^{-2} (Fig. 3). Evaluation data for simulated fuelbeds of slash pine (*Pinus elliottii*) needle litter (Nelson and Adkins 1988) and ponderosa pine (*P. ponderosa*) and Douglas-fir (*Pseudotsuga menziesii*) slash (Brown 1972) reveal a marked underprediction of t_r by Anderson's (1969) model and general agreement with Nelson's (2003) model.

If Nelson's (2003) model is considered to provide an acceptable prediction of t_r, as supported by Fig. 3 and his own evaluation against an array of artificial fuelbeds, the Anderson (1969) model is underpredicting t_r in fuel beds with medium to high available fuel loads. This error is propagated within the modelling system and leads to low fireline intensities, and in turn, a low potential for crown fire initiation as illustrated in Fig. 2.

Underprediction bias in the Rothermel (1972) surface fire rate of spread model

In addition to the incompatibility between the various US fire modelling systems and Van Wagner's (1977) criteria for crown

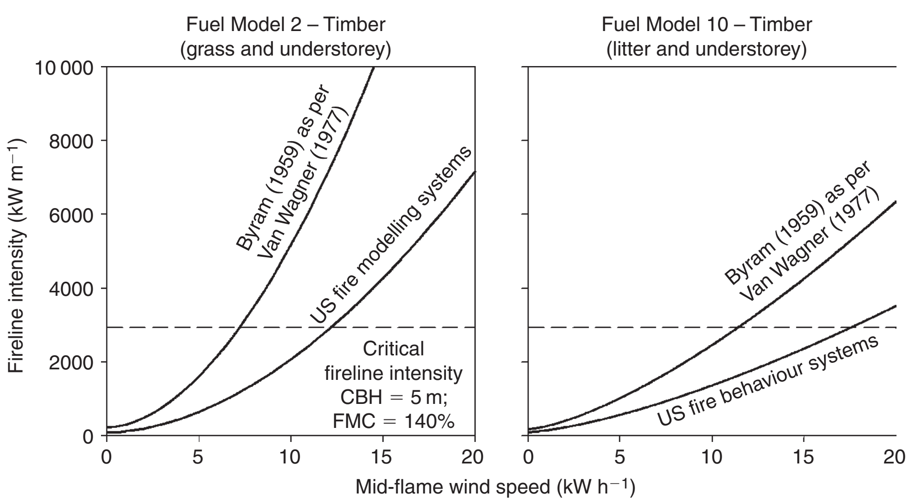

Fig. 2. Critical mid-flame wind speeds required for crown fire initiation as per Van Wagner's (1977) critical surface fire intensity criteria for two US fire behaviour fuel models (Anderson 1982) based on different methods of calculating fireline intensity (i.e. Byram (1959) as per Van Wagner (1977) *v.* US fire behaviour modelling systems) for a particular canopy base height (CBH) and foliar moisture content (FMC) equating to a critical surface fire intensity for initial crown combustion (I_o) of 2920 kW m^{-1}. The following environmental conditions were held constant: slope steepness, 0%; fine dead fuel moisture, 4%; 10- and 100-h time-lag dead fuel moisture contents, 5 and 6% respectively; live woody fuel moisture content, 75%; and live herbaceous fuel moisture content, 75%. The associated 10-m open winds would be a function of forest structure and can be approximated by multiplying the mid-flame wind speed by a factor varying between 2.5 (open stand) and 6.0 (dense stand with high crown ratio) (Albini and Baughman 1979).

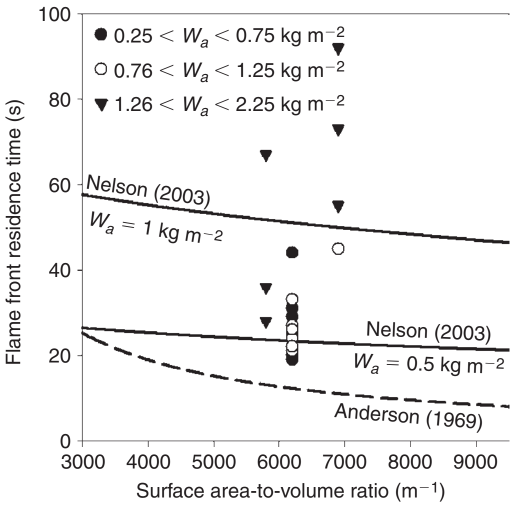

Fig. 3. Sensitivity of Anderson (1969) and Nelson (2003) flame front residence time models to surface area-to-volume ratio and fuel consumed in the active flaming front (w_a). For Nelson's (2003) model, the following environmental conditions were held constant: fuelbed depth, 0.1 m; fuel moisture content, 5%; and mid-flame wind speed, 5 km h^{-1}. Data points represent computed flame front residence times from experimental fires conducted in simulated fuelbeds of slash pine needle litter (Nelson and Adkins 1988) and ponderosa pine and Douglas-fir slash (Brown 1972), where it was implicitly assumed that w was $\sim w_a$.

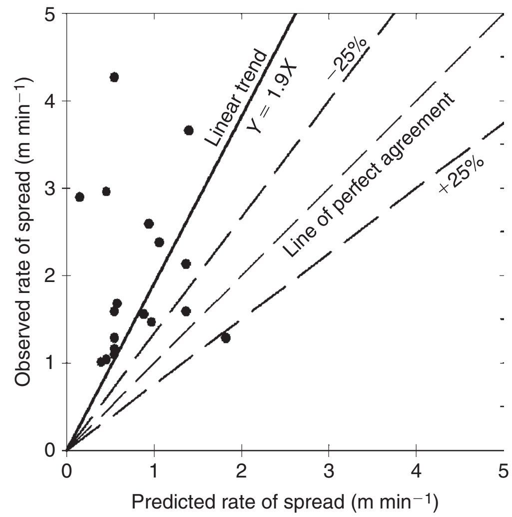

Fig. 4. Observed head fire rates of spread >1 m min^{-1} associated with prescribed burning experiments in ponderosa pine forests of Yosemite National Park, CA, *v.* predictions based on the Rothermel (1972) surface fire rate of spread model for Anderson (1982) Fuel Model 9 – Hardwood litter (adapted from van Wagtendonk and Botti 1984). The dashed lines around the line of perfect agreement indicate the ±25% error interval.

fire initiation with respect to determining w_a, a certain amount of uncertainty exists as to whether the Rothermel (1972) surface fire model can in fact reliably predict, in certain conifer forest stand types, the spread rate of moderate- and high-intensity surface fires that would lead to crowning. Studies that have evaluated Rothermel's (1972) fire spread model for any of the Anderson (1982) stylised 'timber' fuel models (numbers 2, 8, 9 and 10) have identified underprediction trends (Norum 1982; van Wagtendonk and Botti 1984; Grabner *et al.* 1997, 2001). This underprediction trend or bias arises from the sensitivity of the Rothermel (1972) fire spread model to the compactness of the horizontally oriented surface fuelbeds associated with these fuel models (Catchpole *et al.* 1993) and has been discussed in detail by Cruz and Fernandes (2008). Most investigators commonly develop an adjustment factor for rate of spread predictions on the basis of their performance testing (Rothermel and Reinhart 1983). Stephens (1998) for example used the adjustment factors derived by van Wagtendonk and Botti (1984) in his simulation study.

Modelling systems like NEXUS are widely applied to western US ponderosa pine forests (e.g. Johnson *et al.* 2007) and yet performance testing of Rothermel's (1972) model in such fuel complexes is limited to a single outdoor field study by van Wagtendonk and Botti (1984). The same underprediction bias seen in other studies is also evident in their study (Fig. 4 and Table 2). Considering that surface rate of fire spread is a factor in determining the onset of crowning in coniferous forests, the use of unadjusted predictions from stylised fuel models constitutes yet another source of underprediction bias in assessing crown fire potential.

Underprediction bias in the Rothermel (1991) crown fire rate of spread model

Until recently, the only comparison of observed crown fire spread *v.* predictions from Rothermel's (1991) model was that undertaken by Goens and Andrews (1998) on the 1990 Dude Fire that occurred in central Arizona. They found good agreement between predicted and observed spread distances. However, the Dude Fire was considered by Rothermel (1991) as a plume-dominated crown fire as opposed to a wind-driven crown fire, for which he considered his predictive methods were not applicable.

Several studies (Cruz *et al.* 2003*a*, 2005; Stocks *et al.* 2004; Alexander and Cruz 2006) have separately evaluated the Rothermel (1991) crown fire rate of spread model against outdoor experimental crown fire and wildfire datasets (Table 3). A composite summary of those evaluations is presented in Fig. 5. Rothermel's (1991) model underpredicted all 34 experimental observations, with a mean absolute error of 71% (Table 2).

A distinct underprediction bias was also evident in the wildfire observations (Fig. 5*b*). All 54 observations were underpredicted with a mean absolute error of 61%; 63 and 58% for the US and Canadian wildfires respectively (Table 2). The Rothermel (1991) model consistently underpredicted the four observed spread rates in ponderosa pine forests extracted from the 2002 Hayman Fire in north-central Colorado (Finney *et al.* 2003; Graham 2003) by a factor of 2.8 (Alexander and Cruz 2006).

Scott (2006) has acknowledged the underprediction trends evident in Fig. 5 and suggested the use of a correction or adjustment factor (1.7) to obtain what Rothermel (1991) defined as the near-maximum crown fire rate of spread derived on the basis of five 'chance' observations of temporary escalations in

Table 2. Model performance statistics for the Rothermel (1972), Rothermel (1991) and Schaaf *et al.* (2007) rate of fire spread models evaluated against different types of data sources

Statistic	Rothermel (1972)	Rothermel (1991)		Schaaf *et al.* (2007)
	Prescribed fires	Experimental fires	Wildfires	Wildfires
Number of observations	18	34	54	15
Root mean square error	1.54	27	30.7	22.2
Mean absolute error	1.23	22.2	26.0	15.2
Mean absolute percentage error	57	70.8	60.7	41.6
Mean bias error	−1.16	−22.2	−25.9	−15.7
Percentage within ±25% error	6	3	4	20
Over and under predictions	1, 17	0, 34	0, 54	1, 14

Table 3. Basic descriptive statistics associated with the experimental fire and wildfire datasets used in the evaluation of the Rothermel (1991) crown fire rate of spread model as shown in Fig. 5

For Experimental fires, refer to Table 1 in Cruz *et al.* (2005) and to Stocks *et al.* (2004) for the specific details on data sources. For Wildfires, refer to Alexander and Cruz (2006) for the specific details on data sources

Variable	Experimental fires ($n = 34$)				Wildfires ($n = 54$)			
	Mean	s.d.	Min.	Max.	Mean	s.d.	Min.	Max.
10-m open wind speed (km h^{-1})	15.6	5.9	5	35	28.2	9.92	12	51
Air temperature (°C)	25.7	3.9	18.5	31.4	26.6	4.2	20	36
Relative humidity (%)	36.1	7.5	23	52	28	10.6	5	56
Fine dead fuel moisture (%)	7.8	1.9	4	12	7.2	1.37	5	11
Rate of fire spread (m min^{-1})	29.2	16.9	10.7	69.8	39.8	22.1	10.7	107

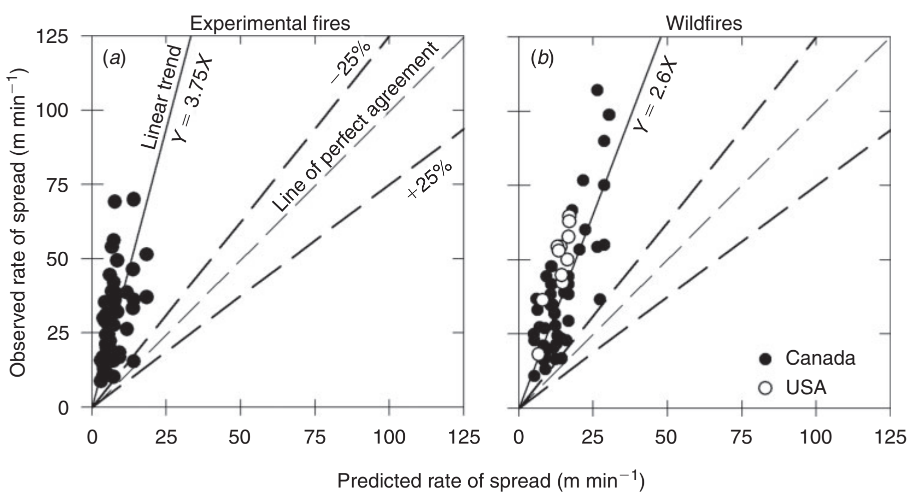

Fig. 5. Observed rates of spread of (*a*) experimental active crown fires; and (*b*) wildfires that exhibited extensive active crowning *v.* predictions based on the Rothermel (1991) crown fire rate of spread model. The dashed lines around the line of perfect agreement indicate the ±25% error interval.

crown fire spread but without any corresponding wind speed measurements. However, according to Rothermel (1991, p. 25), the near-maximum crown fire rate of spread adjustment was intended solely for predicting short bursts in crown fire spread that could be expected to occur during upslope runs and not as a general adjustment factor.

Why is the Rothermel (1991) model consistently under-predicting by a factor of ~2.5–3.0 and why does it also appear to be relatively insensitive to burning conditions? It is likely due to a multitude of interacting factors (Alexander 2006).

The Rothermel (1991) model is a simple relationship consisting of a correlation derived between the observed average crown fire rate of spread based on eight observations involving seven western US wildfires and the output of the Rothermel (1972) surface fire spread model using Fuel Model 10 and a wind-reduction factor of 0.4 (R_{10}, m min^{-1}) in order to adjust the 6.1-m open wind speed to a mid-flame height value (Albini and Baughman 1979). The Rothermel (1991) model for predicting active crown fire rate of spread (R_a, m min^{-1}) is as follows:

$$R_a = 3.34 \cdot R_{10} \quad (7)$$

Only four of the eight observations used in the model development involved level terrain, so the difficulty of obtaining representative winds in complex terrain relative to observed spread rate can be called into question. Furthermore, the overall average observed rate of spread for five of the eight observations used in the model development was 43 m min^{-1}, which seems reasonable for active or fully developed crown fires in light of the wildfire database compiled by Alexander and Cruz (2006). However, three of eight observations had spread rates of only 14 m min^{-1}. Without knowing what the associated canopy bulk density (CBD) values were for these three observations, such spread rates are low for active crown fires (Cruz *et al.* 2005; Alexander and Cruz 2006). This raises the issue as to the stage of development or degree of crown fire activity (i.e. passive crowning *v.* active crowning) associated with these three crown fire observations and their relative magnitude in the derivation of the Rothermel (1991) model.

From a conceptual perspective, it can be argued that the underlying relationships in the Rothermel (1972) model (i.e. developed from shallow surface fuelbeds in a laboratory setting) do not apply to crown fire phenomena, where the dimension of the fuelbed sustaining fire propagation and the heat flux generated are orders of magnitude higher. Rothermel (1972) readily acknowledged this point and clearly stated in the preface of his publication that the nature and mechanisms of heat transfer in a crown fire are considerably different than those for a surface fire and therefore stated that 'the model developed in this paper is not applicable to crown fires'. Thus, using R_{10} as a correlative or independent variable in what amounts to a statistical model is questionable. The underprediction tendency associated with Rothermel's (1991) model shown in Fig. 5 has also been found to occur with the crown fire rate of spread model developed recently by Schaaf *et al.* (2007) as part of the Fuel Characteristic Classification System (Ottmar *et al.* 2007). The Schaaf *et al.* (2007) model, based on a reformulation of the Rothermel (1972) model by Sandberg *et al.* (2007), is specifically designed to predict the rate of spread of crown fires in coniferous forests. Schaaf *et al.* (2007) undertook to test model performance on the basis of data extracted from Alexander and Cruz (2006) for 15 actively crowning wildfires in black spruce (*Picea mariana*) forests of Canada (Fig. 6 and Table 2). Cronan and Jandt (2008) observed the same underprediction bias evident in Fig. 6 with the experimental fires they conducted in Alaskan black spruce forests.

Another possible reason for the underprediction trend in the Rothermel (1991) model is its low sensitivity to changes in wind speed. As noted, the Rothermel (1991) crown fire spread model is a direct function of Fuel Model 10. Considering that heat transfer is optimised for vertically oriented, high-porosity fuelbeds (Rothermel 1972), the wind speed–rate of spread relationship of a litter and understorey fuelbed may not be representative of phenomena occurring in deep, low-packing-ratio fuel layers such as canopy fuels in a conifer forest stand. Cohen *et al.* (2006) have described in some detail the inadequacies of the Rothermel (1972) model framework to represent the processes determining crown fire propagation in conifer forests.

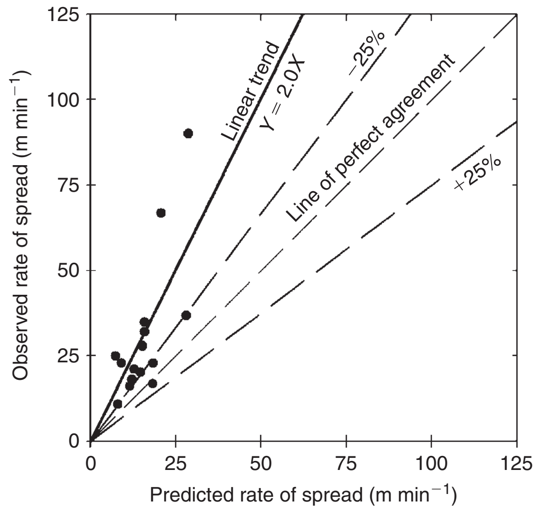

Fig. 6. Observed rates of spread of actively crowning wildfires in black spruce forests *v.* predictions based on the Schaaf *et al.* (2007) crown fire rate of spread model. The dashed lines around the line of perfect agreement indicate the ±25% error interval.

The seven wildfires used in the development of the Rothermel (1991) crown fire rate of spread model encompass a wide range in fuel complex structure and composition, although it is difficult to critically assess this factor because formal case study documentation is only available for two of the seven wildfires (Anderson 1968; NFPA 1990) that Rothermel (1991) used in his model development. The Rothermel (1991) crown fire rate of spread model does not explicitly take into account any stand or canopy fuel structure variables as inputs (e.g. CBH, CBD). Hence, crown fire behaviour in the Rothermel (1991) model is independent of the physical fuel characteristics associated with conifer forest stands (Finney 2004).

Rothermel (1991) indicated that the correlation he obtained between the observed crown fire rate of spread and the prediction of surface fire rate of spread from Fuel Model 10 did 'give reasonable results'. However, he was also quick to point out that 'It is readily apparent that more research is needed to strengthen this analysis', and emphasised that his guide represented 'first-order approximations of crown fire behavior' designed to aid operational decision-making.

All 34 experimental fires and 39 of the 54 wildfire observations presented in Fig. 5 involve boreal or boreal-like forest fuel complexes. Thus, it could be argued that the fires selected for evaluation are not 'applicable to the Northern Rocky Mountains or mountainous areas with similar fuels and climate' as per one of Rothermel's (1991) assumptions. Strictly speaking, this is a valid comment.

However, the Rothermel (1991) model has been directly and also indirectly applied through the application of fire modelling systems like NEXUS, FlamMap, FARSITE, FFE-FVS, FMAPlus and BehavePlus, to other distinctly different forest stand types and in other regions of the western US, including for example, the Sierra Nevada (Stephens and Moghaddas 2005*a*, 2005*b*; Dicus *et al.* 2009), north-central (Kobziar *et al.* 2009) and north-eastern (Ritchie *et al.* 2007) regions of California as well as the whole state (Vaillant *et al.* 2009*a*, 2009*b*), south-central (Hummel and Agee 2003), north-eastern (Graves and Neuenschwander 2001) and western Washington (Agee and Lolley 2006), north-eastern (Williamson 1999; Ager *et al.* 2007), central (Fitzgerald *et al.* 2005) and western Oregon (Raymond and Peterson 2005), south-western Utah (Stratton 2004), central Arizona (Goens and Andrews 1998), northern Arizona (Fulé *et al.* 2001*a*, 2001*b*, 2002, 2004), south-central New Mexico (Mason *et al.* 2007), northern Arizona–north-central New Mexico (Clifford *et al.* 2008), and even the north-eastern US (Duveneck and Patterson 2007). In defence of the datasets incorporated in Fig. 5, the fuel characteristics associated with montane and subalpine forests in the Northern Rocky Mountains – namely, ponderosa pine, lodgepole pine (*Pinus contorta*), Englemann spruce (*Picea engelmannii*) and subalpine fir (*Abies lasiocarpa*) are not that dissimilar structurally from forests composed of pure and mixed stands of red pine, jack pine (*Pinus banksiana*), black spruce, white spruce (*Picea glauca*) and balsam fir (*Abies balsamea*).

Reduction of crown fire rate of spread due to use of crown fraction burned functions

All of the fire modelling systems mentioned here (i.e. NEXUS, FlamMap FARSITE, FFE-FVS and FMAPlus), with the exception of BehavePlus, that integrate or link the Rothermel (1972, 1991) and Van Wagner (1977, 1993) models to predict the full range of fire behaviour apply a reduction factor to the predicted crown fire rate of spread based on a crown fraction burned (CFB) function (Table 4) as used for example in the Canadian Forest Fire Behaviour Prediction (FBP) System (Van Wagner 1989; Forestry Canada Fire Danger Group 1992).

The CFB, which indicates the proportion of tree crowns involved in the spread of the fire, varies from 0.0 (surface fire with no crown fuel involvement) to 1.0 (fully developed crown fire). In the FBP System, passive crown fire spread or intermittent crowning and continuous crowning or active crown fire spread is judged to occur at CFB values ranging from 0.1 to 0.89 and $\geq$0.9 respectively (Forestry Canada Fire Danger Group 1992).

The final rate of fire spread (R, m min^{-1}), whether surface or crown, is computed as follows:

$$R = R_s + \mathrm{CFB} \cdot (R_a - R_s) \quad (8)$$

where R_s is the predicted surface fire rate of spread (m min^{-1}) per Rothermel's (1972) model and R_a by Rothermel (1991) per Eqn 7.

The CFB adjustment scheme devised by Van Wagner (1993) provides for a gradual transition in a fire's spread rate from the initial onset of crowning (i.e. passive crown fire spread), as defined by Eqn 5, to the point of active crown fire development

Table 4. Description of computation procedures involved in predicting passive and active crown fire rate of spread in terms of crown fraction burned (CFB) within the various US fire modelling systems

FMAPlus performs the same crown fire computations as FARSITE and NEXUS

Spread regime	BehavePlus	NEXUS and FFE-FVS	FARSITE and FlamMap
Passive crown fire	Does not calculate a CFB for use in computations. Does not provide a spread rate output specifically associated with passive crown fires but does identify passive crown fires as a distinct type of fire.	Calculates CFB between 0.0 and 1.0 using a simple linear transition function between surface and active crown fire rates of spread (Scott and Reinhardt 2001). CFB values are higher than those produced by the CFB function used in FARSITE or FlamMap. Spread rate for passive crown fires is determined to be intermediate between the active crown fire and surface fire rates of spread based on the calculated CFB value.	Calculates CFB between 0.0 and 1.0 based on an exponential transition function between surface and active crown fire rates of spread developed by Van Wagner (1993). CFB values are lower than those produced by the CFB function used in NEXUS or FFE-FVS. Spread rate for passive crown fires assumed to be the same as the surface fire rate of spread.
Active crown fire	Uses Rothermel's (1991) model to predict the average active crown fire rate of spread.	Uses Rothermel's (1991) model to predict the average active crown fire rate of spread. There is also the option to apply the near-maximum crown fire rate of spread multiplier (i.e. 1.7).	Uses Rothermel's (1991) model to predict a reference active crown fire rate of spread that is then adjusted on the basis of the CFB. Because calculated CFB values are lower than those produced by the CFB function used in NEXUS and FFE-FVS, active crown fire spread rates remain less than that predicted by Rothermel's (1991) model even after an active crown fire is judged to have occurred.

based on Van Wagner's (1977) concept of a critical minimum spread rate for active crowning (R_o, m min^{-1}):

$$R_o = \frac{S_o}{\text{CBD}} \quad (9)$$

where S_o is the critical mass flow rate for solid crown flame (kg m^{-2} min^{-1}) and CBD is the canopy bulk density (kg m^{-3}). Van Wagner (1977) provided one estimate of S_o, namely 3.0 kg m^{-2} min^{-1} (Alexander 1988), based largely on a single experimental crown fire in a red pine plantation plot exhibiting a CBD of 0.23 kg m^{-3} (Van Wagner 1964). Cruz *et al.* (2005) have since confirmed the robustness of this estimate based on an examination of a relative large ($n = 37$) dataset of experimental crown fires carried out in several different conifer forest fuel complexes (Fig. 7*a*).

Dickinson *et al.* (2009) claim to have recalibrated Van Wagner's (1977) model represented by Eqn 9 on the basis of the foliar biomass per unit area or available canopy fuel load (CFL, kg m^{-2}) rather than the CBD:

$$R_o = \frac{23.4}{\text{CFL}} \quad (10)$$

This formulation implies that the propagation of active crown fire is not dependent in any way on the stand structure (i.e. height or crown depth) or, in other words, the vertical distribution of the available canopy fuel. It appears from the available experimental evidence that the Dickinson *et al.* (2009) modification of Van Wagner's (1977) R_o model is not as reliable at distinguishing active crown fires from passive crown fires as originally envisioned (Fig. 7*b*).

In deriving his estimate of S_o, Van Wagner (1977) computed the CBD as the available canopy fuel load divided by the canopy depth (Cruz *et al.* 2003*c*) and assumed that all the fuel was uniformly distributed. Admittedly, this is not always the case, for example, in multistoried stands (Reinhardt *et al.* 2006*b*) and even to a certain extent in red pine plantations (Sando and Wick 1972, pp. 6–7) such as Van Wagner (1964, 1968, 1977) worked in. Nevertheless, Alexander *et al.* (1991*b*) found that Van Wagner's (1977) simple model represented by Eqn 9 worked well at distinguishing between surface and crown fires in a black spruce–lichen woodland fuel complex that exhibited large gaps between clumps of trees and crowns that extended down to the ground surface. In their implementation of Eqn 9 in NEXUS, Scott and Reinhardt (2001) initially defined CBD as the maximum 4.5-m vertical running mean bulk density; this was later changed to a 3.0-m interval, although no reason was given (Peterson *et al.* 2005; Scott and Reinhardt 2005, 2007; Scott 2006). This represents a distinct departure from the manner in which Van Wagner (1977) calculated CBD and undoubtedly leads to higher CBD values and hence lower R_o values required for active crowning to occur. As such, it constitutes a violation of one of the fundamental assumptions of Van Wagner's (1977) active crown fire propagation model represented by Eqn 9.

The form of the CFB function varies among the fire modelling systems. FARSITE uses the original exponential form presented by Van Wagner (1993). NEXUS, however, assumes a linear adjustment when the rate of fire spread is between R_i and R_o (Scott and Reinhardt 2001). This gives distinctly different results even if the core models are the same (Fig. 8). Scott and Reinhardt (2001) explored the impact of Van Wagner's (1993) CFB function in FARSITE and found that even under extreme burning conditions, the crown fire rate of spread predicted by the Rothermel (1991) model was reduced by approximately one-third. Regardless of which CFB function is used, the result is a further increase in the underprediction bias (Stocks *et al.* 2004).

The BehavePlus modelling system (Andrews *et al.* 2008) has separately implemented the Rothermel (1972, 1991) surface and crown fire rate of spread and Van Wagner (1977) crown fire initiation and propagation models rather than attempt to directly link them using a CFB function. Thus, BehavePlus doesn't

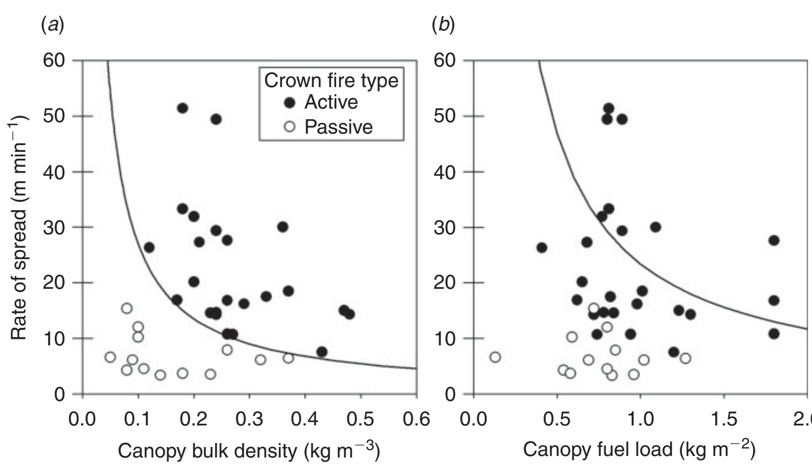

Fig. 7. Scatterplots of experimental crown fire rates of spread by type of spread regime *v.* two canopy fuel properties (adapted from Cruz *et al.* 2005). The curve in (*a*) represents Van Wagner's (1977) criterion for active crowning represented by Eqn 9, assuming an S_o value of 3.0 kg m^{-2} min^{-1}. The curve in (*b*) represents the Dickinson *et al.* (2009) recalibration of the Van Wagner (1977) criterion using canopy fuel load rather than canopy bulk density as represented by Eqn 10.

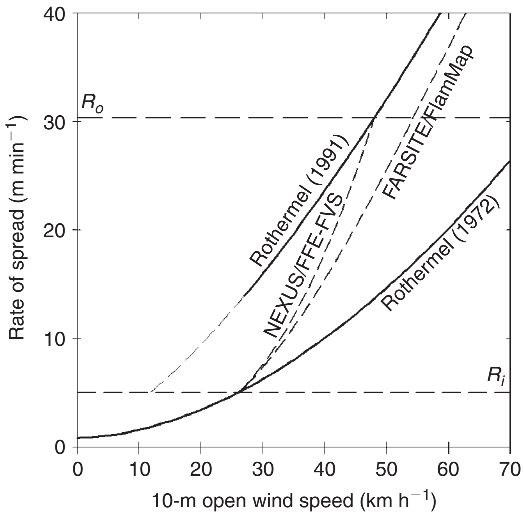

Fig. 8. Comparison of the effect of crown fraction burned functions on rate of fire spread used in the NEXUS and FFE-FVS (Scott and Reinhardt 2001; Reinhardt and Crookston 2003) *v.* FARSITE and FlamMap (Finney 2004, 2006) modelling systems in relation to the Rothermel (1972, 1991) surface and crown fire rate of spread models and Van Wagner's (1977) criteria for the critical minimum spread rates for crown fire initiation (R_i) and active crowning (R_o) for the Anderson (1982) Fuel Model 2 – Timber 2 (grass and understorey) with a canopy bulk density of 0.1 kg m^{-3}, canopy base height of 1.5 m, and a wind reduction factor of 0.2 (Albini and Baughman 1979). The following environmental conditions were held constant: slope steepness, 0%; fine dead fuel moisture, 6%; 10- and 100-h time-lag dead fuel moisture contents, 7 and 8% respectively; live woody fuel moisture content, 75%; live herbaceous fuel moisture content, 75%; and foliar moisture content, 140%. The dashed portion of the Rothermel (1991) curve represents output below the original dataset bounds for rate of spread.

provide a spread rate for passive or intermittent crowning but rather provides a transition to crowning ratio and an active crown fire spread ratio based on the values generated by Eqns 4 *v.* 1 and Eqns 7 *v.* 9 respectively in a manner analogous to Anderson's (1974) index of crowning potential as dictated by the ratio of predicted flame height *v.* an observed or measured CBH.

There is no experimental or sound theoretical evidence for a CFB effect on crown fire rate of spread. Furthermore, general observations of wildfires (e.g. Alexander *et al.* 1991*a*; Cohen *et al.* 2006) and documentation of experimental crown fires (e.g. Van Wagner 1964; Bruner and Klebenow 1979; Burrows *et al.* 1988; Fernandes *et al.* 2004; Stocks *et al.* 2004) indicate that a rather abrupt transition between surface and crown fire regimes is far more commonplace than a gradual transition as implied by a CFB function (Alexander 1998) and as illustrated in Fig. 8.

Use of uncalibrated custom fuel models

Understandably, the use of standard, stylised fuel models (Anderson 1982) in simulation studies examining fuel treatment effectiveness on potential crown fire behaviour limits the extent to which one can gauge the influence of surface fuelbed characteristics on the start and spread of crown fires. Furthermore, there is no empirical proof produced to date to substantiate that by simply increasing the number of fuel models (Scott and Burgan 2005) or reformulating Rothermel's (1972) surface fire rate of spread model (Sandberg *et al.* 2007) would greatly improve matters.

The use of calibrated custom fuel models to represent surface fuelbeds is thus seen by some as a more realistic alternative. However, the use of uncalibrated custom models (e.g. Bessie and Johnson 1995; Battaglia *et al.* 2008; Cheyette *et al.* 2008) can constitute another potential source of underprediction bias. Custom fuel models (Burgan and Rothermel 1984; Burgan 1987) are likely to be unsuccessful when developed without calibrating the predictions or tuning the parameters against field observations of fire behaviour (e.g. Hough and Albini 1978; Cruz and Fernandes 2008).

Studies that have evaluated custom fuel models in horizontally oriented fuels, such as found in conifer litter surface fuelbeds, have identified strong underprediction trends (e.g. Lawson 1972; McAlpine and Xanthopoulos 1989; Hély *et al.* 2001) and in other forest fuel complexes as well (e.g. Burrows 1994; Grabner *et al.* 1997). The effect of this underprediction trend or bias is noticeable in the studies of potential crown fire behaviour that rely on uncalibrated custom fuel models based on field sampling using methods such as those of Brown *et al.* (1982).

Agee and Lolley (2006), for example, predicted a flame height of 1.4 m for their control or untreated ponderosa pine–Douglas-fir fuel complex for simulations based on a 1-h time-lag fuel moisture content of 3% and 6.1-m open wind speeds of 36 km h^{-1}. Comparatively, the Hayman Fire in north-central Colorado (Finney *et al.* 2003; Graham 2003) went from ~5000 to 25 000 ha over a period of 12 h on 9 June 2002 under more moist fuel conditions (FDFM 6–7%) than that of the Agee and Lolley (2006) simulated situation and with a maximum U_{10} of 30–40 km h^{-1} at its peak (Alexander and Cruz 2006).

Similar unrealistic predictions of potential fire behaviour have been reported by others, for example by Page and Jenkins (2007) for lodgepole pine stands infested with mountain pine beetle (*Dendroctonus ponderosae*) in northern and north-eastern Utah and central Idaho (e.g. rates of spread of ~2.0 m min^{-1} for FDFM of 6% and 6.1-m open winds of 50 km h^{-1}) and by Stephens and Moghaddas (2005*a*, 2005*b*) for California mixed-conifer forests (rate of spread of 1.9 m min^{-1} for a 1-h time-lag fuel moisture content of 3.9% and 6.1-m open winds of 22 km h^{-1}). The low spread potential of these custom fuel model predictions explains the need for very dry fuels and high wind speeds in order to induce crown fire activity, as illustrated in Fig. 1*c*.

Other simulation modelling and interpretation issues

Selection of foliar moisture content levels

Van Wagner's (1977) crown fire initiation model is sensitive to FMC (Fuglem and Murphy 1980; Alexander 1988). Changing the FMC from 80 to 140% will almost double the surface fire intensity required for the onset of crowning (Alexander 1988). Within the simulation framework of the fire behaviour modelling systems like NEXUS, this will lead to a large increase in the critical surface fire rate of spread required for crown fire initiation and hence wind speed or fuel dryness (or both) necessary to initiate crown fire activity. Varner and Keyes (2009) recently pointed out that some modellers have assigned FMC 'values without justification or use values that lie on the extremes of published data'.

Scott and Reinhardt (2001) suggested using a constant or default FMC value of 100% as 'a reasonable approach' until better data exist. They also suggested that future research should be directed at compiling existing FMC data and then conducting field research to fill in data gaps. Keyes (2006) concluded on the basis of a review of FMC studies that a single FMC default value 'ignores established differences amongst tree species'. However, he also stated that 'For species lacking published FMC data, a low default value of 90 or 100% remains a prudently conservative assignment'. As a general rule of thumb, an FMC of 90% seems unduly low based on existing information. Chandler *et al.* (1983) regarded crown fire potential as 'high' when the FMC fell below 100%. Some authors have used an FMC of 100% in their simulation studies (e.g. Brown *et al.* 2008; Vaillant *et al.* 2009*b*), whereas others have elected to use much lower values.

Roccaforte *et al.* (2008) used an FMC of 80% in their simulations for ponderosa pine fuel complexes in north-western Arizona without any justification. Although this value might be appropriate for ponderosa pine forests in the south-western US, which typically experience their fire season much earlier in the year, it would be unduly low for other areas in the western US given the seasonal dynamics in FMC found to date in ponderosa pine. Several studies conducted in the western US indicate that the FMC typically ranges from 100 to 120% for 1-year-old ponderosa pine needles between July and September (Philpot and Mutch 1971; Agee *et al.* 2002; Finney *et al.* 2003; Faiella and Bailey 2007), the traditional peak burning period in the western US. Agee *et al.* (2002) and Faiella and Bailey (2007) in turn report FMC in the range of 250–335% and 180–220% respectively for new needle growth. Simulations should consider an aggregate or composite FMC taking into account the differences in moisture contents between new and old needles and the relative proportions of each as well as seasonal changes (cf. Van Wagner 1974). The proportion of new and 1-year and older needle growth is dependent on species, canopy position and site characteristics (Reich *et al.* 1995). Needle longevity for ponderosa pine has been reported to vary between 2 and 4 years in low to moderate elevation sites, but reaching 6 to 9 years in high-stress environments such as arid and alpine habitats (Ewers and Schmid 1981; Richardson and Rundel 1998). Assuming that new needle foliage makes up approximately one-third of the foliage biomass (Van Wagner 1967, 1974) and taking into account the midpoint of Faiella and Bailey's (2007) foliar moisture content ranges for 1-year and older needle foliage (i.e. 110%) and for new growth (i.e. 200%), a nominal FMC value for summertime conditions in ponderosa pine would be ~140%.

It appears the use of low FMC values is becoming commonplace in simulation studies examining potential crown fire behaviour. Stephens and Moghaddas (2005*a*, 2005*b*) used 75% for mixed conifers and Page and Jenkins (2007) used 70% for lodgepole pine. Neither study sampled FMC directly, referenced any previous studies of FMC or otherwise rationalised their FMC selection. Similarly, Stephens *et al.* (2009) used an FMC of 75% without any justification. In their study in ponderosa pine, Ritchie *et al.* (2007) indicated the FMC 'was estimated to be 75% since the Cone Fire burned under dry, north wind conditions following the long, dry summer'. Certainly FMC values this low have occasionally been observed (Keyes 2006). Van Wagner (1993) in fact computed FMC values that average 67% based on a weighting of the moisture contents of old needle foliage and fine, dead woody crown material relative to their separate fuel loadings (Van Wagner 1977). However, such low FMC levels have typically been reported in boreal coniferous tree species just before needle flushing in the spring (Van Wagner 1967, 1974; Fuglem and Murphy 1980).

The National Wildfire Coordinating Group (2008) recently recommended that in the absence of specific information on FMC, one should assume that the FMC is equal to the live woody fuel moisture content input given in BehavePlus, which presently allows for the FMC to vary from 30 to 300%. The moisture content of understorey shrub vegetation can reach 30% (Rothermel 1983) or less and thereby be treated as dead fuel. Existing information on the moisture contents of conifer trees and shrubs sampled at the same time and at the same location does not support this recommendation (e.g. Philpot 1963; Agee *et al.* 2002).

Some authors have selected FMC values below 30% in their application of fire behaviour modelling systems like NEXUS to insect-killed conifer forest stands (e.g. Cheyette *et al.* 2008). Given the empirical nature of Van Wagner's (1977) crown fire initiation model with respect to FMC, applying FMC values any lower than ~70% is not recommended, even if the computer software associated with modelling systems such as NEXUS or BehavePlus allow for it. What is needed is the derivation of a *C* value for use in Eqn 1 based on a carefully documented outdoor experimental fire(s) carried out at very low FMC levels in order to determine crown fire potential in canopy fuel layers comprised largely of fine, dead fuels (e.g. Kuljian and Varner 2010).

Canopy base height criteria

Another input in Van Wagner's (1977) crown fire initiation model, and one that readily favours the occurrence of crowning activity is the CBH. In fact, the natural variation in CBH would allow for a much greater effect on crowning potential than would the observed variation in FMC (Fuglem and Murphy 1980; Alexander 1988).

Van Wagner's (1977) crown fire initiation model has an empirical basis and was parameterised using the mean crown base height of the trees within a red pine plantation experimental plot (Van Wagner 1968). In their simulation studies, Ritchie *et al.* (2007) and Roccaforte *et al.* (2008) used the lowest quartile CBH value. We do not dispute the fact that the lowest quartile could possibly be a better descriptor of a fuel complex's vertical continuity than the average value when applying a physical-based model. Nonetheless, the use of the lowest quartile in the context of Van Wagner's (1977) crown fire initiation model, as represented by Eqn 1, violates one of the fundamental assumptions of this semi-empirical-based model.

Defining what constitutes an effective CBH can admittedly be difficult at times (Williamson 1999; Scott and Reinhardt 2001; Cruz *et al.* 2004; Menning and Stephens 2007; Mitsopoulos and Dimitrakopoulos 2007), especially in forest stands with highly complex vertical fuel distributions. Muraro (1971) was the first to suggest a threshold CBD value (i.e. $0.320\,kg\,m^{-3}$) as a means of quantitatively defining the CBH. Sando and Wick (1972) indicated that 'little is known about the amount of fuel required to support combustion vertically'; they ended up selecting an arbitrary threshold value as well (i.e. $0.037\,kg\,m^{-3}$), which

Williams (1977) simply doubled for his application (i.e. 0.074 $kg\,m^{-3}$). Roussopoulos (1978) arbitrarily defined CBH as the height separating the lower 5.0% of the total needle foliage load from the upper 95%.

In determining CBH, the majority of simulation studies examining potential crown fire behaviour have followed Scott and Reinhardt's (2001) definition – i.e. 'the lowest height above ground at which there is a sufficient amount of canopy fuel to propagate fire vertically into the canopy'. Scott and Reinhardt (2001) also selected an arbitrary CBD value (0.011 $kg\,m^{-3}$) as the basis for determining CBH. In the intervening years, this approach has come to be an accepted standard with little or no questioning of its origin. Reinhardt *et al.* (2006*a*) readily admit that this threshold value is 'not based on any kind of combustion physics, but it seems to perform well', although they offer no details regarding their performance testing. Thus, the lack of an objectively defined threshold CBD value for determining CBH remains a continuing research need (Alexander 2006).

Meaning of the two crown fire hazard indices

TI and CI values are outputs of NEXUS, FFE-FVS and FMA-Plus but not of the BehavePlus, FARSITE or FlamMap modelling systems. The TI and CI concept were initially introduced by Scott (1998*b*) and later elaborated on by Scott and Reinhardt (2001) for the purpose of assessing crown fire hazard in coniferous forests. Scott (2008) has also extended the methodology to shrubland and open forest woodland fuel complexes. The TI might have been more appropriately termed the 'passive or intermittent crowning index' as torching is more commonly associated with calm to light winds (e.g. Lawson 1972; Dyrness and Norum 1983) and a single tree torching does not make for even a passive crown fire (Forestry Canada Fire Danger Group 1992). Similarly, the CI could have been labelled the 'active or continuous crowning index'.

Although the TI and CI are to be regarded as relative numerical values (Fulé *et al.* 2004; Roccaforte *et al.* 2008; Stephens *et al.* 2009), Scott and Reinhardt (2001) chose to express both indices in terms of the wind speed (in either $km\,h^{-1}$ or miles h^{-1}) as taken at a height of 6.1 m (20 feet) above open ground per the standard for fire danger rating and fire behaviour prediction used in the US (Deeming *et al.* 1977; Rothermel 1983). Later on, Scott (2006) expressed TI and CI in terms of the 10-m open wind standard used for fire danger rating and fire behaviour prediction in Canada (Lawson and Armitage 2008) and elsewhere (e.g. Australia and New Zealand).

The present practice of calculating TI and CI values by various authors does not readily allow for direct comparison between different studies or assessments. For example, the fuel moisture contents selected are based on one of the various scenarios presented by Rothermel (1991) or on percentile values derived from a fire weather database, each of which has value. Added to this is the fact that both the FDFM (Rothermel 1983) and the NFDRS 1-h time-lag fuel moisture content (Fosberg and Deeming 1971; Deeming *et al.* 1977) are used in computing the two crown-fire hazard indices and they do not result in the same numerical value for a given set of weather conditions. Some authors have failed to specify the associated environmental conditions (e.g. Graves and Neuenschwander 2001; Fiedler *et al.* 2004; Monleon *et al.* 2004; Mason *et al.* 2007) or the description remains vague (e.g. Moghaddas and Craggs 2007). Furthermore, some authors have failed to explicitly specify the FMC applied in their simulations (e.g. Stephens 1998; Monleon *et al.* 2004; Johnson *et al.* 2007; DeRose and Long 2009). The situation is further complicated by the lack of standardisation of the index scale as dictated by the use of two different units of measure (i.e. $km\,h^{-1}$ and miles h^{-1}) and to a much lesser extent, two different open wind-speed exposure heights (i.e. 6.1 and 10 m). To make matters worse, some authors have now chosen to express TI and CI outputs in $m\,s^{-1}$ (e.g. Ritchie *et al.* 2007; Finkral and Evans 2008). The basic premise of any index is that it has a consistent scale.

Summary and concluding remarks

The ready availability of a multitude of fire modelling systems in the US in recent years has led to their widespread use in numerous simulation studies aimed at assessing various fire behaviour characteristics associated with specific fuel complex structures, including the propensity for crown fire initiation and spread (McHugh 2006). The results of these simulations, often aimed at evaluating fuel treatment effectiveness, are in turn utilised in a whole host of applications (e.g. Scott 2003; Fiedler *et al.* 2004; Skog *et al.* 2006; Johnson *et al.* 2007; Finkral and Evans 2008; Huggett *et al.* 2008; Johnson 2008; Reinhardt *et al.* 2010) and thus have significant implications for public and wildland firefighter safety, community fire protection, fire management policy-making, and forest management practices. As Cheney (1981) has noted, 'The reality of fire behaviour predictions is that overestimates can be easily readjusted without serious consequences; underestimates of behaviour can be disastrous both to the operations of the fire controller and the credibility of the person making the predictions'.

A critical review of several of these simulation studies, as documented here, has found that the results are often unrealistic for a variety of reasons. It's recognised that the authors of these studies commonly point out the limitations of the models and modelling systems being used through a customary disclaimer concerning the unknowns regarding crown fire behaviour (e.g. Stephens *et al.* 2009). Nevertheless, the fact that the fuel treatment evaluation studies referenced here are based on modelling systems that utilised model linkages for gauging potential crown fire behaviour that have not previously undergone any form of performance evaluation against independent datasets or any empirical observations should be of concern. There appears, however, to be an aversion within an element of the fire research community to do so (e.g. Scott and Reinhardt 2001; Scott 2006; Stephens *et al.* 2009). Nevertheless, such testing is now generally regarded as a basic tenet of modern-day model development and evaluation (Jakeman *et al.* 2006).

Fire modelling systems like NEXUS (Scott and Reinhardt 2001), FFE-FVS (Reinhardt and Crookston 2003), FARSITE (Finney 2004), FMAPlus (Carlton 2005), FlamMap (Finney 2006), and BehavePlus (Andrews *et al.* 2008) that are based on separate implementations or linkages between Rothermel's (1972, 1991) rate of fire spread models and Van Wagner's (1977, 1993) crown fire transition and propagation models have been shown to have a marked underprediction bias when used to assess potential crown fire behaviour. What has been allowed to evolve is a family of modelling systems composed of independently developed, linked models that were never intended to work together, are sometimes based on very limited data, and may propagate errors beyond acceptable limits.

We have documented here the sources of the bias based on empirical evidence in the form of published experimental fire and wildfire datasets. By analysing model linkages and components, we have described the primary sources of such bias, namely: (1) incompatible model linkages; (2) use of surface and crown fire rate of spread models that have an inherent underprediction bias; and (3) reduction in crown fire rate of spread based on use of unsubstantiated CFB functions. The use of uncalibrated, custom fuel models to represent surface fuelbeds is considered another potential source of bias.

Our analysis has also shown that the crown fire initiation underprediction bias inherent in all of these fire modelling systems could possibly be rectified by modifying the method used to calculate the surface fireline intensity for the purposes of assessing crown fire initiation potential, namely using Nelson's (2003) model to estimate t_r in place of Anderson's model (1969). Other modelling systems exist for predicting the likelihood of crown fire initiation and other aspects of crown fire behaviour (Alexander *et al.* 2006; Cruz *et al.* 2006*b*, 2008). Mitsopoulos and Dimitrakopoulos (2007) have, for example, made extensive use of this suite of models in their assessment of crown fire potential in Aleppo pine (*Pinus halepensis*) forests in Greece. These systems are based on models that have undergone performance evaluations against independent datasets and been shown to be reasonably reliable (Cruz *et al.* 2003*b*, 2004, 2006*b*; Cronan and Jandt 2008). Resolving the underprediction bias associated with predicting active crown fire rate of spread inherent in the Rothermel (1991) model would require substantial changes, including a reassessment of the use of a CFB function, if not complete replacement with a more robust empirically developed model (Cruz *et al.* 2005) that has been extensively tested (Alexander and Cruz 2006) or a physically based one that has undergone limited testing (Butler *et al.* 2004).

Alexander (2007) has emphasised that assessments of wildland fire potential involving simulation modelling must be complemented with fire behaviour case study knowledge and by experienced judgment. This review has revealed an overwhelming need for the research users of fire modelling systems to be grounded in the theory and proper application of such tools, including a solid understanding of the assumptions, limitations and accuracy of the underlying models as well as practical knowledge of the subject phenomena (Brown and Davis 1973; Albini 1976; Alexander 2009*a*, 2009*b*).

List of symbols, quantities and units used in equations and text

C, criterion for initial crown combustion (kW$^{2/3}$ kJ^{-1} kg m$^{-5/3}$)
CBD, canopy bulk density (kg m^{-3})
CBH, canopy base height (m)
CFL, canopy fuel load (kg m^{-2})
CFB, crown fraction burned
CI, crowning index (km h^{-1})
FDFM, fine dead fuel moisture (%)
FMC, foliar moisture content (%)
h, heat of ignition (kJ kg^{-1})
H, low heat of combustion (kJ kg^{-1})
I_B, fireline intensity (kW m^{-1})
I_o, critical surface fire intensity for initial crown combustion (kW m^{-1})
I_R, reaction intensity (kW m^{-2})
r, rate of fire spread (m s^{-1})
R, final rate of fire spread, surface or crown (m min^{-1})
R_a, active crown fire rate of spread (m min^{-1})
R_i, critical surface fire rate of spread for crown fire initiation (m min^{-1})
R_s, surface fire rate of spread (m min^{-1})
R_o, critical minimum spread rate for active crowning (m min^{-1})
R_{10}, predicted surface fire rate of spread for Fuel Model 10 using a 0.4 wind reduction factor (m min^{-1})
S_o, critical mass flow rate for solid crown flame (kg m^{-2} min^{-1})
t_r, flame front residence time (s)
TI, torching index (km h^{-1})
U_{10}, 10-m open wind speed (km h^{-1})
w, fuel consumed in the active flaming front and by glowing or smouldering combustion following passage of the front (kg m^{-2})
w_a, fuel consumed in the active flaming front (kg m^{-2})

Abstract. There is a widespread view among land managers and others that the protected status of many forestlands in the western United States corresponds with higher fire severity levels due to historical restrictions on logging that contribute to greater amounts of biomass and fuel loading in less intensively managed areas, particularly after decades of fire suppression. This view has led to recent proposals—both administrative and legislative—to reduce or eliminate forest protections and increase some forms of logging based on the belief that restrictions on active management have increased fire severity. We investigated the relationship between protected status and fire severity using the Random Forests algorithm applied to 1500 fires affecting 9.5 million hectares between 1984 and 2014 in pine (*Pinus ponderosa*, *Pinus jeffreyi*) and mixed-conifer forests of western United States, accounting for key topographic and climate variables. We found forests with higher levels of protection had lower severity values even though they are generally identified as having the highest overall levels of biomass and fuel loading. Our results suggest a need to reconsider current overly simplistic assumptions about the relationship between forest protection and fire severity in fire management and policy.

Key words: biodiversity; climate; fire frequency; fire severity; fire suppression; Gap Analysis Program levels; logging; protected areas.

Introduction

It is a widely held assumption among federal land management agencies and others that a lack of active forest management of some federal forestlands—especially within relatively frequent-fire forest types such as ponderosa pine (*Pinus ponderosa*) and mixed conifers—is associated with higher levels of fire severity when wildland fires occur (USDA Forest Service 2004, 2014, 2015, 2016). This prevailing forest/fire management hypothesis assumes that forests with higher levels of protection, and therefore less logging, will burn more intensely due to higher fuel loads and forest density. Recommendations have been made to increase logging as fuel reduction and decrease forest protections before wildland fire can be more extensively reintroduced on the landscape after decades of fire suppression (USDA Forest Service 2004, 2014, 2015, 2016). The concern follows that, in the absence of such a shift in forest management, fires are burning too severely and may adversely affect forest resilience (North et al. 2009, 2015, Stephens et al. 2013, 2015, Hessburg 2016). Nearly every fire season, the United States Congress introduces forest management legislation based on this view and aimed at increasing mechanical fuel treatments via intensive logging and weakened forest protections.

However, the fundamental premise for this fire management strategy has not been rigorously tested across broad regions. We broadly assessed the influence of forest protection levels on fire severity in pine and mixed-conifer forests of the western United States with relatively frequent-fire regimes to test this assumption. We used vegetation burn severity data from all fires >405 ha over a three-decade period, 1984–2014, in forests with varying levels of protection.

Study area

Pine and mixed-conifer forests at low/mid-elevations, where historical fires were relatively frequent, are broadly distributed across several ecoregions in the western United States (Fig. 1; Appendix S1: Table S1). Although ponderosa pine often dominates these forests, they can also include Jeffrey pine (*Pinus jeffreyi*), which in places intermix with, and are similar to, ponderosa pine forests, and Madrean pine–oak (*Quercus* spp.) forests with a diversity of pines. Mixed-conifer forests at low/mid-elevations are also broadly distributed across multiple ecoregions (Fig. 1). They can include additional pines (e.g., lodgepole pine, *Pinus contorta*; sugar pine, *Pinus lambertiana*), true firs (*Abies* spp.), Douglas-fir (*Pseudotsuga menzeisii*), and incense-cedar (*Calocedrus decurrens*).

Methods

We used Gap Analysis Program (GAP) protection classes (USGS 2012), as described below, to determine whether areas with the most protection (i.e., GAP1 and GAP2) had a tendency to burn more severely than areas where intensive management is allowed (i.e., GAP3 and GAP4). We compared satellite-derived burn severity data for 1500 fires affecting 9.5 million hectares from years for which there were available data (1984–2014) among four different forest protection levels (Fig. 1), accounting for variation in topography and climate. We analyzed fires within relatively frequent-fire forest types comprised of pine and mixed-conifer forests mainly because these are the predominant forest types at low to mid-elevations in the western United States, there is a large data set on fire occurrence, and they have been a major concern of land managers for some time due to decades of fire suppression. We defined geographic extent of forest types from the Biophysical Settings data set (BpS) (Rollins 2009; *public communication*, http://www.landfire.gov) that derived forest maps from satellite imagery and represents plant communities based on NatureServe's Ecological Systems classification. Baker (2015) noted that some previous work found ~65% classification accuracy of this system with regard to specific forest types and, accordingly, he analyzed groups of related forest types in order to improve accuracy. We followed his approach (see Appendix S1: Table S1). The categories selected from the Biophysical Settings map were ponderosa/Jeffrey pine and mixed-conifer forest types with relatively frequent-fire regimes (e.g., Swetnam and Baisan 1996, Taylor and Skinner 1998, Schoennagel et al. 2004, Stephens and Collins 2004, Sherriff et al. 2014), compared to other forest types with different fire regimes such as high-elevation forests and many coastal forests not studied herein. Forest types in our study totaled 29.2 million hectares (Fig. 1; Appendix S1: Table S1). We used the BpS data to capture areas that were classified as forests before fire, because postfire vegetation maps can potentially show these same areas as temporarily changed to other vegetation types. We sampled our response and predictor variables on an evenly spaced 90 × 90 m grid within these forest types using ArcMap 10.3 (ESRI 2014). This created a data set of 5,580,435 independent observations from which we drew our random samples to create our models. The 90-m spacing was chosen because it was the smallest spacing of points that was computationally practical with which to operate.

Fires

The Monitoring Trends in Burn Severity project (MTBS, *public communication*, http://www.mtbs.gov) is a U.S. Department of Interior and Department of Agriculture-sponsored program that has compiled burn severity data from satellite imagery, which became available in 1984, for fires >405 ha, and was current up to 2014 (Eidenshink et al. 2007). The MTBS Web site allows bulk download of spatial products that include two closely related indices of burn severity: differenced normalized burn ratio (dNBR) (Key and Benson 2006) and relative differenced normalized burn ratio (RdNBR) (Miller and Thode 2007). Both indices are calculated from Landsat TM and ETM satellite imagery of reflected light from the earth's surface at infrared wavelengths from before and after fire to

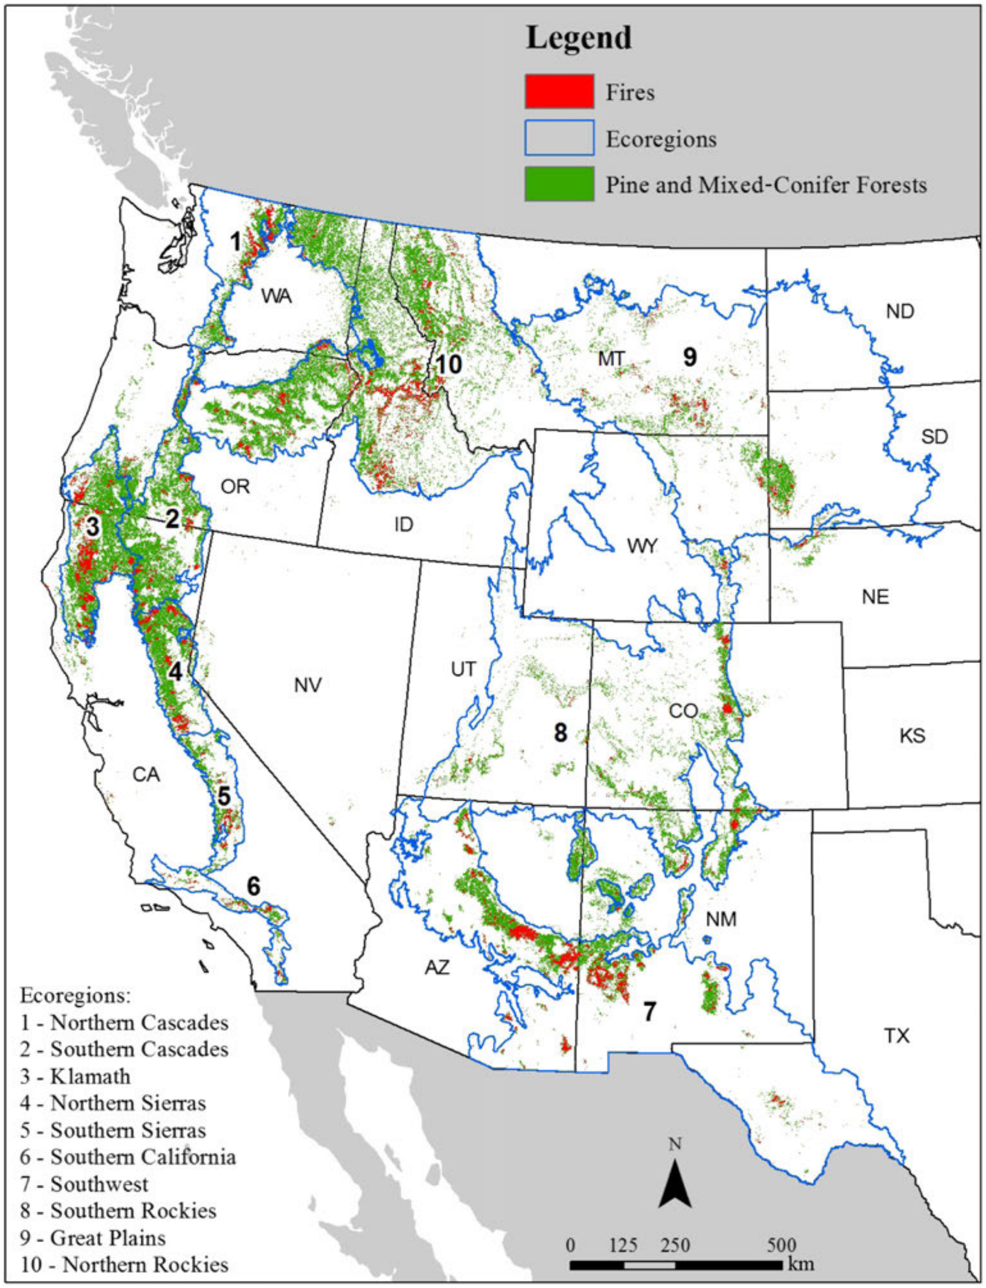

Fig. 1. Pine and mixed-conifer forests, fires, and ecoregions analyzed in this study.

measure associated changes in vegetation cover and soil characteristics. We defined burn severity with the RdNBR index because it adjusts for prefire conditions at each pixel and provides a more consistent measure of burn severity than dNBR when studying broad geographic regions with many different vegetation types (Miller et al. 2009*a*, Norton et al. 2009). RdNBR values typically range from negative 500 to 1500 with values further away from zero representing greater change from prefire conditions. Negative values represent vegetation growth and positive values increasing levels of overstory vegetation mortality. The RdNBR values could be used to classify fires into discrete burn severity classes of low, medium, and high but this was not performed in our study, as we desired to have a continuous response variable in our models.

We intersected forest sampling points with fire perimeters downloaded from MTBS to determine fires that occurred in our analysis area, and censored fires with <100 sampling points (81 ha). The remaining points represented sampling locations from 2069 fires (Fig. 1). We extracted RdNBR values at each sampling point as our response variable as well as predictor variables that included topography, geography, climate, and GAP status. These sampling points were used to investigate the relationship between forest protection levels and burn severity (Appendix S1: Tables S2 and S3). We chose topographic and climatic variables based on previous studies that quantified the relationship between burn severity, topography, and climate (Dillon et al. 2011, Kane et al. 2015).

Topographic and climatic data

To account for the effects of topographic and climatic variability, we derived several topographic indices (Appendix S1: Table S2) from seamless elevation data (*public communication*, http://www.landfire.gov/topographic.php) downscaled to 90-m^2 spatial resolution due to computational limits when intersecting sampling points. These indices capture categories of topography, including percentage slope, surface complexity, slope position, and several temperature and moisture metrics derived from aspect and slope position. We used the Geomorphometry and Gradient Metrics Toolbox version 2.0 (*public communication*, http://evansmurphy.wix.com/evansspatial) to compute these metrics. We also computed several temperature and precipitation variables (Appendix S1: Table S3) by downloading climatic conditions for each month from 1984 to 2014 from the PRISM climate group (*public communication*, http://prism.oregonstate.edu). Climate grids record precipitation and minimum, mean, and maximum temperature at a 4-km grid scale created by interpolating data from over 10,000 weather stations. To determine the departure from average conditions, we subtracted each climate grid by its 30-yr mean monthly value. These "30-yr Normals" data sets were also downloaded from the PRISM Web site and reflected the mean values from the most recent full decades (1981–2010). We determined mean seasonal values with summer defined as the mean of July, August, and September of the year before a given fire; fall being the mean of October, November, and December of the previous year; winter the mean of January, February, and March of the current year of a given fire; and spring the mean of April, May, and June of the current year.

Protected area status and ecoregion classification

We used the Protected Areas Database of the United States (PAD-US; USGS 2012) to determine forest protection status, which is the U.S. official inventory of protected open space. The PAD-US includes all federal and most State conservation lands and classifies these areas with a GAP ranking code (see map at: http://gis1.usgs.gov/csas/gap/viewer/padus/Map.aspx). The GAP status code (herein referred to interchangeably as GAP class or protection status) is a metric of management to conserve biodiversity with four relative categories. GAP1 is protected lands managed for biodiversity where disturbance events (e.g., fires) are generally allowed to proceed naturally. These lands include national parks, wilderness areas, and national wildlife refuges. GAP2 is protected lands managed for biodiversity where disturbance events are often suppressed. They include state parks and national monuments, as well as a small number of wilderness areas and national parks with different management from GAP1. GAP3 is lands managed for multiple uses and are subjected to logging. Most of these areas consist of non-wilderness USDA Forest Service and U.S. Department of Interior Bureau of Land Management lands as well as state trust lands. GAP4 is lands with no mandate for protection such as tribal, military, and private lands. GAP status is relevant to the intensity of both current and past managements.

We made one modification to GAP levels by converting Inventoried Roadless Areas (IRAs) from the 2001 Roadless Area Conservation Rule (S_USA.RoadlessArea_2001, *public communication*, http://data.fs.usda.gov/geodata/edw/datasets.php) to GAP2 unless these areas already were defined as GAP1. We considered most IRAs as GAP2 given they are prone to policy changes and because they allow for certain limited types of logging (e.g., removal of predominately small trees for fuel reduction in some circumstances).

However, we note that very little logging has occurred within IRAs since the Roadless Rule, although there occasionally have been proposals to log portions of some IRAs pre- and postfire, and fire suppression often occurs.

We modified level III ecoregions (U.S. Environmental Protection Agency (EPA) 2013) to create areas of similar climate and geography (Fig. 1). We did this by extracting ecoregions and combining adjacent provinces in our study region.

Random Forests analysis

We investigated the relationship between protection status and burn severity using the data-mining algorithm Random Forests (RF) (Breiman 2001) with the "randomForestSRC" add-in package (Ishwaran and Kogalur 2016) in R (R Core Team 2013). This algorithm is an extension of classification and regression trees (CART) (Breiman et al. 1984) that recursively partitions observations into groups based on binary rule splits of the predictor variables. The main advantage of using RF in our study is that it can work with spatially autocorrelated data (Cutler et al. 2007). It can also model complex, nonlinear relationships among variables, makes no assumption of variable distributions (Kane et al. 2015), and produces accurate predictions without overfitting the available data (Breiman 2001).

Our independent observations were a random subset of our 5.5 million points, from which we drew three random samples of 25,000 points each. Each sample consisted of 500 fires randomly selected without replacement from the pool of 2069 fires. Fifty points were then randomly selected within each of the 500 fires. Our dependent variables were all continuous (Appendix S1: Tables S2 and S3) except for the main variable of interest, protected area status, which included the four GAP levels. The three observation samples were used to create three RF model runs, each consisting of 1000 regression trees. We conducted three RF model runs to assess whether our random samples of 25,000 points produced fairly consistent results.

The RF algorithm samples approximately 66% of the data to build the regression trees, and the remaining data are used for validation and to assess variable importance. We used this validation sample to determine the amount of variance explained and variable importance. The algorithm also produces individual variable importance measures by calculating differences in prediction mean-square-error before and after randomly permuting each dependent variable's values. Variable importance is a measure of how much each variable contributes to the model's overall predicative accuracy.

Unlike linear models, RF does not produce regression coefficients to examine how a change in a predictor variable affects the response variable. The analogy to this in RF is the partial dependence plot which is a graphical depiction of how the response will change with a single predictor while averaging out the effects of the other predictors, such as the climatic and topographic variables (Cutler et al. 2007). We used this approach, in addition to using RF to determine overall variable importance as described above, in order to determine the effect of GAP status, in particular, on fire severity, while averaging out effects of climate and topography.

Mixed-effects analysis

We performed a linear mixed-effects analysis using the "nlme" add-on package in R (Pinheiro et al. 2015). We used a random intercept model and identified year of fire (n = 31) and ecoregion (n = 10) as random effects. Similar to our RF models, our independent observations were a random subset of our 5.5 million points but for these models we drew three random samples of 50,000 points each. Each sample consisted of 500 fires randomly selected without replacement, and within each of those fires, 100 points were randomly selected. Our dependent variables were the same used in our RF models, and we log-transformed the non-normal variables of slope, surface roughness, and topographic radiation aspect index. We removed dependent variables that were correlated with each other (Pearson's $r > 0.5$), retaining 21 of 45 candidate dependent variables, and centered these on their means. Model reduction was performed in a stepwise process using bidirectional elimination with Bayesian information criterion selection criterion.

Spatial autocorrelation analysis

Spatial autocorrelation (SA) is the measure of similarity between pairs of observations in relationship to the distance between them. Ecological variables are inherently autocorrelated because

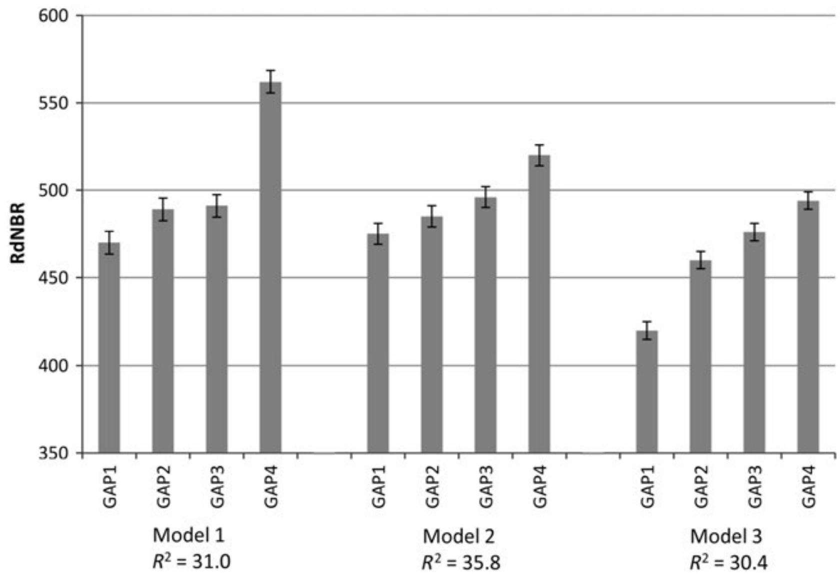

Fig. 2. Random Forests partial dependence of protection status vs. RdNBR burn severity for each model (n = 25,000). The variance explained is shown as pseudo R^2.

landscape attributes that are closer together are often more similar than those that are far apart.

We assessed the SA in the Pearson residuals with inspection of Moran's I autocorrelation index using the "APE" package add-in in R (Paradis et al. 2004) after removing points that shared the same x and y coordinates. Moran's I is an index that ranges from −1 to 1 with the sign of the values indicating strength and direction of SA. Values close to zero are considered to have a random spatial pattern. Our mixed-effects models all had a Moran's I values statistically different from 0 at the 95% confidence level ($P < 0.001$) so we included a spatial correlation structure in our model using the "nlme" package in R. Of Gaussian, exponential, linear, and spherical spatial correlation structures, we determined that the exponential structure produced the lowest Akaike's information criterion (AIC). Despite these additions, our second measurements still found relatively small, but significant, autocorrelation (Moran's I for model runs 1, 2, 3 = 0.10, 0.08, 0.10, all $P < 0.001$).

Results

With regard to ranking of variables in the model runs, variable importance plots from the three RF model runs show that protection status was consistently ranked as one of the 10 most important of the 45 variables in explaining burn severity (Appendix S1: Table S4). The most important variable explaining burn severity was ecoregion for models 1 and 2 and maximum temperature from the previous fall for model 3.

With regard to the GAP status variable in particular, after averaging out the effects of climatic and topographic variables, the RF partial dependence plots show an increasing trend of fire severity with decreasing protection status (Fig. 2). Fires in GAP4 had mean RdNBR values greater than two standard errors higher than all other GAP levels. Fires in GAP3 had mean RdNBR values two standard errors higher than GAP1 in all model runs. GAP3 differences with GAP2 were less pronounced with only one model showing differences greater than two standard errors. Fires in GAP1 were consistently the least severe, being two standard errors less than GAP3 in all model runs and two standard errors less than GAP2 in two of three model runs.

Our mixed-effects models validated these findings with similar results (Fig. 3, Appendix S1: Table S5). Like our RF models, our linear mixed-effects models showed GAP4 fires to have significantly higher RdNBR values and GAP1 fires to have significantly lower RdNBR values when compared to all other GAP classes. Fires in GAP

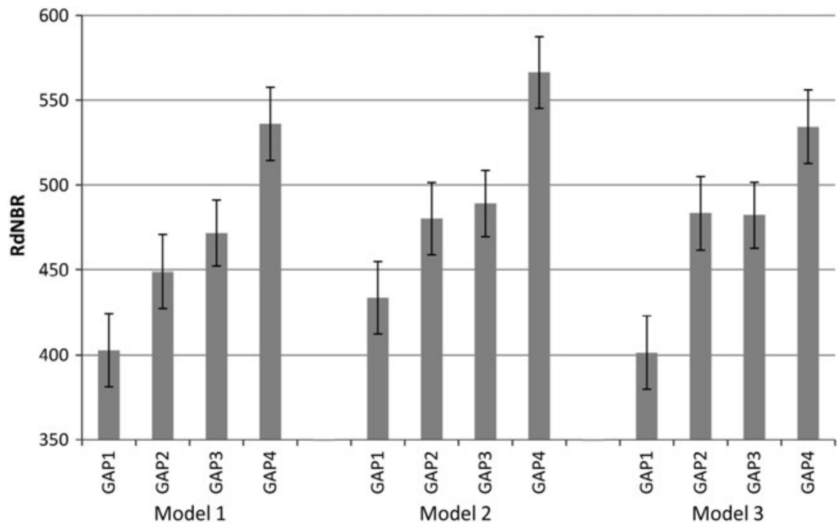

Fig. 3. Linear mixed effects models of protection status vs. RdNBR burn severity (n = 50,000).

status levels 2 and 3 were not significantly different in the mixed-effects models. Although the level of autocorrelation was significant, it was small in our model (Moran's I ~0.1) and not enough to account for such a substantial difference in burn severity among protection classes.

Discussion

Protected forests burn at lower severities

We found no evidence to support the prevailing forest/fire management hypothesis that higher levels of forest protections are associated with more severe fires based on the RF and linear mixed-effects modeling approaches. On the contrary, using over three decades of fire severity data from relatively frequent-fire pine and mixed-conifer forests throughout the western United States, we found support for the opposite conclusion—burn severity tended to be higher in areas with lower levels of protection status (more intense management), after accounting for topographic and climatic conditions in all three model runs. Thus, we rejected the prevailing forest management view that areas with higher protection levels burn most severely during wildfires.

Protection classes are relevant not only to recent or current forest management practices but also to past management. Millions of hectares of land have been protected from logging since the 1964 Wilderness Act and the 2001 Roadless Rule, but these areas are typically categorized as such due to a lack of historical road building and associated logging across patches >2000 ha, while GAP3 lands, for instance, such as National Forests lands under "multiple use management," have generally experienced some form of logging activity over the last 80 yr.

We expect that the effects of historic logging from nearly a century ago to gradually lessen over time, as succession and natural disturbance processes reestablish structural and compositional complexity, but it was beyond the scope of this study to attempt to assess the relative role of recent vs. historical logging. Similarly, industrial fire suppression programs that intensified in the 1940s influenced fire extent across forest protection classes. While more recent let-burn policies have been applied in GAP1 and GAP2 forests in some circumstances, evidence indicates that protected forests nevertheless remain in a substantial fire deficit, relative to the prefire suppression era (Odion et al. 2014, 2016, Parks et al. 2015). Thus, we believe it is unlikely that recent decisions to allow some backcountry fires to burn, largely unimpeded, account for much of the differences in fire severity among protection classes that we found, simply because such let-burn policies have not been extensive enough to remedy the ongoing fire deficit.

While forests in different protection classes can vary in elevation, with protected forests often occupying higher elevations, our results indicate that protection class itself produced notable differences in fire severity after averaging out the effects of elevation and climate (see Fig. 2 and *Results* above). In our study, GAP1 forests were 284 m on average higher in elevation than GAP4 forests, while GAP1 forests experienced lower fire severity. This is the opposite of expectations if elevation was a key influence because higher elevation forests are associated with higher fire severity (see, e.g., Schoennagel et al. 2004, Sherriff et al. 2014). We note that we are not the first to determine that increased fire severity often occurs in forests with an active logging history (Countryman 1956, Odion et al. 2004).

Prevailing forest–fire management perspectives vs. alternative views

An extension of the prevailing forest/fire management hypothesis is that biomass and fuels increase with increasing time after fire (due to suppression), leading to such intense fires that the most long-unburned forests will experience predominantly severe fire behavior (e.g., see USDA Forest Service 2004, Agee and Skinner 2005, Spies et al. 2006, Miller et al. 2009*b*, Miller and Safford 2012, Stephens et al. 2013, Lydersen et al. 2014, Dennison et al. 2014, Hessburg 2016). However, this was not the case for the most long-unburned forests in two ecoregions in which this question has been previously investigated—the Sierra Nevada of California and the Klamath-Siskiyou of northern California and southwest Oregon. In these ecoregions, the most long-unburned forests experienced mostly low/moderate-severity fire (Odion et al. 2004, Odion and Hanson 2006, Miller et al. 2012, van Wagtendonk et al. 2012). Some of these researchers have hypothesized that as forests mature, the overstory canopy results in cooling shade that allows surface fuels to stay moister longer into fire season (Odion and Hanson 2006, 2008). This effect may also lead to a reduction in pyrogenic native shrubs and other understory vegetation that can carry fire, due to insufficient sunlight reaching the understory (Odion et al. 2004, 2010).

Another fundamental assumption is that current fires are becoming too large and severe compared to recent historical time lines (Agee and Skinner 2005, Spies et al. 2006, Miller et al. 2009*b*, Miller and Safford 2012, Stephens et al. 2013, Lydersen et al. 2014, Dennison et al. 2014, Hessburg 2016). However, others have shown that this is not the case for most western forest types. For instance, using the MTBS (www.mtbs.gov) data set, Picotte et al. (2016) found that most vegetation groups in the conterminous United States exhibited no detectable change in area burned or fire severity from 1984 to 2010. Similarly, Hanson et al. (2009) found no increase in rates of high-severity fire from 1984 to 2005 in dry forests within the range of the northern spotted owl (*Strix occidentalis caurina*) based on the MTBS data set. Using reference data and records of high-severity fire, Baker (2015) found no significant upward trends in fire severity from 1984 to 2012 across all dry western forest regions (25.5 million ha), nearly all of which instead were too low or were within the range of historical rates. Parks et al. (2015) modeled area burned as a function of climatic variables in western forests and non-forest types, documenting most forested areas had experienced a fire deficit (observed vs. expected) during 1984 to 2012 that was likely due to fire suppression.

Whether fires are increasing or not depends to a large extent on the baseline chosen for comparisons (i.e., shifting baseline perspective, Whitlock et al. 2015). For instance, using time lines predating the fire suppression era, researchers have documented no significant increases in high-severity fire for dry forests across the West (Williams and Baker 2012*a*, Odion et al. 2014) or for specific regions (Williams and Baker 2012*b*, Sherriff et al. 2014, Tepley and Veblen 2015). Future trends, with climate change and increasing temperatures, may be less simple than previously believed, due to shifts in pyrogenic understory vegetation (Parks et al. 2016).

This is more than just a matter of academic debate, as most forest management policies assume that fire, particularly high-severity fire, is increasing, is in excess of recent historical baselines, and needs to be reduced in size, intensity, and occurrence over large landscapes to prevent widespread ecosystem damages (policy examples include USDA Forest Service 2002, Healthy Forests Restoration Act 2003, USDA Forest Service 2009, HR 167: Wildfire Disaster Funding Act 2015). However, large fires (landscape scale or the so-called megafires) produce myriad ecosystem benefits underappreciated by most land managers and decision-makers (DellaSala and Hanson 2015*a*, DellaSala et al. 2015). High-severity fire patches, in particular, provide a pulse of "biological legacies" (e.g., snags, down logs, and native shrub patches) essential for complex early seral associates (e.g., many bird species) that link seral stages from new forest to old growth (Swanson et al. 2011, Donato et al. 2012, DellaSala et al. 2014, Hanson 2014, 2015, DellaSala and Hanson 2015*a*). Complex early seral forests are most often logged after fire, which, along with aggressive fire suppression, exacerbates their rarity and heightens their conservation importance (Swanson et al. 2011, DellaSala et al. 2014, 2015, Hanson 2014).

Limitations

One limitation of our study is that, due to the coarseness of the management intensity variables that we used (i.e., GAP status), we cannot rule out whether low intensities of management decreased the occurrence of high-severity fire in some circumstances. However, the relationship between forest density/fuel, mechanical fuel treatment, and fire severity is complex. For instance, thinning without subsequent prescribed fire has little effect on fire severity (see Kalies and Yocum Kent 2016) and, in some cases, can increase fire severity (Raymond and Peterson 2005, Ager et al. 2007, Wimberly et al. 2009) and tree mortality (see, e.g., Stephens and Moghaddas 2005, Stephens 2009: Figure 6)—the effects depend on the improbable co-occurrence of reduced fuels (generally a short time line, within a decade or so) and wildfire activity (Rhodes and Baker 2008) and can be over-ridden by extreme fire weather (Bessie and Johnson 1995, Hély et al. 2001, Schoennagel et al. 2004, Lydersen et al. 2014). Empirical data from actual fires also indicate that postfire logging can increase fire severity in reburns (Thompson et al. 2007), despite removal of woody biomass (tree trunks) described by land managers as forest fuels (Peterson et al. 2015). While our study did not specifically test for these effects, such active forest management practices are common on GAP3 and GAP4 lands. Recognizing these limitations, researchers have stressed the need for managers to strive for coexistence with fire by prioritizing fuel reduction nearest homes and allowing more fires to occur unimpeded in the backcountry (Moritz 2014, DellaSala et al. 2015, Dunn and Bailey 2016, Moritz and Knowles 2016).

Follow-up research at finer scales is needed to determine management emphasis and history in relation to fire severity. However, we believe our findings are robust at the subcontinental and ecoregional scales.

Conclusions

In general, our findings—that forests with the highest levels of protection from logging tend to burn least severely—suggest a need for managers and policymakers to rethink current forest and fire management direction, particularly proposals that seek to weaken forest protections or suspend environmental laws ostensibly to facilitate a more extensive and industrial forest–fire management regime. Such approaches would likely achieve the opposite of their intended consequences and would degrade complex early seral forests (DellaSala et al. 2015). We suggest that the results of our study counsel in favor of increased protection for federal forestlands without the concern that this may lead to more severe fires.

Allowing wildfires to burn under safe conditions is an effective restoration tool for achieving landscape heterogeneity and biodiversity conservation objectives in regions where high levels of biodiversity are associated with mixed-intensity fires (i.e., "pyrodiversity begets biodiversity," see DellaSala and Hanson 2015*b*). Managers concerned about fires can close and decommission roads that contribute to human-caused fire ignitions and treat fire-prone tree plantations where fires have been shown to burn uncharacteristically severe (Odion et al. 2004). Prioritizing fuel treatments to flammable vegetation adjacent to homes along with specific measures that reduce fire risks to home structures are precautionary steps for allowing more fires to proceed safely in the backcountry (Moritz 2014, DellaSala et al. 2015, Moritz and Knowles 2016).

Managing for wildfire benefits as we suggest is also consistent with recent national forest policies such as 2012 National Forest Management Act planning rule that emphasizes maintaining and restoring ecological integrity across the national forest system and because complex early forests can only be produced by natural disturbance events not mimicked by mechanical fuel reduction or clear-cut logging (Swanson et al. 2011, DellaSala et al. 2014). Thus, managers wishing to maintain biodiversity in fire-adapted forests should appropriately weigh the benefits of wildfires against the ecological costs of mechanical fuel reduction and fire suppression (Ingalsbee and Raja 2015) and should consider expansion of protected forest areas as a means of maintaining natural ecosystem processes like wildland fire.

Acknowledgments

We would like to thank Monica Bond and Derek Lee for statistical advice and Randi Spivak and Jay Lininger for providing helpful comments on this manuscript. We also thank the reviewers for suggestions, which improved the manuscript.

Are Wildland Fires Increasing Large Patches of Complex Early Seral Forest Habitat?

Dominick A. DellaSala [1,*] and Chad T. Hanson [2]

Abstract: High-severity fire creates patches of complex early seral forest (CESF) in mixed-severity fire complexes of the western USA. Some managers and researchers have expressed concerns that large high-severity patches are increasing and could adversely impact old forest extent or lead to type conversions. We used GIS databases for vegetation and fire severity to investigate trends in large (>400 ha) CESF patches in frequent-fire forests of the western USA, analyzing four equal time periods from 1984 to 2015. We detected a significant increase in the total area of large patches relative to the first time period only (1984–1991), but no significant upward trend since the early 1990s. There was no significant trend in the size of large CESF patches between 1984 and 2015. Fire rotation intervals for large CESF patches ranged from ~12 centuries to over 4000 years, depending on the region. Large CESF patches were highly heterogeneous, internally creating ample opportunities for fire-mediated biodiversity. Interior patch areas far removed from the nearest low/moderate-severity edges comprised a minor portion of high-severity patches but may be ecologically important in creating pockets of open forest. There was ample historical evidence of large CESF patches but no evidence of increases that might indicate a current risk of ecosystem-type shifts.

Keywords: complex early seral forest; conifers; biodiversity; high-severity fire; western USA

1. Introduction

High-severity fire patches represent the component in fires that kill all or nearly all of the overstory trees within mixed-severity fire areas in conifer forests of the western USA [1,2], creating a unique forest habitat type known as the complex early seral forest (CESF) [3]. CESFs are distributed as small (<1 ha) to large patches (>400 ha) in mixed-severity burns in the lower/middle-montane conifer forests of the Sierra Nevada [2] and within other frequent-fire forest types of the western USA [4–6]. Unlike early seral produced by a clear-cut or otherwise intensively logged area, a CESF is more complex in its structure, and is characterized by a heterogeneous mix of abundant standing dead trees (snags) and downed logs, naturally regenerating conifers, other trees, shrub patches, and abundant wildflowers [3].

Whether high-severity fire is increasing and the ultimate causes of presumed increases (e.g., climate change, increase in tree densities) is the subject of much recent debate. For instance, the areal extent and proportion of high-severity fire within large fire complexes have not changed markedly in recent decades in most forested regions of the West [4,7–11], but results are equivocal in the Rocky Mountains and Southwestern US, e.g., see [9,11,12]. In the Sierra Nevada, some studies have reported increasing trends for high-severity fire, e.g., [13,14], whereas subsequent research [15,16] indicated no increases. Moreover, the size of CESF patches within large fire complexes has been used as a key metric to hypothesize whether fire regimes are operating within historical bounds [6,17–21]. Some have expressed concerns that large high-severity patches are increasing as a component of a recent increase in so-called megafires and that this may signal ecosystem-type shifts and the loss of old-growth forests [6,18,20,22], while others have predicted potential overall decreases in the future occurrence of high-severity fire in general [23]. Concern over high-severity fires and the resulting large patches of CESF has been a catalyst for fundamental changes to federal forest management policies (e.g., Healthy Forest Restoration Act of 2003, 2012 National Forest Management Act Planning Rule) and has been recently used to promote proposed congressional legislation that would substantially curtail environmental protections and dramatically increase logging in federal forests (e.g., The Resilient Federal Forests Act of 2019). Concerns over high-severity fires overall are missing a biodiversity perspective that is necessary to fully evaluate fire management proposals in the context of ecosystem benefits from such fires and not just their potential impacts on people [24,25].

Notably, patches of CESF support unique fire-adapted communities, including many plants [26], avifauna [27,28], mammals [29], bats [30], terrestrial [31] and aquatic invertebrates [32]. The Black-backed Woodpecker (*Picoides arcticus*) is associated with large CESF patches (typically ~100–800 ha for a single pair, depending on habitat quality) for nesting and foraging [33–36]. The California Spotted Owl (*Strix occidentalis occidentalis*), which is being petitioned for federal listing under the Endangered Species Act, actively forages in CESF patches [37,38]. Thus, policies aimed at suppressing large fires that otherwise would maintain and replenish CESF patches may have unintended consequences for fire-mediated biodiversity [24,25].

Our objectives were to determine whether there has been a recent trend (increase or decrease) in large CESF patches in fire areas within frequent-fire conifer forests of the western USA [4,39], to evaluate the spatiotemporal extent of such patches in these forests, assess their internal heterogeneity, and investigate historical evidence for the occurrence of such patches. Our study is the first to analyze the occurrence of large high-severity fire patches by distinct time periods. Additionally, our findings may have relevance to policy makers and forest-fire managers seeking to integrate biodiversity benefits of large CESF patches with wildfire risk reduction to people and natural resource management [24,25].

2. Methods

We analyzed the same western USA frequent-fire forest types, and used the same vegetation databases as in our related study [40] (Figure 1). These areas are dominated by mixed-conifer forests, as well as ponderosa pine (*Pinus ponderosa*) and Jeffrey pine (*Pinus jeffreyi*) forests.

We downloaded burn severity maps derived from satellite imagery from the Monitoring Trends in Burn Severity project (MTBS; http://www.mtbs.gov). Within the conifer forests of our study area, we defined CESF patches as areas experiencing high-severity fire, using a threshold of Relative Delta Normalized Burn Ratio (RdNBR) values ≥641 [41]. The same or similar thresholds have been used to define high-severity fire in multiple forest regions of western USA [21,42–44] and thus, our findings are directly applicable with consistent use of MTBS across studies. Although there is no accepted or standard definition of large CESF patches, we chose to analyze patches >400 ha in order to address concerns expressed by researchers that CESF patches hundreds of hectares or larger may not have occurred historically [6,18,21], may create homogeneity and inhibit post-fire forest regeneration due to lack of seed sources [20,22] and/or may reduce forest resilience to climate change [45–47]. We used an inclusive approach such that any high-severity fire pixels of conifer forest (30 × 30-m each) with sides touching were considered to be part of the same patch.

We used a Mann–Kendall test to determine whether there is any trend in (a) the combined total annual area of CESF patches >400 ha, and (b) the size of individual CESF patches >400 ha, for the years 1984–2015 (the period for which consistently mapped MTBS datasets were available for the US), analyzing both the annual area of large CESF patches, and the size of individual large CESF patches, as continuous variables. Mann–Kendall is a non-parametric test for monotonic upward or downward trends over time and has been used in similar studies [9,15,48]. Compared to other tests, including parametric tests, the Mann–Kendall has been found to have an equal or greater statistical power to detect trends in environmental time series data when the data are non-parametric, such as wildland fire trend data [15].

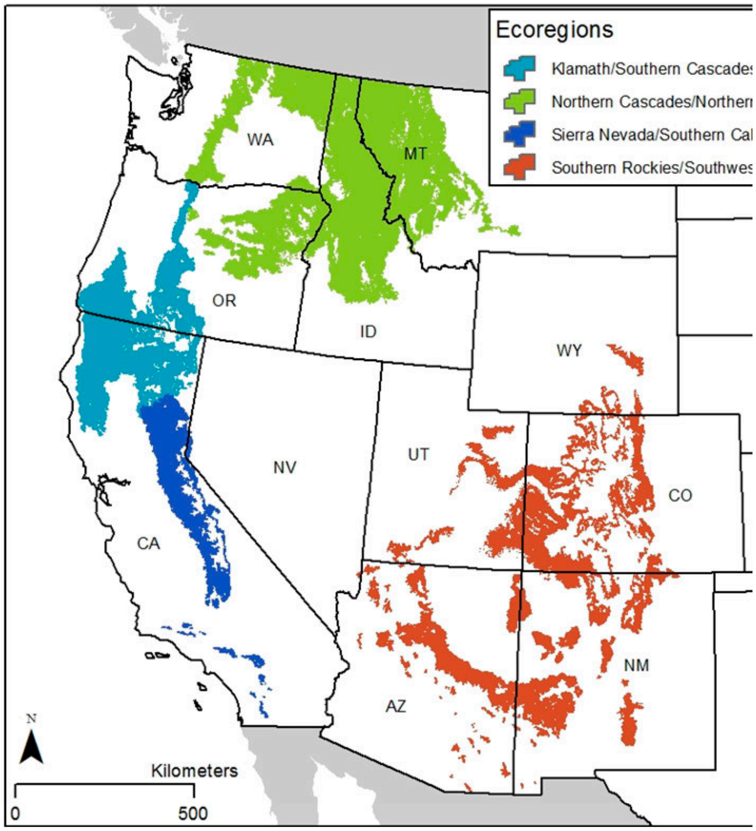

Figure 1. Ecoregions with pine and mixed conifer forests analyzed for large high-severity fire patches in our study modified from [40]. Two-letter acronyms shown on the map represent different U.S. states.

Since we were interested in determining the specific timing of any differences in occurrence in large CESF patches, we used a Nemenyi non-parametric test for multiple comparisons among groups with an equal sample size [49] to analyze whether there have been increases or decreases in large (>400 ha) patches of CESF, created by high-severity fire, for total annual area across four equal time periods (1984–1991, 1992–1999, 2000–2007, 2008–2015). To determine which specific time groups were significantly different with regard to individual patch sizes, we used a Dunn non-parametric test for multiple comparisons with unequal sample sizes [49]. In all analyses, significance was assessed at α = 0.05. We conducted this analysis because we wanted to determine whether any trend in the occurrence of large CESF patches is current and ongoing or happened at some point in the past, during the 1984–2015 time series, but may not be ongoing. This is not possible when large CESF patch occurrence is analyzed as continuous variables across the entire time series. For these two multiple comparison analyses, we chose to assess four groups of eight years each, rather than, for example, eight groups of four years each because the latter reduces sample size within each group to levels considered to be statistically inadvisable, and because using eight groups of four years increases the critical threshold to determine differences among groups, thus making it more difficult to reveal such differences when they exist [49].

In order to understand the spatiotemporal extent and context of large CESF patches across the forested landscape, we calculated fire rotation intervals [9] for high-severity fire patches >400 ha in each of four regions in the western USA: Sierra-Nevada/Southern-California, Klamath/Southern-Cascades, Northern-Cascades/Northern-Rockies, and Southern-Rockies/Southwest. The rotation interval for the occurrence of large CESF patches is equal to the average interval between occurrences of large patches across the study landscape [9].

We also analyzed the internal heterogeneity of CESF patches >400 ha in the four western USA regions by determining the percentage of the total area of such patches that was 1–100 m, 101–200 m, 201–300 m, and >300 m from the nearest unburned, low, or moderate-severity pixel (from either outside or inside the patch) within the frequent-fire conifer forest types analyzed in this study [40]. We included a specific analysis of internal heterogeneity of large high-severity patches because some authors have hypothesized that such patches would be internally homogeneous and have expressed concern about the potential for natural succession in this regard [6,20]. The distance intervals selected for this analysis were based on biologically meaningful relationships in levels of natural post-fire conifer regeneration at increasing distances from seed sources. We assumed lower levels of conifer recruitment at greater distances from live trees, consistent with natural succession to more open forest conditions [45,50–53].

Finally, although it was beyond the scope of this study to attempt to compare current versus historical rates of occurrence of large CESF patches, we included a table summarizing evidence for historical occurrence of patches >400 ha, focusing on low/middle-montane, frequent-fire forest types, given questions expressed about whether large CESF patches occurred historically in these forests [6,18,21].

3. Results

Over the entire time series, 1984–2015, there was a significant increasing trend in the combined total area of CESF patches >400 ha in each year (τ = 0.407, p = 0.001), but no trend in patch size (τ = 0.009, p = 0.802). However, when the data were analyzed by time periods, there was only one significant difference in the annual area of CESF habitat created by high-severity fire relative to the earliest time period (1984–1991), but no significant differences were detected among time periods since the early 1990s (Table 1, Figure 2). With regard to the size of individual large CESF patches, there were no significant differences detected among time periods (Table 2). Figure 3 shows the distribution of individual large CESF patches over the entire time series.

Table 1. Critical values ($q_{0.05,\,4}$), absolute difference between mean of ranks ($|R_A$-$R_B|$), standard errors (SE), and test statistics (q) to assess statistical significance, at α = 0.05 of any differences among the four time groups (1 = 1984–1991, 2 = 1992–1999, 3 = 2000–2007, and 4 = 2008–2015) for total annual area of CESF patches >400 ha using the Nemenyi non-parametric test for multiple comparisons between groups with an equal sample size (n = 8 years for each time group). The statistical significance of the levels of q are shown as "Y" (significant) or "N" (not significant).

Time Group Comparison	$q_{0.05,4}$	$\lvert R_A$-$R_B \rvert$	SE	q	Significant? (Is q > $q_{0.05,4}$?)
1–2	3.63	45.0	26.53	1.70	N
1–3	3.63	108.0	26.53	4.07	Y
1–4	3.63	107.0	26.53	4.03	Y
2–3	3.63	63.0	26.53	2.37	N
2–4	3.63	62.0	26.53	2.34	N
3–4	3.63	1.00	26.53	0.04	N

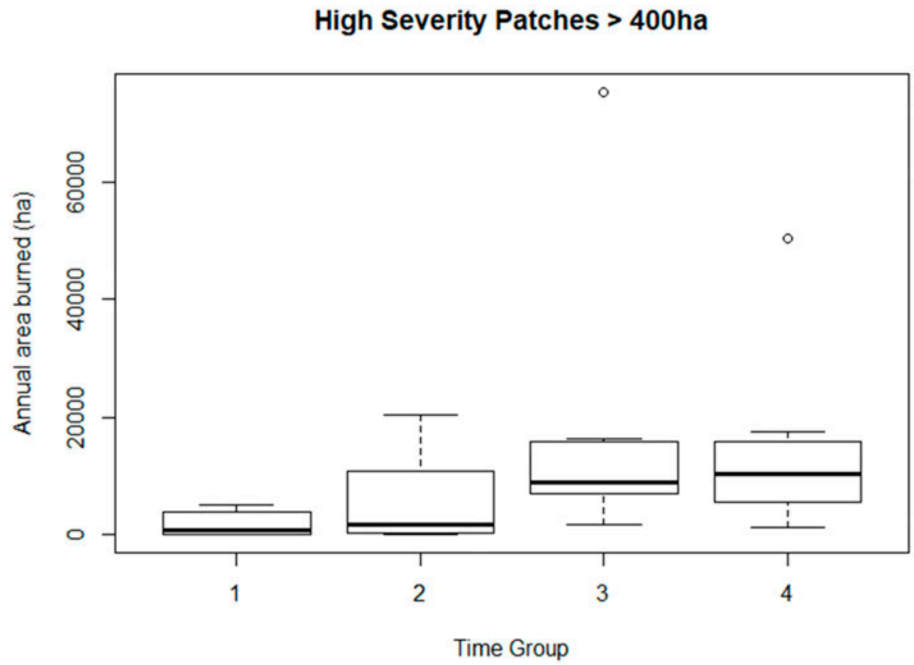

Figure 2. Annual area of large (>400 ha) CESF patches in the four time periods (see Tables 1 and 2 for time periods).

Table 2. Critical values ($q_{0.05,4}$), absolute difference between mean of ranks. ($|_{A}-_{B}|$), standard errors (SE), and test statistics (Q) to assess statistical significance at α = 0.05 of any differences among the four-time groups (1 = 1984–1991, 2 = 1992–1999, 3 = 2000–2007, and 4 = 2008–2015) for the size of individual CESF patches >400 ha using the Dunn non-parametric test for multiple comparisons. The statistical significance of levels of Q are shown as "Y" (significant) or "N" (not significant). For time groups 1, 2, 3, and 4, n = 17, 46, 134, and 130 CESF patches >400 ha, respectively.

Time Group Comparison	$Q_{0.05,4}$	$|_{A}-_{B}|$	SE	Q	Significant? (Is Q > $Q_{0.05,4}$?)
1–2	2.64	2.73	26.91	0.10	N
1–3	2.64	26.50	24.37	1.09	N
1–4	2.64	15.08	24.42	0.62	N
2–3	2.64	23.77	16.23	1.46	N
2–4	2.64	12.35	16.29	0.76	N
3–4	2.64	11.42	11.60	0.98	N

Over the 32-year study period, high-severity fire patches >400 ha occurred on ~0.7% to ~2.7% of the total area of frequent-fire conifer forest, depending on the region, such that the rotation intervals for occurrence of large (>400 ha) CESF patches, created by high-severity fire, ranged from 1181 years to 4354 years (Table 3).

Table 3. Total area and fire rotation interval for occurrence of CESF patches >400 ha in the four regions of the study area from 1984 to 2015.

Region	Area of Forest (ha)	Area (ha) of Patches >400 ha (% of Ecoregion)	Rotation Interval [1] (Years)
Sierra Nevada/Southern California	2,395,288	64,895 (2.709)	1181
Klamath/Southern Cascades	5,741,930	100,112 (1.744)	1835
Northern Cascades/Northern Rockies	10,057,451	73,936 (0.735)	4354
Southern Rockies/Southwest	6,956,201	72,851 (1.047)	3056

[1] Rotation intervals for high-severity patches were calculated by dividing the total area of the conifer forest by the average area of large high-severity patches per year.

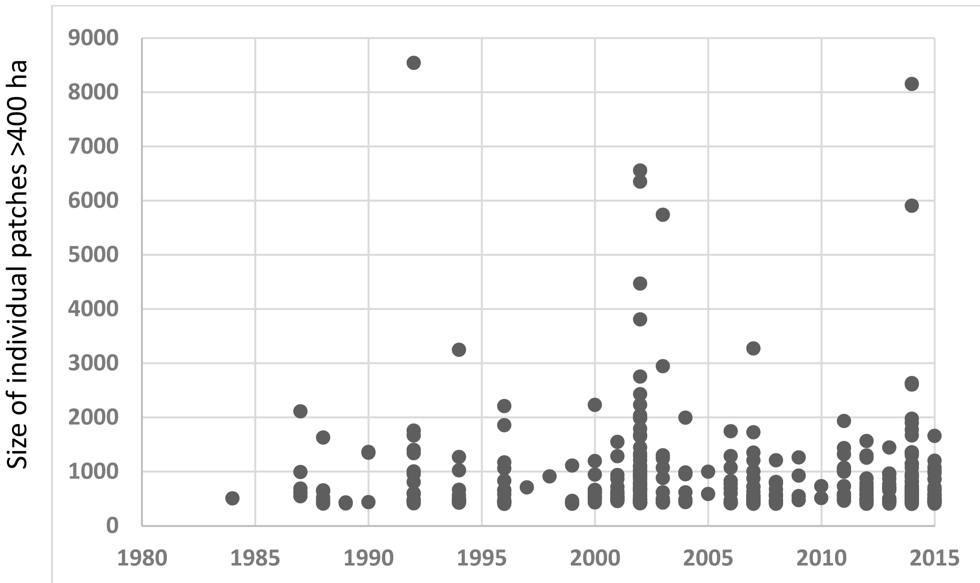

Figure 3. Scatter plot of size of individual large (>400 ha) CESF patches, 1984–2015.

Overall, 52% of the area within the boundaries of CESF patches >400 ha was within 100 m of unburned, low, or moderate-severity edges/inclusions, and 78% of the total area was within 200 m of such edges and inclusions. The results were similar in all four western USA regions (Table 4). Figure S1 is an example illustration of various distances from potential seed sources in very large (>1000 ha) high-severity patches in two areas: Rim fire 2013 (Stanislaus National Forest, Sierra Nevada, CA) and Hayman Fire 2002 (northwest Colorado Springs area).

Table 4. Percentages of the total area within the boundaries of CESF patches >400 ha, created by high-severity fire, that were at increasing distances from unburned or low/moderate-severity edges and inclusions.

Distance (m)	Sierra-Nevada/ Southern-California	Klamath/ Southern-Cascades	Northern-Cascades/ Northern-Rockies	Southern-Cascades/ Southwest
<100	49.3	55.6	46.8	54.7
101–200	27.6	25.5	25.2	26.0
201–300	13.5	11.2	12.8	10.6
>300	9.6	7.7	15.3	8.7

There is historical evidence of numerous large CESF patches created by high-severity fire prior to widespread fire suppression in every region of the western USA in low/middle-montane forests (Table 5). Historical patches >400 ha ranged from ~400 ha to >20,000 ha for our study area.

Table 5. Examples of historical occurrence of CESF patches >400 ha, created by high-severity fire, in low/middle-montane forests of the western USA [1].

Source	Region	Forest Type	Evidence Type	Patch Size/s (ha)	Time Period
[54,55]	Northern Sierra Nevada	Mixed-conifer and ponderosa pine	Historical USGS mapping, and current GIS analysis	400–~9000	19th century
[8]	Sierra Nevada	Mixed-conifer and ponderosa pine	Reconstruction, using 19th-century General Land Office data	Largest = 8050 (northern) and 9400 (southern)	19th century
[56]	Eastern Washington Cascades	Mixed-conifer	Reconstructions of past high-severity from historical aerial photos	400–10,500	19th century, and early 20th
[57]	Eastern Oregon Cascades	Mixed-conifer and ponderosa pine	Reconstruction from 19th-century General Land Office data	400–~5000	19th century
[58]	Oregon Klamath	Mostly ponderosa pine	Historical account, early 20th century U.S. Geological Survey report	~14,000	19th century
[59]	Colorado Front Range	Mostly ponderosa pine	Reconstruction from 19th-century General Land Office data	400–~22,000	19th century
[59]	Blue Mountains, Oregon	Ponderosa pine	Reconstruction from 19th-century General Land Office data	400–~12,000	19th century
[59]	Central/eastern Arizona	Ponderosa pine	Reconstruction from 19th-century General Land Office data	400–~40,000	19th century
[60]	Black Hills, South Dakota	Ponderosa pine, some lodgepole pine	Historical account	~19,000	mid-19th century
[61,62]	Northern Rockies	Ponderosa pine, some Douglas-fir	Reconstruction from historical aerial photos	~35,000	1910

[1] Some patches may have resulted from more than one fire. This represents all available data on historical occurrence of high-severity fire patches >400 ha known to currently exist within western US frequent-fire conifer forest types. For context, the largest individual high-severity fire patches in each of the four current time periods analyzed in this study are (in chronological order, by time period) 2109, 8539, 6554, and 8153 ha.

4. Discussion

Despite concerns about there being too many large CESF patches produced by big fires, we found that while an increase in the total area of such patches did occur initially in the time series, this happened over two decades ago and there has been no subsequent increase since the 1990s. We did not find an increase in the size of individual CESF patches >400 ha at any point during the time series (1984–2015)—i.e., patches >400 ha did not get significantly larger in more recent time periods. The rotation intervals for large patches ranged from about twelve centuries to over four millennia, depending on the region. A posteriori, we conducted the same analyses regarding whether there had been an increase in the area of large high-severity fire patches, but with a smaller patch size threshold (>100 ha), and we found the same result—i.e., significant differences between the first time period and the third and fourth time periods, but no other significant differences (Table S1, Figure S2). We did not conduct a posteriori analysis for patches >100 ha regarding the question of whether individual high-severity patches had been getting larger, since there were no significant or marginally significant differences with the >400 ha threshold.

Importantly, in large CESF patches, within-patch heterogeneity was high, with the great majority of patch area occurring within 200 m of the potential seed sources of unburned, low, or moderately burned conifer forest. In this regard, our findings are similar to those in the Northern US Rockies [63]. Depending on site factors, natural post-fire conifer regeneration generally occurs most quickly and abundantly within 100 m of low/moderate-severity and unburned recruitment areas, and secondarily at 100–200 m from unburned or low/moderate-severity areas [45,50–53,64]. It also occurs—typically more slowly and less densely—in the portion of large CESF patches that are >200 m from unburned or low/moderate-severity areas [51,53,64]. However, in these more distant areas, we can expect pockets of more open conifer forest or dense vegetation dominated primarily by oaks (*Quercus* spp.) and aspen (*Populus* spp.) and secondarily by conifers [51,64]. This internal patch heterogeneity indicates that large CESF patches play an important role in creating and maintaining pockets of open forest stands and increasing the heterogeneity (beta diversity) of forest structure across the landscape [64].

We also found considerable evidence of historical occurrence of large CESF patches in all regions, indicating that such patches are a component of natural fire regimes in low/middle-elevation, frequent-fire conifer forests of the western USA. More research is needed to compare current versus historical extents of such patches.

Modeling studies regarding wildland fire in western forests project overall increases [65], or more complex mixes of increases and decreases within and among regions, mediated by interactions between climate and vegetation shifts [65–67]. Thus, it will be important to continue to monitor high-severity fire occurrence and patch sizes periodically to understand any patterns that emerge in patch dynamics and conifer recruitment rates. Our findings also differ from some previous work regarding high-severity fire trends in western U.S. conifer forests. Some researchers [13,14], for instance, noted increasing trends in overall high-severity fire occurrence in mixed-conifer forests of the Sierra Nevada. Subsequent analyses [15,16] found that the use of a vegetation database by these researchers post-dated the time series being analyzed and led to an unintended omission of much of the high-severity fire in the earlier years of the time series, causing the appearance of an upward trend where no such trend existed. In other words, it was later found that the vegetation database used by these studies often did not reflect the vegetation that existed at the time of the fires analyzed, since much of the conifer forest that experienced high-severity fire in the earlier years of the time series was later reclassified as chaparral or other non-conifer vegetation—a phenomenon that occurred less for more recent fires in the time series.

Others [46,68,69] reported an increasing trend in the interior area of high-severity fire patches in the Sierra Nevada, but also used a vegetation database that post-dated the time series and omitted more of the high-severity fire in the earlier years of the time series [15]. They did not account for small low/moderate-severity inclusions within large high-severity fire patches, while inclusions of this size were common in our analyses.

Our results indicate that large CESF patches have high levels of heterogeneity (beta diversity), even within the most interior portions, which may facilitate heterogeneous natural forest regeneration in ecologically beneficial ways [25,53,55,70]. Some delayed tree mortality can, of course, occur in the years following a fire in low/moderate-severity inclusions, and this could potentially influence the internal patch complexity along with conifer seedling establishment. Yet, even in such cases, individual trees experiencing delayed mortality would provide seed source in the interim years, and research into delayed post-fire mortality indicates fairly modest levels of such occurrences in low/moderate-severity pixels [71].

Some researchers have expressed concern about type conversion to non-forest following fires, especially high-severity fires, e.g., [47,72]. Although a detailed discussion of this issue is beyond the scope of our study, we note that areas described as examples of possible post-fire type conversion nevertheless had substantial post-fire conifer regeneration, generally within the described natural range of variability for the specific forest type [72], and the areas with no regeneration occurred at the spatial scale of very small plots [47,72]. Thus, we suggest that there may be a scale-of-observation issue at work here, and much larger plots indicate more consistent post-fire regeneration [64]. Moreover, while recent research has suggested somewhat lower regeneration in more recent fires, time-since-fire was not accounted for, and far fewer years of post-fire succession had occurred at the time of field sampling in the more recent fires, which might account for the difference [47]. Nevertheless, some researchers have predicted that in a hotter and drier climate in certain areas, such as the Klamath region of northwestern California, recurrent high-severity fire could limit the recruitment of some conifer species in future decades [73]. Thus, more research is needed to address this question after taking spatial and temporal scale and time-since-fire into account.

5. Conclusions

Our findings have specific management and policy relevance. In particular, we counter claims made by some researchers, and often used by decision-makers, to justify large-scale forest “thinning” and post-fire logging projects—specifically, the assumption that such logging projects are needed to prevent type conversion in response to a perceived increase in CESF patch sizes and conifer regeneration failures in “megafires” (see [6,18,20,22]). Lack of a biodiversity perspective has created underlying tensions among researchers over the role of high-severity fires in maintaining CESF, and we hope that our findings will now inform this ongoing discussion. Additionally, contrary to assumptions made by land managers in the course of proposing extensive post-fire logging and creation of artificial tree plantations following large fires, we found ample evidence of patch heterogeneity–and presumably natural conifer establishment–in large severely burned patches, in addition to the occurrence of large high-severity patches in the historical record. This finding has key relevance to current forest management policy, since the assertion that current large CESF patches are unprecedented is not substantiated by our data but is being used to justify legislative and regulatory proposals to severely weaken environmental laws on U.S. federal lands.

Notably, numerous studies have found high levels of native plant and animal richness and abundance in large fires of mixed severity that produce CESF patches in severely burned areas, see [3,24–31,70,74,75]. Such fires facilitate high levels of beta diversity at landscape scales, providing a broad suite of habitat for both fire-seeking and fire-avoiding species [25], including many early seral birds that have been declining due to a lack of “diverse early seral habitat” [76]. Thus, far from being indicative of “catastrophic” (or “megafire”) ecosystem shifts, large CESF patches have consistently been found to support a unique ecological community that is otherwise most often post-fire logged because of perceptions that this forest type has limited wildlife value, see [25,75]. Instead, we found that large CESF patches are extremely infrequent at landscape scales in ponderosa/Jeffrey-pine and mixed-conifer forests of the western U.S., and whether high-severity fire that produces this important seral stage is increasing in western USA forests remains debatable, e.g., [4,9–11,13–16,19,21,23].

Regarding the human implications of our findings, we recommend that land managers focus limited resources on community fire safety and defensible space of homes as a means of getting to coexistence with wildfire [77–79] and for managing wildfire under safe conditions for a myriad of ecosystem benefits.

Supplementary Materials: The following are available online at http://www.mdpi.com/1424-2818/11/9/157/s1: Figure S1: Example of CESF patches >1,000 ha, showing distances from areas of unburned, low, and moderate severity fire within the patch boundaries in the Rim (Stanislaus National Forest, CA) and Hayman fires (Colorado Front Range). Figure S2: Annual area of large patches (>100 ha) of CESF in the four time periods; Table S1: Critical values ($q_{0.05,\infty,4}$), absolute difference between mean of ranks ($|R_A\text{-}R_B|$), standard errors (SE), and test statistics (q) to assess statistical significance, at $\alpha = 0.05$ of any differences between the four time groups (1 = 1984–1991, 2 = 1992–1999, 3 = 2000–2007, and 4 = 2008–2015) for total annual area of CESF patches >100 ha using the Nemenyi non-parametric test for multiple comparisons between groups with an equal sample size (n = 8 years for each time group). The statistical significance of levels of q is shown as Y (significant) or N (not significant).

Author Contributions: D.A.D. and C.T.H. were equally involved in all aspects of this study.

Funding: We thank the Leonardo DiCaprio Foundation, the Weeden Foundation, and the Wilburforce Foundation for project funding; however, the views herein are strictly those of the authors.

Acknowledgments: Curtis Bradley, Center for Biological Diversity, did all the GIS analyses and project mapping. We thank 3 anonymous reviewers and the journal editors for improvements to the manuscript and Randi Spivak, Center for Biological Diversity, for policy implications of our findings.

Conflicts of Interest: We declare no conflict of interest. The funders had no role in the design of the study; in the collection, analyses, or interpretation of data; in the writing of the manuscript, or in the decision to publish the results.

An Ecologically Based Strategy for Fire and Fuels Management in National Forest Roadless Areas

Dominick A. DellaSala[1] and Evan J. Frost[2]

Dominick DellaSala is a Forest Ecologist and Director of the Klamath-Siskiyou Regional Program for the World Wildlife Fund, Ashland, OR; and Evan Frost is an Ecologist for Wildwood Environmental Consulting, Ashland, OR.

[1] World Wildlife Fund, 116 Lithia Way, Suite 7, Ashland, OR 97520; 541-482-4878 (-4895 fax) – dellasal@wwfks.org

[2]Wildwood Environmental Consulting, 84-Fourth[th] St., Ashland, OR 97520; 541-488-2716; efrost@internetcds.com

During the challenging 2000 fire season, the local and national headlines trumpeted daily news about the "worst fires in recent memory." The media showered us with the latest statistics on wildland fires in the West: "More than 6 million acres charred in 13 Western States…more than 25,000 firefighters deployed…over 80 blazes raging out of control…hundreds of homes consumed."

Amid the media frenzy, one Presidential candidate—George W. Bush—sought to improve his position in the public opinion polls by stating that greatly reduced logging levels on national forests during the previous decade had "made the forests more dangerous to fire." The implication was that the USDA Forest Service's proposed policy for protecting roadless areas was akin to putting a lit match into a tinderbox.

Others called for massive logging, roadbuilding, and a rash of prescribed fires as a quick fix for the previous 50-100 years of fire suppression. While conservationists advocated for roadless area protection on the grounds that roadless areas are the last remnants of formerly large and intact forests, critics asserted that fiery conflagrations would inevitably occur if the same forest remnants were not intensively managed. The rest of us pondered: Where is the science in all this? Is every acre doomed to "catastrophic" fire if not intensively managed? Is it appropriate to treat all forests the same, regardless of whether or not they contain existing road systems?

After all the hyperbole – a combination of media hype, electoral politics, and misinformation spread to promote special interests – it's time to take a sober look at the questions raised by the 2000 fire season. Specifically, what evidence exists on the relationship between wildland fire and timber management in roaded vs. roadless areas? What effects might silvicultural treatments and prescribed fire have on ecosystems in roadless areas? Is there an ecologically based strategy for identifying, on a case-by-case basis, where active management might be appropriate for maintaining fire-dependent forest ecosystems?

Fire and Roadless Areas

Level of Fire Hazard. Scientists widely agree that protecting roadless areas on the national forests from roadbuilding, logging, and other forms of development will greatly enhance biodiversity and ecosystem conservation (Ercelawn 1999; Henjum and others 1994; Noss and Cooperider 1994; Strittholt and DellaSala [in press]). However, some critics of roadless area protection (Bernton 1999; Hansen 1999; Schlarbaum 1999) have repeatedly made two assertions:

- Road building prohibitions in roadless areas will restrict access and timber management, which in turn will increase the frequency of large, intense fires.
- Widespread silvicultural treatments (such as low thinning and crown thinning) in roadless areas will be necessary to reduce the fire hazard.

Does the relevant scientific literature support these claims?

Broad scientific assessments were completed in 1996 and 1997, respectively, for Federal lands in the Sierra Nevada in California and the Interior Columbia River Basin in portions of Idaho, Montana, Nevada, Oregon, Washington, and Wyoming. These studies provide the most comprehensive analysis to date for comparing fire, fuel, and vegetation conditions in intensively managed areas to conditions in roadless areas. Both assessments found the fire hazard to be significantly higher in intensively managed areas.

According to the Sierra Nevada assessment, “Timber harvest, through its effects on forest structure, local microclimate and fuel accumulation, has increased fire severity more than any other recent human activity” (SNEP 1996). The Interior Columbia Basin assessment similarly concluded that “fires in unroaded areas are not as severe as in roaded areas because of less surface fuel….Many of the fires in the unroaded areas produce a forest structure that is consistent with the fire regime, while the fires in the roaded areas commonly produce a forest structure that is not in sync with the fire regime. Fires in the roaded areas are more intense, due to drier conditions, wind zones on the foothill/valley interface, high surface-fuel loading, and dense stands” (Hann and others 1997).

Even within the forest types most altered as a result of fire suppression (such as dry forests with a regime of frequent low-intensity fires), intensively managed forests on federal lands in the Interior Columbia Basin are denser and carry higher fuel loads than do roadless areas. Accordingly, intensively managed lands were found to be at higher risk of tree mortality from fire, insects, disease, and other disturbance agents (Hann and others 1997).

Others have reported similar findings for portions of the interior West. In the Sierra Nevada, McKelvey and others (1996) and Weatherspoon (1996) identified timber harvest as the single most important factor responsible for an increase in potential fire severity. In the Klamath Mountains of northwestern California, Weatherspoon and Skinner (1995) found that partial-cut stands with fuels treatment (lop and scatter or broadcast burning) burned more intensely and suffered higher levels of tree mortality than adjacent areas left uncut and untreated. Fire and fuel models also suggest that mechanical treatments alone, including silvicultural thinning and biomass removal, are not likely to be effective at reducing fire severity in dense stands (van Wagtendonk 1996).

In eastern Oregon and Washington, Lehmkuhl and others (1995) and Huff and others (1995) reported a positive correlation between logging, on the one hand, and fuel loadings and predicted flame lengths, on the other hand. They attributed the increased fire hazard in intensively managed areas to leftover slash fuels from tree removal activities (including thinning) and to the creation of dense, early-successional stands through overstory removal. A postfire study of the effectiveness of fuels treatments (including thinning) on previously nonharvested lands on the Wenatchee National Forest in Washington found that harvest treatments likely exacerbated fire damage (USDA Forest Service 1995).

Overall, the scientific literature shows that forests in areas without roads are less altered from historical conditions and present a lower fire hazard than forests in intensively managed areas, for three reasons:

1. Timber management activities often increase fuel loads and reduce a forest's resilience to fire.
2. Areas without roads have been less influenced by fire suppression than intensively managed lands.
3. Widespread road access associated with intensively managed lands raises the risk of human-caused ignitions.

As summarized in a recent review of national forest management organized by the Ecological Society of America, "There is no evidence to suggest that natural forests or reserves are more vulnerable to disturbances such as wildfire than intensively managed forest stands. Indeed, there is considerable evidence to the contrary, evidence that natural forests are actually more resistant to many types of both small- and large-scale disturbances" (Aber and others 2000). Assertions about increased wildfire made by critics of roadless area protection are not based in fact, as the evidence is clear that the forests most in need of fuels treatment are not roadless areas but areas that have already been roaded and logged, "where significant investments have already been made" (USDA/USDI 1997).

Effectiveness of Fire Suppression. Some evidence exists that fire suppression activities have had a lower impact on roadless areas than on roaded portions of the national forests (Hann and others 1997; SNEP 1996). The lower impact may be attributable to limited access and steep terrain, which prevent the application of large, ground-based suppression strategies in roadless areas (Agee 1993; Fuller 1991; Pyne 1996; Schroeder and Buck 1970).

Fires in roadless areas tend to be more remote from human habitations than are fires on roaded lands. Accordingly, they are often the lowest priority for suppression during years when fire-fighting resources are in short supply. Although data are limited, findings from the Interior Columbia Basin assessment on this topic might apply to other regions as well. The assessment concluded that a “combination of past harvest practices and more effective fire suppression moved the roaded landscapes much further from their unaltered biophysical templates, as measured by dominant species, structures, and patterns, relative to unroaded areas….In general, all forests which show the most change from their historical condition are those that have been roaded and harvested” (Hann and others 1997). Furthermore, the forests that are most susceptible to moisture stress, insects, disease, and unnaturally intense fire tend to be at the lowest elevations, which typically border private, state, tribal, or other landownerships (Everett and others 1994).

Another reason why fire suppression has had less impact on forests in roadless areas is associated with differences in vegetation and fire regimes. Most roadless areas on the national forests, particularly in the interior West, are at mid- to high-elevations (Beschta and others 1995; Henjum and others 1994; Merrill and others 1995). The exceptions are in the Eastern United States, where elevational gradients are limited, and the Klamath–Siskiyou ecoregion in northwest California and southwest Oregon, where very steep slopes at lower elevations have limited road construction (Strittholt and DellaSala [in press]).

Higher elevations are cooler, receive more moisture, and have a shorter summer dry season than lower elevations. They are typically characterized by a regime of low frequency, high-intensity fires (Agee 1993; Baker 1989; van Wagner 1983). Roadless areas are therefore less likely to have current fire regimes that are significantly different from historical conditions (Agee 1997; Beschta and others 1995).

For fires in high-elevation forests, weather rather than fuels is often the primary variable determining fire severity and extent (Agee 1997; Bessie and Johnson 1995; Flannigan and Harrington

1988; Johnson and Wowchuck 1993; Turner and others 1994). Under severe fire weather, the efficacy of fire suppression decreases dramatically in forest types characterized by high-intensity fires (Agee 1998, SNEP 1996). Even substantial investments of financial and human firefighting resources often fail to control large fires; they are extinguished only when the weather changes (Romme and Despain 1989).

Risk of Human-Caused Ignitions. Roadless areas have a lower potential for high-intensity fires than roaded areas partly because they are less prone to human-caused ignitions (DellaSala and others 1995; USDA Forest Service 2000; Weatherspoon and Skinner 1996). Roads constructed for timber management and other activities provide unregulated motorized access to most national forestlands and are heavily used by the general public.

In the Western United States, many of the more than 378,000 miles of national forest roads traverse heavily managed forests with the greatest potential for high-severity fire. According to the Forest Service, more than 90 percent of wildland fires are the result of human activity, and ignitions are almost twice as likely to occur in roaded areas as they are in roadless areas (USDA Forest Service 1998, 2000). While it can be argued that roads provide improved access for fire suppression, this benefit is more than offset by much lower probabilities of fire starts in roadless areas.

The Case Against Mechanical Fuels Treatments in Roadless Areas

Some land managers and policy makers advocate the widespread use of silvicultural treatments (often mechanical thinning of merchantable trees) in western roadless areas to reduce fuel loads and tree stocking levels and thereby decrease the probability of large, intense fires. Although thinning has long been a part of intensive forest management, its efficacy as a tool for fire hazard reduction at the landscape scale is controversial, largely unsubstantiated, and fundamentally experimental in nature (DellaSala and others 1995; FEMAT 1993; Henjum and others 1994; SNEP 1996; USDA Forest Service 2000).

Few empirical studies have tested the relationship, even on a limited basis, between thinning or other fuels treatments and fire behavior. These studies, supported by anecdotal information and the analysis of recent fires, suggest that thinning treatments have highly variable results. In some instances, thinning intended to reduce the fire hazard appeared to have the opposite effect (Huff and others 1995; van Wagtendonk 1996; Weatherspoon 1996). Thinning might reduce fuel loads, but it also allows more solar radiation and wind to reach the forest floor. The net effect is usually reduced fuel moisture and increased flammability (Agee 1997; Countryman 1955).

Moreover, mechanical treatments fail to mimic the ecological effects of fire, such as soil heating, nutrient cycling, and altering forest community structure (Chang 1996; DellaSala and others 1995; Weatherspoon and Skinner 1999). In fact, according to the SNEP (1996), "although silvicultural treatments can mimic the effects of fire on structural patterns of woody vegetation, virtually no data exist on their ability to mimic the ecological functions of natural fire. Silvicultural treatments can create patterns of woody vegetation that appear similar to those that fire would create, but the consequences for nutrient cycling, hydrology, seed scarification, non-woody vegetation response, plant diversity, disease and insect infestation, and genetic diversity are almost unknown."

Although our current understanding of the ecological effects of thinning is incomplete, evidence indicates that mechanical treatments, even when carefully conducted, can have additional environmental impacts:

- Damage to soil integrity through increased erosion, compaction, and loss of litter layer (Harvey and others 1994; Meurisse and Geist 1994);
- Increased mortality of residual trees due to pathogens and mechanical damage to boles and roots (Filip 1994; Hagle and Schmitz 1993);
- Creation of sediment that might degrade streams (Beschta 1978; Grant and Wolff 1991);
- Increasing levels of fine fuels and near-term fire hazard (Fahnestock 1968; Huff and others 1995; Weatherspoon 1996; Wilson and Dell 1971);
- Disruption of mycorrhizal fungi – plant relationships that are important to ecosystem function – and shrubs and perennial native bunchgrasses involved in fungal linkages (Amaranthus and Perry 1994, Massicotte and others 1999, pers. comm. D. Southwort and L. Valentine, Southern Oregon University);

- Dependence on roads, which have numerous adverse effects of their own (Henjum and others 1994; Megahan and others 1994); and
- Reduced habitat quality for sensitive species associated with cool, moist microsites or closed-canopy forests (FEMAT 1993; Thomas and others 1993).

These adverse impacts of mechanical treatments should be of particular concern in managing roadless areas, where ecological values are especially high. Moreover, roadless areas are often in steep, unstable terrain that is highly sensitive to human disturbance (Henjum and others 1994; Wilderness Society 1993). According to the Forest Ecosystem Management Assessment Team, most existing roadless areas "are considered inoperable because timber harvest and road construction would result in irretrievable loss of soil productivity and other watershed values. These lands consist of erosion- and landslide-prone landforms such as inner gorges, unstable portions of slump earthflow deposits, deeply weathered and dissected weak rocks, and headwalls" (FEMAT 1993).

Similarly, the Interior Columbia Basin assessment found "a high risk to watershed capabilities from further road development in these [roadless] areas. In general, the effects of wildfires in these areas are much lower and do not result in the chronic sediment delivery hazards exhibited in areas that have been roaded. In contrast, the already roaded areas have high potential for restoration action" (USDA/USDI 1997). Given the potential for adverse impacts from silvicultural treatments in roadless areas, many scientists recommend limiting experimental treatments to previously managed lands already degraded by fire suppression and logging (Aber and others 2000, Beschta and others 1995; DellaSala and others 1995; Franklin and others 1997; Hann and others 1997; Henjum and others 1994; McKelvey and others 1996; Perry 1995).

In summary, scientific assessments of federal lands in several western regions generally conclude that previously roaded and logged areas should be the highest priority for fuels reduction and forest restoration treatments (FEMAT 1993; Hann and others 1997; SNEP 1996). Silviculture has a role to play in a scientifically based approach to fire and fuel management on federal lands, but current evidence indicates that widespread mechanical treatments in roadless areas would most likely increase rather than decrease ecosystem degradation. Therefore, experimentation with mechanical treatments for fire hazard reduction should proceed primarily in areas with road access and adjacent to private lands where the ecological risks are lower and the threat of fire to human lives and property is far greater.

Roadless areas should only be considered for mechanical treatment after all other, higher priority areas are addressed and only if it can be demonstrated that such treatments will not degrade ecological values. Any experimental treatments in roadless areas should occur in small roadless areas (less than 5,000 acres (2,000 ha)) that have relatively good access, are near the wildland-rural interface, and exhibit high fire hazard due to past suppression. Only small trees (generally less than 12" diameter) should be considered for removal and under no circumstances should new or temporary roads be built to conduct mechanical treatments.

The Case for Prescribed Fire in Roadless Areas

The Forest Service should treat roadless areas primarily by reintroducing fire, both natural and prescribed. Restoration of ecological processes is key to ecosystem integrity and biological diversity (Samson and Knopf 1993), particularly in unroaded areas. Use of prescribed fire has been successful in restoring wildland fire regimes to many fire-adapted ecosystems (Wright and Bailey 1982), and a widespread consensus exists that additional burning is necessary (Arno 1996; Mutch 1994, 1997; USDA/USDI 1995; Walstad and others 1990).

Prescribed fire has important advantages over mechanical treatments in areas where ecological integrity and biodiversity conservation are important management objectives (Hann and others 1997; SNEP 1996; Weatherspoon and others 1992). Prescribed fire also appears to be the most effective treatment for reducing fire severity and rate of spread (Stephens 1998; van Wagtendonk 1996). In addition to reducing fuel loading and continuity, prescribed fire may decrease pest outbreaks, provide germination sites for shade-intolerant species, release nutrients, and create wildlife habitat (Agee 1993; Biswell 1999; Chang 1996; Walstad and others 1990).

Positive outcomes associated with prescribed fire are, of course, contingent on detailed site-specific planning, adequate budgetary support, and careful execution by trained personnel. In roadless areas with forests characterized by low-intensity, high-frequency fire regimes, repeated prescribed burns within a relatively short timeframe might be required to sufficiently reduce fuels and ensure that fire intensities remain within an acceptable range (Biswell 1999). After initial treatment, the frequency of prescribed burns can be designed to reflect the inherent disturbance regime and range of variability associated with particular forests. Data from the Sierra Nevada suggest that prescribed burning is likely to be considerably cheaper for treating fuels than either mechanical treatments or fire suppression (Husari and McKelvey 1996; see Deeming (1990) for a summary of the literature on the cost-effectiveness of prescribed burning versus other fuel treatments).

In addition to prescribed fire, ecological benefits could flow from allowing some naturally ignited fires to burn in roadless areas under specific environmental conditions. Traditionally, the Forest Service has suppressed most wildland fires without adequately considering the potential resource benefits of a “confine-and-contain” strategy. However, Federal policies introduced in 1995 encourage careful management of naturally ignited wildland fires if they meet resource objectives and are consistent with historical fire regimes (USDA/USDI 1995). Less than full control strategies for fire suppression could be employed, provided the strategy chosen is projected to incur the least cost of suppression and the least loss of resource values (McKelvey and others 1996).

Carefully planned wildland fire use should be fully considered for roadless areas, based on fire regime, expected fire behavior, and other variables, as an alternative to costly firefighting in remote areas where there is little or no danger to lives and property. In 2000, the Forest Service spent more than $91 million fighting two large fires in Idaho, the Burgdorf Junction Fire and the Clear Creek Complex Fire. Together, the fires burned more than 280,000 acres, mostly in remote roadless and wilderness areas (Morrison and others 2000; NIFC 2000a). On such fires, wildland fire is likely to be the most sensible as well as ecologically appropriate strategy.

Roadless areas could instead benefit from proactive fuels management using fire. Fire management in roadless areas should be based on (1) a standard set of guidelines for identifying and prioritizing roadless areas based on their fire hazard and risk at the national or regional level (see sidebar); and (2) a subsequent step-down process for planning fire treatments at the local level, designed to allow fire to play a more important role while minimizing risks to ecological values.

[DESIGNER: Please place the first sidebar near here.]

Integrated Management Strategies are Needed

Roadless areas do not exist in isolation from other land designations. It follows that an effective fire and fuel management strategy should be developed at the landscape scale. This means first identifying areas of highest priority for fire/fuels treatments and then planning treatments that are consistent with management standards to ensure protection of soil, water, wildlife and other ecological values. For roadless areas, high-priority treatment areas should first be identified at the national and regional scale. Then site-specific burn plans can be developed for individual roadless areas, or for complexes of areas, by integrating spatial information on fire hazard (fuel load, fuel continuity, and topography); fire risk (ignition history and weather); and ecosystem values (old-growth forests, wildlife habitat, and sensitive watersheds) (Agee 1995; Bunting 1996; Crutzen and Goldhammer 1993; Johnson and others 1997; Weatherspoon and Skinner 1996). By employing this kind of tiered prioritization, limited resources can be directed to areas that are most in need of fire and fuels reduction.

Over time, as fire is reintroduced into roadless areas – coupled with fire and other fuels treatments on adjacent, intensively managed lands – the occurrence of large, high-intensity wildland fires might become of less concern. In rare cases, limited low thinning (removal of small understory trees) may be appropriate in some roadless areas as a prerequisite for prescribed fire. However, more experimentation and research on the efficacy of mechanical treatments should first be conducted in intensively managed forests before broadly applying them to roadless areas. Such a cautious approach is warranted, given that a mere 4 percent of roadless lands present a high fire hazard; the vast majority of areas at risk of uncharacteristically intense fire are in the intensively managed, roaded landscape (USDA Forest Service 2000).

[DESIGNER: Please place the second sidebar near here.]

Although much can be done to reduce fire hazards, there is no “magic bullet” to reverse many decades of fire suppression activities. Despite our best intentions, the fire situation may yet worsen as more homeowners build cabins deeper into fire-prone forests and climate change potentially produces hotter and drier conditions in some areas. Moreover, it is important to note that despite all the media hype, the 2000 fire season was relatively light by historical standards: In the 1930’s, more than 39 million acres (15.6 million ha) burned on average each year (NIFC 2000b).

The strategy outlined here is consistent with the Clinton Administration’s recent policy recommendations that emphasize treatment of the highest priority areas first in non-controversial areas – the wildland-rural interface and designated municipal watersheds (Council on Environmental Quality 2000). To ensure that current fire management policy avoids ecological risks associated with the logging of large trees and other ecosystem values, we recommend that thinning in priority areas target only the removal of small, non-commercial material that has most likely increased as a result of fire exclusion and is of greatest concern for hazardous fuel reduction. This is consistent with Chief Dombeck’s letter (5/23/00 file code 1500) to Senator Bingaman emphasizing that emergency appropriations be used to remove small trees <12 inch dbh (30 cm) from priority areas.

In contrast, timber industry representatives such as Butch Bernhardt of the Western Wood Products Association insist that “cutting some larger trees” is “the incentive” needed to “markedly improve forest health” by allowing “more sunlight and nutrients to reach the remaining growth” (Associated Press 2000). Commercial harvest is designed for profit, not to address ecological need; the timber industry’s claims to the contrary are inconsistent with the available science on fire and fuels management. Only through an integrated approach that emphasizes protection of roadless values and focuses treatment where it is most needed – in the roaded landscape – are we likely to make significant progress in restoring the resiliency of western forest ecosystems.

Prioritizing Roadless Areas for Prescribed Fire

Land managers need a comprehensive set of criteria for prioritizing roadless areas for prescribed fire treatments. The following list provides a preliminary guidepost for determining high-priority areas for treatment. Prescribed fire should be considered for roadless areas where:

- Most of the area is covered by dry forest types that are characterized by low-intensity, high-frequency fire regimes;
- A long interval has passed since the last major fire (for example, more than three natural fire cycles have been missed);
- The topographic and elevational gradients are relatively gentle, permitting relatively low-risk prescribed fire treatments and raising the likelihood that past firefighting efforts have increased the fire hazard;
- Areas of high fire risk are nearby, such as the wildland–rural interface, major population centers, transportation routes, or residential developments and other infrastructure; and
- Ecological risk factors are absent or low, such as—
    - Populations of threatened and endangered species or rare communities that are known to be adversely affected by fire;
    - Vegetation changes that would predictably result from fire treatments; or
    - Fish refugia where burning could impair hydrological processes or degrade critical fish habitat through sedimentation.

[DESIGNER: Please set up the following as the second sidebar.]

Principles for Fire and Fuels Management

Land managers need a comprehensive, landscape-level strategy for fire/fuels management that takes into account the important values associated with roadless areas and directs treatments where they are needed the most. The strategy should be based on the following principles:

- Limit mechanical treatments to high-priority areas, primarily roaded areas of dense, dry forest within the wildland–rural interface.
- Define the wildland–rural interface by treating areas immediately adjacent to rural settlements as a first line of defense. Provide homeowners with assistance grants to reduce the fire hazard on private land by creating a defensible space around homes.
- Conduct watershed or landscape-scale assessments that identify restoration priorities before fire/fuel treatments are initiated.
- Eliminate commercial incentives for mechanical removal of merchantable trees by decoupling goods from services (that is, pay a fixed fee for tree removal services that is not tied to timber volume).
- Restrict thinning to small-diameter trees (e.g., less than 12 inches (30 cm) in diameter at breast height or less than the average stand diameter) where it can be demonstrated that current forest stand densities are outside the historical range of variability.
- Minimize impacts to soils, below-ground processes and related species, accumulation of surface fuels from thinning, and exposure to solar radiation and reduction of soil moisture retention.
- Conduct mechanical treatments in priority areas in compliance with all relevant environmental statutes (e.g., National Environmental Policy Act, National Forest Management Act, Endangered Species Act, etc).

Roadless areas and clean water

Dominick A. DellaSala, James R. Karr, and David M. Olson

Clean water, like biodiversity, is most closely linked to undisturbed natural ecosystems. When undisturbed watersheds in roadless and protected areas (e.g., national parks, state parks, wilderness areas, national monuments) are fragmented by roads, logging, and intensive recreation development, both water quality and biodiversity decline as hydrological integrity is lost (USFS 1972, 1979, 2001; Alexander and Gorte 2008; Anderson 2008). In the United States, inventoried roadless areas (IRAs) are lands without roads exceeding 2,000 ha (5,000 ac) that have been inventoried by the USDA Forest Service. IRAs collectively amount to approximately one third of the 77 million ha (193 million ac) of the 155 national forests but are disproportionately concentrated in western states (figure 1) (Trout Unlimited 2004; Anderson 2008). The roaded, intensively managed landscapes of the other national forest lands have been closely correlated with heavily sediment-laden streams and dramatic changes in flow regimes (Espinosa et al. 1997; Trombulak and Frissell 2000; CBD et al. 2001; Coffin 2007; Frissell and Carnefix 2007). While the biodiversity benefits of IRAs are well documented (DeVelice and Martin 2001; Strittholt and DellaSala 2001; Loucks et al. 2003; Strittholt et al. 2004; Gelbardi and Harrison 2005), little has been made of the importance of IRA water for downstream users and wildlife.

In this paper, we assess the importance of IRAs from a water quality perspective, including the likely water quality effects of developing IRAs. We provide conservative estimates of the economic impact of intact unroaded watersheds on national forests for clean water and associated water resource benefits. In particular, rising demand and shrinking water supply associated with changing climate will likely make intact areas in drought-prone regions of the West even more valuable and crucial to protect. Thus, our findings are especially relevant to drought-prone states considering development of IRAs. The state of Colorado, for example, with approximately 1.7 million ha (4.2 million ac) of IRAs, has been seeking federal permission to develop its IRAs for logging, expanding ski areas, coal-bed mining, and producing oil and gas (figure 2) (Anderson 2008; Colorado Division of Wildlife 2010; Colorado, State of 2010; Straub 2010, USFS 2011). Although we focus on IRAs throughout the western United States, we also emphasize the importance of uninventoried roadless areas (unroaded) <2,000 ha (Henjum et al. 1994; Greenwald 1998; Beschta et al. 2004) that collectively cover an area roughly 1.5 times that of the total IRA network (USFS 2000; Strittholt et al. 2004). Those smaller unroaded areas also play a strategic role in maintaining reliable supplies of high-quality water and protecting aquatic ecosystems.

Dominick A. DellaSala is Chief Scientist and President of the Geos Institute, Ashland, Oregon. **James R. Karr** is professor emeritus of ecology and environmental policy at the University of Washington, Seattle, Washington. **David M. Olson** is a conservation biologist at the Conservation Earth Consulting, Burbank, California.

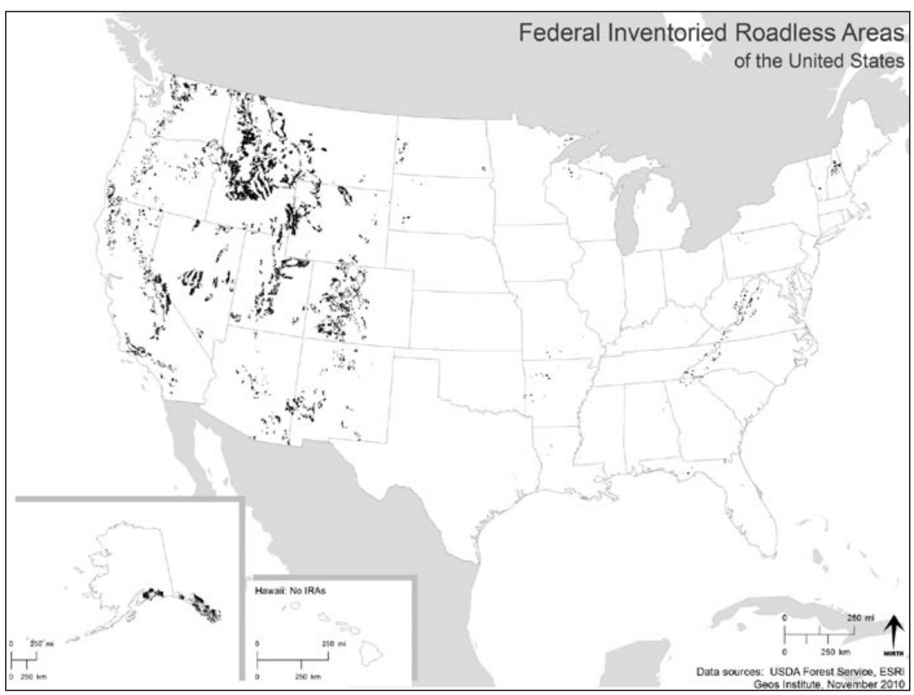
ROADLESS AREAS PROVIDE SUBSTANTIAL WATER RESOURCE BENEFITS

IRAs benefit society in many ways, including providing a valuable and increasingly rare natural supply of abundant, clean, and naturally reliable water (Sedell et al. 2000); affordable drinking water for municipal and rural communities; water for agricultural and industrial uses; flood control; in-stream aquatic recreation; aquifer recharge; flood protection; reliable water supply; diverse and productive fisheries; healthy aquatic ecosystems; resident and migratory waterfowl habitat; recovery of endangered species; and, increasingly, the vitality and sustainability of local economies (table 1). These benefits accrue nationally and at the local and regional levels.

National Benefits of Clean Roadless-Area Water. At least 124 million Americans directly benefit from water

Figure 1

Federal inventoried roadless areas (IRAs) of the United States (Source: USDA Forest Service).



originating from national forests (Sedell et al. 2000). In fact, national forests provide about 15% of the nation's runoff with an estimated net value of $3.7 (Sedell et al. 2000) to $27 billion (Krieger 2001). The water treatment value alone of National Forests ranges from $490 million (Loomis 2005) to $18 billion (Krieger 2001).

Because IRAs represent roughly a third of national forestland, by inference they contribute significantly to the overall runoff volume and value (Anderson 1997, 2008) estimated in billions of dollars annually (Loomis and Richardson 2001; Sechhi et al. 2005). For instance, using Forest Service data (USFS 2000), IRAs make up 661 of the 914 national forest watersheds, with 55% of the 914 watersheds acting as source areas for facilities that treat and distribute drinking water to the public. The cost-savings to water treatment plants and highway departments from avoiding sedimentation caused by logging in IRA watersheds is estimated at up to $18 billion annually (Loomis 1988). IRAs provide $490 million annually in waste treat-

Figure 2

Colorado's 2001 inventoried roadless areas (IRAs) are shown in light gray, the 2011 proposed Colorado roadless areas (CRAs) are shown in gray, and overlap between CRAs and IRAs is shown in black. Water quality will be most impacted by changes of allowable activities within existing IRAs relative to changes in designated areas (USFS 2011).

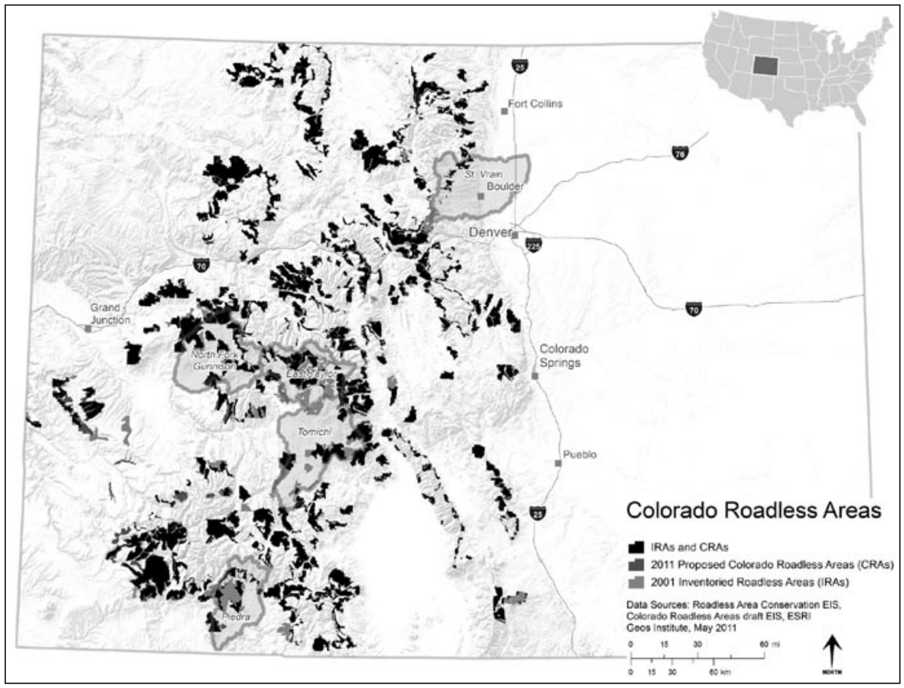


Table 1

General ecosystem services and benefits related to water that are provided by undisturbed IRAs and watersheds (derived from Greenway 1996; Costanza et al. 1997; Talberth and Moskowitz 1999; GAO 2000;Heal 2000, Loomis and Richardson 2001; Sedell et al. 2000; Krieger 2001; Dombeck 2003; Berrens et al. 2006).

	Benefits
Off-stream benefits	Low treatment costs for water for all beneficiaries
	Low price per unit volume costs for water for all beneficiaries
	High-quality and abundant drinking water for rural communities and municipal water supplies
	High-quality water for agricultural and industrial purposes
	High-quality water for downstream livestock production
	High-quality water for reduced health care and epidemic control
	Reduced costs of flood damage and flood control; enhanced local economies and property values
	Community benefits, including jobs, income, favorable trends for key economic indicators, and economic sustainability and stability
	Recharging of groundwater aquifers
	Healthy terrestrial and riparian ecosystems and their component species, sustained ecological and evolutionary processes, and resilient ecosystems
In-stream benefits	Healthy aquatic ecosystems
	Recovery of endangered species and protection of refugia
	Diverse and productive fisheries
	High-quality habitat for wildlife, including migratory waterfowl and game and nongame species
	Aquatic recreation such as swimming, rafting, and boating; enhancement of hiking and camping
	The inherent value of wild rivers and wilderness (including passive use benefits such as option, bequest, and existence values)
	Moderation of runoff and streamflows (e.g., lower peak flows, higher low flows, year-round water)
	Soil stabilization and erosion control
	Scientific value (intact watersheds are very rare today)
	Maintaining sediment production to streams at normal background rates
	Reducing potential for damage to downstream properties and water users during periods of high flow
	Breakdown and containment of waste and toxins (e.g., atmospheric, prior use)

Journal of Soil and Water Conservation 66(3):78A-84A www.swcs.org

ment services through recovering mobile nutrients and cleansing the environment, both processes that involve water flow through intact watersheds (Loomis and Richardson 2001).

Regional Benefits of Clean Roadless-Area Water. In the US Rocky Mountains, roughly one third of utilized streamflow is derived directly from IRAs (which cover a quarter of Colorado's headwaters), with cities like Denver receiving about 30% of their water supply from IRA watersheds. Annually, IRAs in Colorado are estimated to provide an equivalent of nearly 2.5 times Denver's annual water use (Doyle and Gardner 2010; Denver Water 2010). Similarly, IRAs in New Mexico provide an estimated water quality benefit up to $42 million annually (Berrens et al. 2006).

Flood Control Protection and Inventoried Roadless Areas. The intact watersheds of IRAs are especially important for ameliorating the frequency and intensity of flooding, saving millions of dollars annually from averted floods and associated sedimentation, a service that will only increase in value as climate change drives more floods (Seeds 2010). Dredging reservoirs to increase capacity and channels to enable navigation costs cities, states, and ultimately taxpayers millions annually. Salem, Oregon, spent approximately $100 million on new treatment facilities after logging in upper watersheds created conditions leading to mass sedimentation in its watershed following storms in 1996 (Schwickert and Mauldin 1997; Talberth and Moskowitz 1999). In addition, Seattle, Washington, deferred a $150 million filtration plant expenditure through an intensive watershed rehabilitation program that will decommission 480 km (300 mi) of roads over a 10-year period, fix road erosion problems, and limit access and high-risk activities for fire and sedimentation within their watersheds (Seeds 2010).

Recreation Benefits and Strong Local Economies. IRA water benefits outdoor recreation and the people that either engage in or earn their living from outdoor recreation. The nation's IRAs generate $600 million annually from recreation (Loomis and Richardson 2001). Passive-use values (i.e., the intrinsic value of wilderness, wildlands, and benefits for the future) are estimated at an additional $280 million annually. At the regional scale, New Mexico IRA water provides an estimated $27 million active outdoor recreation benefit and a $14 million passive-use benefit annually (Berrens et al. 2006). For many visitors, much of the attraction to wildlands is associated with the presence of clean and abundant water—a dwindling resource as logging, grazing, and road-building continues across mountain landscapes and droughts from a changing climate intensify in much of the West (Saunders et al. 2008).

Freshwater Biodiversity and Healthy Fisheries. Clean water from IRAs also maintains healthy fisheries, such as salmon and trout fisheries, sustains viable aquatic ecosystems, and helps protect threatened species and ecosystems (Abell et al. 2000; Trout Unlimited 2004). Indeed, IRAs may act as important refugia for many salmon and trout populations, as well as for a diversity of endangered freshwater species (Henjum et al. 1994; Huntington 1998; NRC 1996; Trombulak and Frissell 2000; CBD et al. 2001; Strittholt and DellaSala 2001; Oechsli and Frissell 2002; Strittholt et al. 2004; Petersen 2005). Restoration of salmon and trout fisheries in places with high road densities will likely fail without the pivotal role provided by IRAs as fishery strongholds.

ROADLESS AREAS ARE IMPORTANT SOURCES FOR DRINKING WATER

The distribution of IRAs across prime hydrologic real estate—headwaters and upper watersheds—makes them particularly valuable for providing reliable supplies of clean water. In Colorado, IRAs occur in the headwaters of all major drainages, covering roughly a third of upper watersheds in the state. Indeed, most IRAs are located in mountainous terrain in western states, including Oregon, Idaho, New Mexico, Utah, Montana, California, and Washington. This extensive coverage of IRAs in headwaters, and because they are often the last minimally disturbed watersheds within larger landscapes of degraded lands, makes them hydrologic hotspots—areas with relatively small spatial extent that have a disproportionately important role in producing abundant and reliable clean water (Frissell and Carnefix 2007).

For many major drainages (entire watersheds of major rivers, such as the Columbia River Basin), IRAs and other wilderness areas represent the last few percentages (typically 1% to 5%) of the landscape with a minimally disturbed, or near natural, hydrology. As in many other ecological contexts, losing the last relatively natural systems typically results in major losses in water resource benefits, losses that can only be compensated by very expensive actions. The known relationship between watershed degradation and water quality decline deserves to be more rigorously incorporated as a central foundation for decisions on watershed management and protection.

Developing Roadless Areas Degrades Water Quality. In addition to their keystone location within watersheds, roadless areas typically encompass the most fragile of natural landscapes—montane forests and meadows. Road building and other intensive management in these otherwise intact areas damage their ability to provide clean water for downstream communities and biodiversity over both short and long terms (Beschta 1978; Forman and Alexander 1998; Lugo and Gucinski 2000; Trombulak and Frissell 2000; Gucinski et al. 2001; Coffin 2007). Logging, including post-disturbance, fire-risk reduction, forest health, and insect control; livestock grazing; mining; and road building are responsible for chronic and acute sedimentation of aquatic ecosystems, alter overland flow and stream structure, and change a range of physical and biological features by causing more frequent and intense floods, decreasing available water throughout the year, increasing stream and ambient temperatures, and elevating turbidity and nutrient levels (Beschta 1978; Fleischner 1994; Trombulak and Frissell 2000; DellaSala et al. 2006; Coffin 2007). Logging roads have been linked to great increases in erosion rates and sediment delivery to streams—up to 850% over rates in undisturbed habitat—with long-term and often catastrophic impacts on stream biota, aquatic ecosystems, and water quality (Fredricksen 1970; Megahan and Kidd 1972; Amaranthus et al. 1985; Bilby et al. 1989; King 1989, 1993; Haynes and Horne 1997; Jones et al. 2000; Wemple and Jones 2003).

Depending on severity and duration of impacts, disturbance can elevate average turbidity levels well above background levels (Seeds [2010] provides examples from Oregon), along with triggering more frequent and intense turbidity spikes that are a major source of excess costs to municipal water supply departments. Relative to roadless watersheds with intact natural vegetation, intensively managed watersheds also produce less available water (i.e., average monthly usable raw water) due to intensified high flows with very high turbidity and exacerbated low flow conditions (Seeds 2010). The monthly reliability of water is also diminished.

Even small disturbances in upper watersheds can result in significant, cumulative, and long-term impacts to downstream water and aquatic ecosystems (Platts and Nelson 1985; Boise National Forest 1993; McIntosh et al. 1994, 1995). In unstable terrain, for instance, small areas (e.g., less than 10% of a watershed's area) of low-intensity disturbance, including roads, may greatly increase the frequency and size of mass erosion events, with subsequent acute and chronic reduction in downstream water quality. Management activities that damage natural vegetation typically result in loads of suspended solids that exceed background levels and more frequent and intense spikes in suspended solids stemming from an increase in mass erosion events like landslides, debris flows, and bank failures. These impacts are strongly correlated with roads, as well as with logging and grazing (Amaranthus et al. 1985; Fleischner 1994; Trombulak and Frissell 2000; Coffin 2007).

Rising Demand and Climate Change Diminish Water Supply. Population in the West is projected to increase by 300% within just 30 years, with similar increases in demand for water (Sedell et al. 2000). Urban and exurban areas are growing exponentially, including communities adjacent to wilderness areas and IRAs (Theobald 2005). The demand for water in Colorado is expected to triple by 2050. Similarly, the number of people relying on national forest water has doubled in Oregon in the last 30 years, and 86% of the population of Washington rely on national forest water to some degree (Sedell et al. 2000).

The dramatic population growth in the West is concurrent with a warming and drying climate in many places. Temperatures are increasing, snow pack is declining and melting sooner, and drought and summer water deficits are more frequent and longer (Barnett et al. 2008; Mohammed and Tarboton 2008; Saunders et al. 2008; Miller et al. 2010). Streamflow reductions ranging from 10% to 35% are likely for the western states over the next half century as a consequence of climate change (Barnett and Pierce 2009). A 10% drop in streamflow is considered calamitous by municipal water districts. More frequent and intense flood events are also likely in places (Raff et al. 2009), despite drying conditions. Costs for flood control, repair and reconstruction, and insurance rates will also increase (GAO 2007). These events will worsen the severe and unprecedented droughts already afflicting much of the West (Drechsler et al. 2006; Saunders et al. 2008).

SOLUTION: A LIGHT HYDROLOGICAL FOOTPRINT IN ROADLESS AREAS

IRAs should be managed in the same way many municipalities manage their watersheds—sustaining a light ecological and hydrological footprint and hydrologic restoration through decommissioning or, even better, obliteration of roads (Barten et al. 1998; NRC 2000; Payne et al. 2004; Gallo et al. 2005; Postel and Thompson 2005; Seeds 2010). The most cost-effective and prudent approach to maintain water supplies and high-quality fresh water in the face of population growth and climate change is to manage upper watersheds in a roadless condition with undisturbed natural vegetation. The high, long-term economic cost of degrading clean water for millions of people, by itself, is argument strong enough to continue protection of the current roadless areas network either at national or state levels. Development of IRAs, as proposed in Colorado, would primarily provide opportunities for short-term gains, but the substantial and long-term impacts on water quality and availability will come at a time of increasing demand and shrinking supply. Managers should, therefore, treat IRAs as natural reservoirs of high quality water for downstream users before approving development projects. Cost-benefit analyses should include regionally and locally specific estimates of water quality to better inform project management decisions that may reduce the value of high-quality water in the short and long run.

CONCLUSIONS

Roadless areas and the relatively intact ecosystems they maintain provide many important biodiversity benefits, including acting as strongholds for threatened freshwater species. Beyond these important values, their role in producing clean and reliable water for people and economies is more likely to compel decision-makers to leave roadless areas undeveloped. We reviewed the importance of inventoried roadless areas on national forests in the United States to determine their importance in providing clean water for downstream users. We concluded that (1) many intact watersheds are in headwaters, (2) they supply downstream users with high-quality drinking water, and (3) developing these watersheds comes at significant costs associated with declining water quality and availability. Several case studies from the western United States, particularly Colorado, demonstrated the importance of assessing the diverse consequences of developing roadless areas. Managers should perform comprehensive cost-benefit analyses when weighing development options. A light-touch hydrological footprint is recommended to sustain the many values that derive from roadless areas, especially clean and abundant water.

ACKNOWLEDGEMENTS

We thank the many individuals and organizations that have contributed to this evaluation. In particular, we appreciate the reviews of earlier drafts of the manuscript by Robert Beschta of Oregon State University, Corvallis, Oregon; Josh Seeds of Oregon Department of Environmental Quality, Portland, Oregon; and Linda Farley of Conservation Earth. Natural Areas Journal 34:310–324

ABSTRACT: Complex early seral forests (CESFs) occupy potentially forested sites after a stand-replacement disturbance and before re-establishment of a closed-forest canopy. Such young forests contain numbers and kinds of biological legacies missing from those produced by commercial forestry operations. In the Sierra Nevada of California, CESFs are most often produced by mixed-severity fires, which include landscape patches burned at high severity. These forests support diverse plant and wildlife communities rarely found elsewhere in the Sierra Nevada. Severe fires are, therefore, essential to the region's ecological integrity. Ecologically detrimental management of CESFs, or unburned forests that may become CESF's following fire, is degrading the region's globally outstanding qualities. Unlike old-growth forests, CESFs have received little attention in conservation and reserve management. Thus, we describe important ecological attributes of CESFs and distinguish them from early seral conditions created by logging. We recommend eight best management practices in CESFs for achieving ecological integrity on federal lands in the mixed-conifer region of the Sierra Nevada.

Index terms: complex early seral forests, ecological integrity, mixed-severity fire, Sierra Nevada

INTRODUCTION

Early seral forests are ecosystems that occupy potentially forested sites after a stand-replacement disturbance and before re-establishment of a closed forest canopy (Swanson et al. 2011). Such forests are generated by disturbances that reset successional processes and follow a pathway that is influenced by biological legacies (e.g., large live and dead trees, downed logs, seed banks, resprout tissue, fungi, and other live and dead biomass) that were not removed during the initial disturbance (Franklin et al. 2000; Donato et al. 2012). Where these legacies are intact, complex early successional forests (CESFs) develop with rich biodiversity due to the function of the remaining biomass in providing resources to many life forms and because of habitat heterogeneity provided by mixed-severity fires that generated them (Odion and Sarr 2007; Swanson et al. 2011). In general, mixed-severity fires, which include patches of high-severity fire, create coarse-grained, high-contrast heterogeneity that results in CESFs, and, over time, a complex mosaic of seral stages at the landscape and local scales. Low to moderate fire severities create fine-grained, lower contrast heterogeneity that generate very little if any CESFs, although they create other conditions favorable to biodiversity. Many effects of fire cannot be mimicked by land-use disturbances (Odion and Sarr 2007). Suppression of fire and removal of biomass after a fire are thus causes of reduced biodiversity and ecological integrity.

While the unique "floral phoenix" that follows stand-replacing fire in many vegetation types such as the California chaparral has long inspired botanists in the United States (Brandegee 1891; Howell 1946) and elsewhere (Bond and van Wilgen 1996), similar attention has not been given to stand-replacing fire in Sierran forests. Instead, fire has been suppressed in these forests for many decades. Traditionally, stand-replacement processes have also been considered historically unimportant in these forests, simply because they occur less frequently than surface fires, which are largely non-lethal (Skinner and Chang 1996). Stand-replacing fire also has a negative connotation in resource management disciplines because of their narrow focus on impacts to timber values, and such fires frequently receive negative coverage from the mass media.

While much of the conservation attention in the Sierra Nevada has rightfully focused on iconic conifers like the giant sequoia (*Sequoiadendron giganteum*) and other old-growth forest types, even in the context of multiple-use management and conservation, there is still little appreciation for CESFs, which do not have the charismatic old-growth species and living structures (Swanson et al. 2011). Thus, for a variety of reasons, there is a paucity of literature on, or appreciation of, CESFs. Indeed, CESFs are not even recognized as a distinct habitat type in any current vegetation mapping used by the U.S. Forest Service in the Sierra Nevada (e.g., California Wildlife Habitat Relations). However, in terms of their contribution to biodiversity and vital life-history stages of many species, CESFs have disproportionately important ecological roles in the overall ecological integrity of forested landscapes. Thus, we call attention to this successional stage (Swanson et al. 2011) and the need for its inclusion in conservation strategies in the Sierra Nevada ecoregion.

It is timely to consider CESFs in Sierra conservation strategies because the Sequoia, Sierra, and Inyo National Forests (Figure 1) are undergoing forest plan revisions as part of the "early adopters" of the forest-planning rule (36 Code of Federal Regulations Part 219). The forest-planning rule directs the U.S. Forest Service to maintain or improve ecological integrity, defined as "the quality or condition of an ecosystem when its dominant ecological characteristics (for example, composition, structure, function, connectivity, and species composition and diversity) occur within the natural range of variation and can withstand and recover from most perturbations imposed by natural environmental dynamics or human influence" (Forest Planning Rule 36 CFR 219.19). Given the global importance of the Sierra Nevada ecoregion (Ricketts et al. 1999), many scientists and the public expect a high level of protection and stewardship in forest-planning decisions and they support managing for ecological integrity. But, as an often-overlooked seral stage, the role of CESFs in ecological integrity and conserving biodiversity has not been addressed.

We address three questions of management relevance to CESFs in the Sierra Nevada: (1) what are CESFs and why are they important to ecological integrity; (2) are there tradeoffs for managing species of conservation concern that occur at opposite ends of the successional continuum such as Black-backed Woodpeckers (*Picoides villosus*; avian taxonomy follows American Ornithologists' Union checklist of North and Middle American birds; http://checklist.aou.org/; active May 20, 2013) and California Spotted Owls (*Strix occidentalis occidentalis*); and (3) what are the principal threats to these forests? We also provide general recommendations for conserving, restoring, and researching the ecological integrity and biodiversity of Sierran CESFs.

STUDY AREA

The Sierra Nevada ecoregion spans some 63,111 km^2 along a north-south axis in California, and the USDA Forest Service manages the majority of montane forests in this region (Davis and Stoms 1996; Figure 1). The ecoregion is among the most diverse temperate conifer forests in the world and its conservation status is considered critically endangered due to extensive forest fragmentation and other land-use stressors (Ricketts et al. 1999). An extraordinary assortment of vegetation types and diverse forest successional stages occur across the region. For instance, based on potential vegetation mapping, 25 conifer, 23 hardwood forest/woodland types, 34 shrub and chaparral, and 5 herbaceous alliances are distributed across elevations, slopes, aspects, and soil types (USDA Forest Service 2008). Plant alliances mix together at zones of overlap resulting in high levels of beta diversity (change in numbers of species across environmental gradients). There are exceptional levels of endemic plants (e.g., approximately 405 vascular plants are endemic and 218 taxa are rare; Shevock 1996), especially in the southern Sierra, and some of the highest levels of mammal endemism in North America (Ricketts et al. 1999). Notably, areas with high concentrations of endemic species are a conservation priority because the restricted distribution of endemics predisposes them to extinction from habitat losses.

Mixed-conifer forests are the predominant forests in the Sierra that are typically found at middle elevations (760–1400 m) in the northern Sierra, higher elevations south (915–3050 m), and, to a lesser extent, on upper elevations (2130 m to 3040 m) along the east slopes (Chang 1996). They are replaced at higher elevations by pure red fir (*Abies magnifica,* Andr. Murray) and red and white fir (*A. concolor,* Gordon & Glend.) (Barbour et al. 2007). There are three forest types that comprise mixed-conifer forests in this region: (1) white fir/Jeffrey pine (*Pinus jeffreyi,* Grev. & Balf.) /lodgepole pine (*P. contorta,* Loudon); (2) Pacific Douglas-fir (*Pseudotsuga menziesii menziesii,* Franco), and ponderosa pine (*P. ponderosa*; at lower elevations); and (3) mid-elevation Douglas-fir (does not occur south of Yosemite National Park). These more typical conifers are associated with sugar pine (*P. lambertiana,* Douglas), incense cedar (*Calocedrus decurrens,* Torrey), black oak (*Quercus kelloggii,* Newb.), and patches of giant sequoia. Mixed-conifer forest types also support shrubs such as greenleaf manzanita (*Arctostaphylos patula,* E. Greene), huckleberry oak (*Q. vaccinifolia*, Kellogg), curleaf mountain mahogany (*Cercocarpus ledifolius,* Nutt.), snowbrush (*Ceanothus velutinus,* Dougl.), mountain alder (*Alnus incana* ssp. *tenuifolia,* Nutt.), mountain sagebrush (*Artemisia tridentate* ssp. *vaseyana,* Rydb.), and bitterbrush (*Purshia tridentata,* Pursh) (USDA Forest Service 2013a). Most of these forests consist of mid-sized trees that average 30–60 cm dbh and include areas with larger trees (>60 cm dbh; North 2013); nearly half of the mixed-conifer forest in the giant sequoia type is late seral (USDA Forest Service 2013a).

Very-long-interval, stand-replacement fire occurs in a patchwise fashion within low- and mixed-severity fires in moist mixed-conifer and white fir forests in this region, and variable (both short- and long-interval) stand-replacement fires occur in Douglas-fir and lodgepole pine (*Pinus contorta,* Loudon) forests (Leiberg 1902; Chang 1996). Prior to fire suppression, drier low-elevation forests burned relatively frequently and often at a low severity; but they also had significant mixed-severity effects, including occasional large high-severity fire patches (USDA Forest Service 1911).

What are Early Seral Forests and Why Are They Important?

In general, CESFs are rich in post-disturbance legacies (Photo Plates 1a, 1b, 1c) and post-fire vegetation (e.g., native fire-following shrubs/herbs, resprouting broad-leaved trees, and natural conifer regeneration) (Photo Plates 2a, 2b, 2c). We identify 12 ecological attributes that contribute to the prolific biological response common in CESFs and which are, therefore, key to the ecological integrity present in CESFs

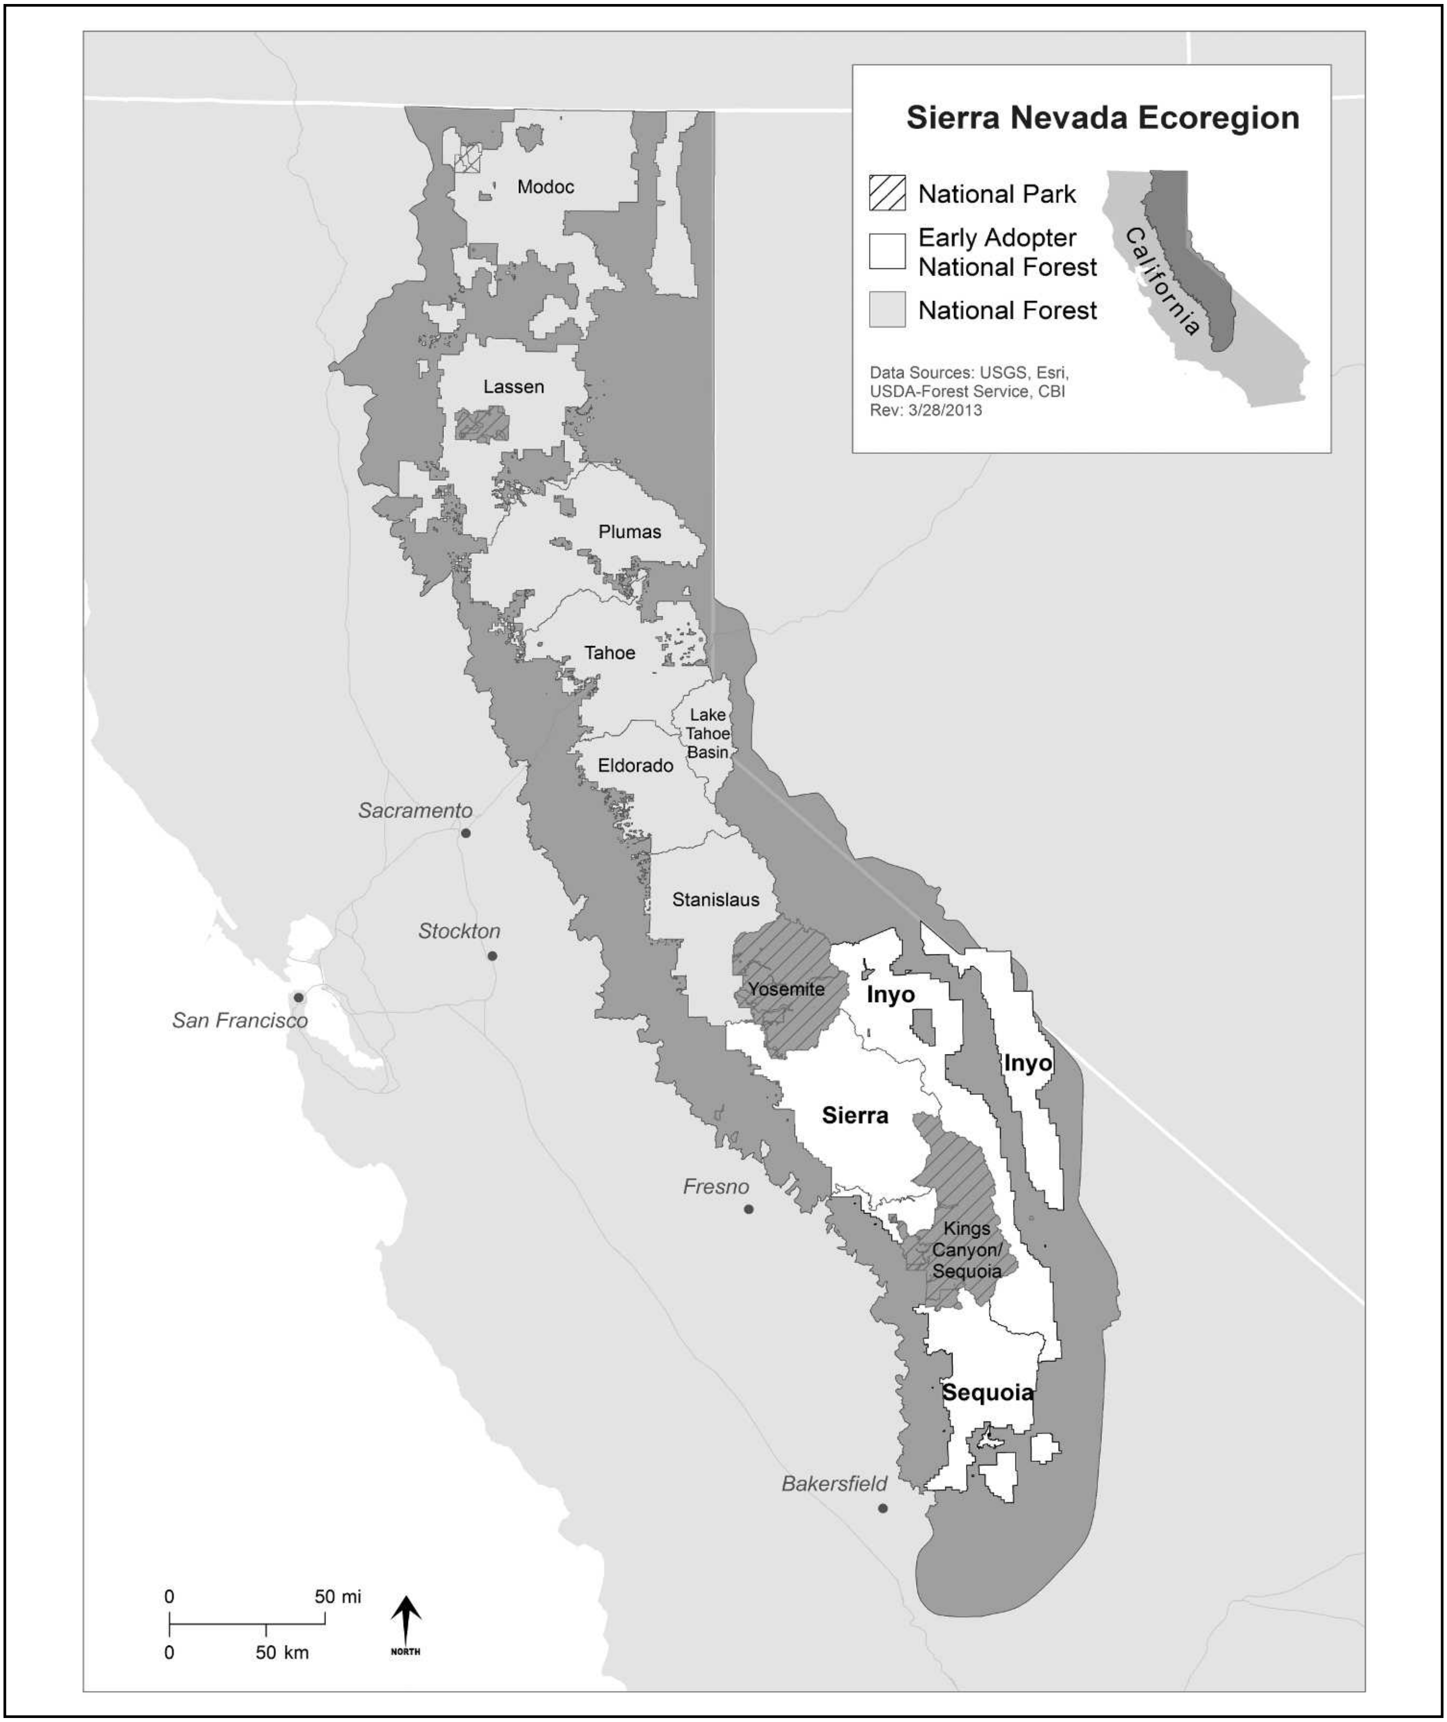

Figure 1. Location of Sierra Nevada ecoregion, northern California, and "early adopters" of the forest-planning rule involved in forest plan revisions.

Photo Plates. Extensive biological legacies, abundant forb cover, and abundant conifer regeneration present in complex early seral forests vs. early seral that has been post-fire logged. Post-fire logging in the Sierra Nevada and elsewhere sets back ecosystem processes creating a successional debt.

Plate 1a Plate 1b Plate 1c

Photo Plate 1. Star Fire of 2001, Northern Sierra, CA. (a) unmanaged with forbs (Doug Bevington, 2008); (b) natural conifer re-establishment (Chad Hanson, 2012); Storrie fire of 2000, Southern Cascades, CA. (c) unmanaged with snags and forbs (Chad Hanson, 2007).

Plate 2a Plate 2b Plate 2c

Photo Plate 2. Postfire logged portions of Fred's fire in the Eldorado National Forest, CA, showing lack of nitrogen-fixing shrubs (a) and presence of Klamath weed (*Hypericum perfoliatum*) and many readily ignitable, invasive grasses (b) (Dennis Odion, August 2011); (c) simplified system from Dinkey post-fire thin on west slopes of Southern Sierra (Chad Hanson, 2012).

(Table 1). When logging compounds the natural disturbance that created a CESF (Photo Plates 3a, 3b, 3c), each of these attributes is reduced or eliminated (Table 1). Such multiple disturbances often lead to alternative successional pathways, or loss of resilience (Paine et al. 1998; Odion and Sarr 2007), as has been documented in the Sierra Nevada following post-fire logging, which leads to dominance by the non-native ecosystem transformer, cheatgrass (*Bromus tectorum,* Linnaeus) (McGinnis et al. 2010).

Overall, compared to logged areas, CESFs are structurally more complex, contain more large trees and snags that originated from the pre-disturbed forest, have more diverse understories, functional ecosystem processes, and more diverse gene pools that, theoretically, should provide greater resilience in the face of climate change than that provided by the simplified early seral forests produced by logging. CESF attributes promote a high level of species richness, particularly bird communities that utilize these forests extensively (Hutto 1995; Kotliar et al. 2002; Fontaine et al. 2009; Appendix). The residual biomass of CESFs reduces disturbance stressors and provides for the rapid proliferation of new life (Odion and Sarr 2007). For example, seed banks and vegetation tissues give rise to dense, often rampant, forb cover, abundant grasses, and shrubs – especially nitrogen fixers (e.g., *Ceanothus* spp.) (Conard 1985; Busse et al. 1996; Busse 2001) and ectomycorrhizal associates (e.g., *Manzanita* spp.) that facilitate conifer growth (Zavitovsky and Newton 1968; Horton et al. 1999). Serotinous (closed cone) conifers like giant sequoia (Stephenson et al. 1991) also do well in these forests. Other plants that can abundantly colonize burns, such as conifers and fireweed (*Epilobium angustifolium,* Linnaeus), arrive by wind or animal dispersed seed. Thus, plant species richness of CESFs can be much higher than in unburned forests (Donato et al. 2009).

Other bird and small mammal communities that utilize CESFs forage extensively on the abundant insects and increased abundance of seeds from the post-fire flora (Lawrence 1966; Fontaine et al. 2009). These species, in turn, support an increase in raptors (Lawrence 1966). Bird species such as the Black-backed Woodpecker, Olive-sided Flycatcher (*Contopus cooperi*), Mountain Bluebird (*Sialia currucoides*), Chipping Sparrow (*Spizella passerina*), and Mountain Quail (*Oreortyx pictus*) (Appendix)

Table 1. Differences between early seral systems produced by natural disturbance processes vs. logging. For natural disturbances, assume that a disturbance originates from within a late-successional forest as legacies are maintained throughout succession. For logged sites, assume site preparation includes conifer plantings but no herbicides, which, if also applied, would magnify noted differences.

Attribute	Regeneration Harvest or Postfire Logged	Natural Disturbance
Large trees	rare	abundant and widely distributed
Large snags/downed logs	rare	abundant and widely distributed
Understory	dense conifer plantings followed by sparse vegetation as conifer crowns close (usually within 15-20 years depending on site productivity)	varied and rich flora
Species composition	few species mostly commercially stocked, deer initially abundant then excluded as conifer crowns close	varied and rich flora, rich invertebrates and birds, abundant deer
Structural complexity	simplified	highly complex; many biological legacies
Soils and below-ground processes	compacted and reduced mycorrhizae	complex and functional below ground mats
Genetic diversity	low due to emphasis on commercial species and nursery genomes	complex and varied
Ecosystem processes (predation, pollination)	moderate initially then sparse as conifer crowns close; limited food web dynamics	rich pollinators and complex food web dynamics
Susceptibility to invasives	moderate to high depending on site preparation, soil disturbances, livestock, road densities (see McGinnis et al. 2010)	low due to resistance by diverse and abundant native species and low soil disturbances
Disturbance frequency	commercial rotations (40-100 years or so)	varied and complex
Landscape heterogeneity	low	high; shifting mosaics and disturbance dynamics
Resilience/resistance to climate change	low due to nursery stock genomes but conifer plantings can be adjusted for locally anticipated climate envelopes	varied and complex genomes allow for resilience and resistance to climate change

achieve highest abundances in CESFs. In fact, in the Sierra Nevada, CESF habitat is comparable or higher in bird species richness and total bird abundance relative to unburned mature forest (Burnett et al. 2010). Bats (*Myotis, Idionycteris, Lasionycteris*, and *Eptesicus)*, which are an increasing conservation concern, are also favored by CESFs, likely because of greater insect prey as well as suitable roosts (Buchalski et al. 2013). Stand-replacing fires stimulate a flux of aquatic prey to terrestrial habitats, driving increases in riparian consumers (Malison and Baxter 2010). The trees killed by fire are highly beneficial to the ecological integrity of stream communities because they are a main source of large woody debris inputs (Minshall et al. 1997). There is also reproduction by some forest fungi species that are restricted to burns (e.g., morels, *Morchella* spp.) and the dead wood provides substrate for fungal growth that supports many arthropod species, including unique fire-following native beetles (Lindsey 1943; Bradley and Tueller 2001). Beetles, in general, colonize fire-killed trees in CESFs and their abundant larvae support species like Black-backed Woodpeckers (Hutto 2008).

Indicator Species for CESF Biodiversity (Figure 3)

Indicator species are valuable tools for conservation management because it is not practicable to monitor all biodiversity. When burned forests are logged after fire, one species that serves well as an ecological indicator for post-fire biodiversity, the Black-backed Woodpecker, declines substantially (Hutto 2008). Given that this woodpecker already is an indicator of the biodiversity supported by CESFs in the Sierra Nevada (USDA Forest Service 2013b), and is a fire specialist, we propose it as a Species of Conservation Concern. Designated Species of Conservation Concern are those whose population viability, or continued representation within a particular plan area, is of management concern. The forest-planning rule provides guidance to forest managers to use Species of Conservation Concern as a means for maintaining species diversity and wildlife population viability.

CESF habitat represented by Black-backed Woodpeckers is biologically unique (Hutto 1995; Bond et al. 2012). The Black-backed Woodpecker is an important primary excavator of nesting holes for many other cavity-nesting birds and mammals because it discards cavities after excavating them, and it uses a given cavity for one year (Tarbill 2010). Under a scenario with stand-replacing fire operating in a patchwise fashion in a landscape containing healthy populations of Black-backed Woodpeckers, the availability of nesting cavities across the landscape over time may be greatly enhanced compared to where fire is suppressed and/or fire-killed trees are removed. Black-backed Woodpeckers use CESFs for only several years (typically seven or eight) after fire and they depend upon the regular creation of CESFs to replenish their habitat (Hanson and North 2008; Tarbill 2010; Dudley et al. 2012; Siegel et al. 2013). When this does not occur, many other species that rely on nesting cavities are likely to be negatively affected. Thus, many species probably depend directly, or indirectly, on the continued occurrence of high-intensity natural disturbance across large landscapes to maintain their populations (Hanson and North 2008; Tarbill 2010; Dudley et al. 2012; Siegel et al. 2013).

Black-backed Woodpeckers have become increasingly rare because their optimal habitat has shrunk to a fraction of its historical extent (Figure 2 a – d); populations are estimated at <700 nesting pairs in burned forests (Bond et al. 2012). Importantly, the CESF habitat that the remaining pairs depend on has little or no protection on public lands managed by the U.S. Forest Service. Much of this CESF habitat is under mounting pressure from fire suppression and both pre- and post-fire logging (Hutto and Gallo 2006; Hanson and North 2008; Hutto 2008; Siegel et al. 2013), which prevent high-quality woodpecker habitat. That, in turn, may affect the biodiversity for which this woodpecker serves as an indicator.

Figure 3. Black-backed woodpecker – a fire dependent species in the Sierra (Photo – Monica Bond).

Are There Management Tradeoffs for Species of Conservation Concern at Opposite Ends of the Successional Continuum?

Wildlife management often involves tradeoffs when habitat for a particular species is emphasized. That is a problem with single-species management (managing for what one species needs), but is not a problem when managing for the maintenance of natural systems that a species may indicate. In the latter case, we would not enhance but would maintain natural levels of habitat for CESF indicators like the Black-backed Woodpecker, and for the biodiversity associated with its presence.

However, the California Spotted Owl is also a management indicator species but for late-seral forests in this region. Notably, all three subspecies (Mexican, California, Northern; Bond et al. 2002; Jenness et al. 2004; Roberts 2008; Bond et al. 2009; Clark et al. 2011; Roberts et al. 2011; Lee et al. 2012; Clark et al. 2013) appear to tolerate, or even benefit, from some degree of moderate- to high-severity fire within territories.

Managing CESFs for high levels of ecological integrity may provide important prey habitat (e.g., dusky-footed woodrat *Neotoma fuscipes*; Munton et al. 2002) for the spotted owl. In fact, the owl is known to reproduce in territories burned at all fire severities in this region, and preferentially selects high-severity fire areas for foraging (Bond et al. 2009). Owl reproduction has been found to be 60% higher in unmanaged mixed-severity fire areas than in unburned forests (Roberts 2008), and mixed-severity fire (with an average of 32% high severity) (Lee et al. 2012) does not reduce owl occupancy, though post-fire logging may precipitate territory abandonment (Clark et al. 2011, 2013; Lee et al. 2012). Moreover, because high-severity fire has been reduced by fire suppression, and current high-severity fire rotations are very long in the Sierra Nevada, if high-severity fire rates increased by even two- or three-fold, it would benefit CESF-associated species like the Black-backed Woodpecker, but would only reduce current old forest by a very small amount given old forest recruitment from ingrowth (Odion and Hanson 2013). Thus, protecting CESFs from post-fire logging and maintaining the spatial heterogeneity created by mixed-severity fires should provide habitat for all seral associates – there really are no management trade-offs when we manage for the maintenance of natural processes and systems.

What are Principal Threats to CESFS?

Management of CESFs has most often included post-fire (salvage) logging followed by tree planting, including burning of slash piles and associated soil disturbances, reseeding with grasses (often introducing invasive species inadvertently), use of straw-bales and other erosion prevention methods, herbicides to reduce shrub competition with conifers,

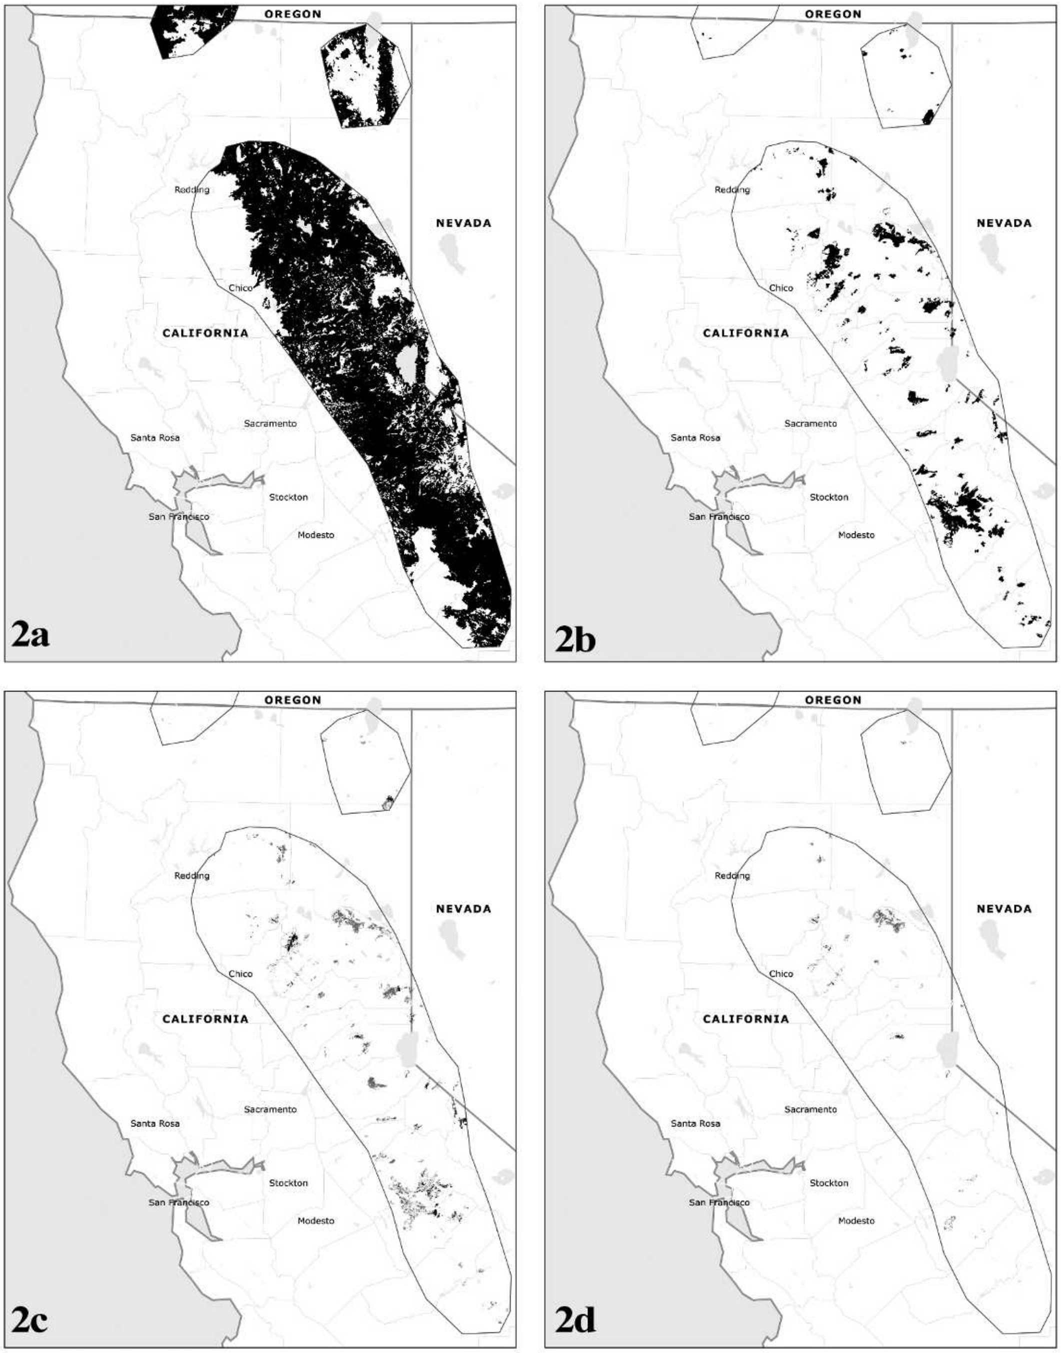

Figure 2. (a) Forest types used by Black-backed Woodpeckers in the Sierra Nevada management region; (b) fires since 1984 within the relevant forest types (private lands not included since they are rapidly logged); (c) moderate/high-severity fires resulting in >50% mortality (RdNBR >574 – see Hanson et al. 2010) of forests on public lands within the relevant forest types in the most recent decade for which there are fire severity data (2001–2010) (i.e., both high quality Black-backed Woodpecker habitat and moderate/low quality (older) habitat combined); and (d) moderate/high-severity fire on public lands within the relevant forest types in the most recent 5-year period for which fire severity data are available.

planting with conifer nursery stock, and livestock grazing (Swanson et al. 2011; Long et al. 2013; Table 1). These activities remove, or severely degrade, CESFs or, at a minimum, can narrow the window of duration for CESFs (Swanson et al. 2011), contributing to "landscape traps," whereby entire landscapes are shifted into, and then maintained in, a highly altered state as the result of cumulative impacts (Lindenmayer et al. 2011).

Climate change and forest fragmentation also have been identified as threats to biodiversity in the Sierra Nevada (USDA Forest Service 2013b). Since the 1980s, the region has experienced a decrease in annual number of days with below-freezing temperatures at higher elevations with more rain and less snowfall mainly in northern latitudes, more extreme heat days at lower elevations, earlier (5 to 10 days) snowmelt than decades ago, earlier (5–15 days) peak stream flows (Safford et al. 2012; Harpold et al. 2012), as well as an increase of approximately 1 °C since the early twentieth century, though some areas of the northern Sierra Nevada have seen a decrease in temperature (North 2012). Some regional climate models project further decreases in mountain snowpack, earlier snowmelt and peak stream flows, and greater drought severity (Overpeck et al. 2012). Such climatic changes are likely to affect the low-elevation ponderosa pine, which is projected to extend upward, while red fir and subalpine communities are projected to lose much of their climate envelope in the coming century (USDA Forest Service 2013b). It is unclear how such changes will affect CESFs. If fire increases in severity or frequency (Miller et al. 2009; Miller and Safford 2012), this could provide more opportunities for development of CESFs. This assumes there is not a concomitant increase in post-fire logging, and that fire suppression activities either cannot keep pace with climate-related fire events or prove ineffective due to the increasing influence of climate as a top-down driver of fire behavior. On the other hand, a number of climate models predict decreasing fire activity in these forests – even as temperatures rise – due to increasing precipitation, including summer precipitation and changes in vegetation (McKenzie et al. 2004; Krawchuk et al. 2009), and recent research using the largest fire severity data set to date has found no increase in fire severity in the Sierra Nevada since 1984 (Hanson and Odion, 2014; also see Odion et al. 2014 for related discussion).

Land-use stressors also magnify climate change effects on forest communities. For instance, Thorne et al. (2008) documented significant regional changes due to climate and land-use practices resulting in greater levels of disturbance compared to historical. Millar (1996) identified three paramount influences on Sierra Nevada ecosystems: (1) climate change and shifting hydrological patterns; (2) dense forests; and (3) rapidly expanding human populations. It is not known, however, whether these changes will act in concert to make CESFs more vulnerable to invading species, particularly those more suited to the changing climate and land-use disturbances.

Suggested Best Management Practices for CESF

For all the reasons outlined above, CESFs represent a neglected seral stage subject to multiple stressors that compromise ecological integrity. We, therefore, propose eight "best management practices" for stimulating conservation, restoration, and research interests in these unique forests. These principles can serve as appropriate guidelines where management goals include the maintenance of ecological integrity.

Conservation Focus

Principle 1 – "Rehabilitation" Is Not Needed After Fire Creates a Complex Early Seral Forest (Beschta et al. 2004; Swanson et al. 2011).

Fire acts as a natural restorative agent by resetting the successional clock and providing habitat for disturbance-dependent species. Although CESFs lack live trees initially and are populated by dead ones, this does not mean they require site rehabilitation or are "unhealthy" forests. In the context of ecological integrity, a functional forest system is one where the natural fire regime is of mixed-severity and has all stages of succession following stand-replacing fire. CESFs should be mapped and managed as a distinct forest habitat type.

Principle 2 – Protect Large, Old Forest Structures Across Seral Stages, and Retain Dense, Old Forests to Improve Ecological Integrity at Landscape Scales.

Large old-forest structures take decades to centuries to develop, and forest management has created a deficit through extraction. Dense, old forests provide high-quality habitat not only when they are green, but also when they experience mixed-severity fire (Hutto 2006, 2008), or snag pulses from beetles (Bond et al. 2012), as biological legacies remaining also serve to connect seral stages along the successional gradient.

Principle 3 – Mixed-severity Fire Should Be a Management Goal for Reserves.

Robust, reserve-based conservation strategies are needed to maintain the suite of seral stages and allow for climate-forced wildlife dispersals into suitable habitat. Thus, managers should allow fires to run their course in the backcountry and in reserves when not a risk to people or dwellings. This includes maintaining a landscape that includes diverse seral stages across environmental gradients (elevation, latitudinal).

Restoration and Management Focus

Principle 4 – Adopt Comprehensive Approaches to Restore Ecological Integrity in CESFs.

This starts with a restoration needs assessment (DellaSala et al. 2003) to evaluate and prioritize drivers of ecosystem degradation and best practices aimed at reducing specific stressors (see Principle 6). Most importantly, forests restored through fire usually do not need "restoration" otherwise.

Principle 5 – Limit Post-fire Management to Early Seral Forests Previously Degraded by Logging, Grazing, and Other Stressors.

Restoration approaches should identify comparable areas of high ecological integrity (e.g., unmanaged CESFs, DellaSala et al. 2003) to serve as a baseline or reference condition from which to restore degraded areas (e.g., burned plantations), and then surveillance, implementation, effectiveness, and ecological effects monitoring (Hutto and Belote 2013) should always be an integral part of the restoration activity.

Principle 6 – Reduce Land-use Stressors That Compromise the Ecological Integrity of CESFs.

Restorative measures can be active or passive depending on site-specific needs and should always be followed with well-funded monitoring (DellaSala et al. 2003). Examples include removal of livestock, invasive species abatement, road closures and obliteration, and reintroduction of fire.

Research Focus

Principle 7 – Determine Historical, Current, and Projected Future Distributions and Spatio-temporal Extent of CESFs as Well as Other Seral Stages Across the Planning Area.

This can be informed through "back-casting" approaches that reconstruct an historical baseline from combining age-structure reconstructions (e.g., from either FIA plot data or General Land Surveys from the 1800s; see techniques in Baker 2012; Williams and Baker 2012) with studies that link stand structure, disturbances and fire scar data (e.g., Sherriff and Veblen 2006), or other sources of information (e.g., USDA Forest Service 1911). Historical baselines can then be compared to current and future projected conditions under a changing climate in order to determine appropriate representation levels of CESFs and other seral stages in a planning area.

Principle 8 – Designate the Black-backed Woodpecker a "Species of Conservation Concern."

Continue, and expand upon, current monitoring efforts and, in partnership with the U.S. Fish and Wildlife Service and other experts, determine how best to meet population viability and habitat needs of this important CESF species. Although Black-backed Woodpecker populations decline as this seral stage advances (within seven years following fire), this species still functions as an indicator of early successional species because stable woodpecker populations would mean a steady supply of CESFs over time. Olive-sided Flycatcher, Chipping Sparrow, Mountain Bluebird, and other early seral species that have population peaks after declines in woodpeckers, may need to be monitored to ensure CESF conservation.

CONCLUSIONS

The forest-planning rule and its emphasis on ecological integrity, plant and animal community diversity, and Species of Conservation Concern provides the Forest Service with a unique opportunity to revise forest plans in the Sierra Nevada to meet the primary and cumulative threats that these forests now face – climate change and land-use stressors. Where the region's forests are to be managed for ecological integrity, managers will need to determine spatio-temporal occurrence of CESFs (historical and current) to allow for adequate representation of all seral stages across planning areas, particularly the rare ones that occupy opposite ends of the successional continuum (CESFs and late seral). This also means conducting field inventories in CESFs to better describe their unique attributes and ecological importance, treating CESFs as a distinctive wildlife habitat type in habitat classifications, and incorporating mixed- to high-severity fire into management goals at middle to upper elevations.

Clearly, climate change introduces uncertainties regarding how fire and other disturbance agents will operate on these forests in the future. Whether this will increase or further reduce CESFs remains to be seen. While managing for resilient ecosystems is a desired ecological objective of climate adaptation planning on the national forest system (36 Code of Federal Regulations § 219.5), it is important for managers to go beyond mechanical fuel reduction as a means for maintaining resilient ecosystem properties, and this includes acceptance of mixed- and high-severity fires as important ecosystem processes. However, resilient to natural disturbance does not necessarily mean resistant to disturbance. Sierran forests are disturbance dependent; they require severe fire for the production of CESFs.

The eight principles recommended for best management practices in CESFs in the Sierra Nevada would promote ecological resilience and allow the National Forests in this globally outstanding ecoregion to better adapt to climate change and increasing human development in the surroundings. We encourage conservationists and park managers to emphasize CESFs in reserve design and related conservation strategies as these forests are at least as important as their late-successional counterparts.

AUTHORS ENDNOTE

At the time of this publication, the Stanislaus National Forest was proposing extensive (~18,000 ha) post-fire logging of live (injured) and dead trees (including "roadside-hazard trees"), conifer re-planting, and shrub-eradication in the wake of the 2013 Rim Fire along the border of Yosemite National Park. The agency also proposes to plant conifers in high severity patches, thereby leap frogging important non-conifer dominant stages. Post-fire logging is incompatible with the needs of legions of species that depend on the presence of standing dead trees and montane chaparral.

Because of the significance of the Rim Fire as a pulse disturbance for generating CESFs, its proximity to an iconic national park, and the opportunity to educate the public about the importance of burned forest habitat, we believe the area warrants consideration for a national monument designation as did Mount St. Helens after the historic 1980 eruption. We urge managers and conservationists to give more attention to the ecological importance of CESFs in new protected areas proposals. This is especially important as we see the threat to these unique forests escalating due to increasing emphasis by federal agencies on extensive and intensive post-fire management projects.

ACKNOWLEDGMENTS

This work was supported by a grant from the Environment Now Foundation to DellaSala. We are grateful to D. Sarr for review of an earlier version of the manuscript.

Dominick A. DellaSala, Ph.D., is President Chief Scientist of the Geos Institute and President of the Society for Conservation Biology, North America Section, and Courtesy Faculty at Oregon State University in the Department of Crop and Soil Sciences. He is an internationally renowned author of over 150 technical papers on forest and fire ecology, conservation biology, endangered species management, and landscape ecology. His recent book "Temperate and Boreal Rainforests of the World: Ecology and Conservation" (Island Press), received an academic excellence award in 2012 from Choice magazine, and he has leadership awards from the Wilburforce Foundation and World Wildlife Fund for his work on roadless areas and national monuments.

Monica L. Bond is a co-founder and Principal Scientist with the Wild Nature Institute. She has worked as a research biologist for The Institute for Bird Populations, PRBO Conservation Science, NOAA's National Marine Fisheries Service, Humboldt State University, the University of Minnesota, and as a staff biologist with the Center for Biological Diversity. Over the past decade, Bond has been conducting ground-breaking research on the use of complex early seral forests by spotted owls and Black-backed Woodpeckers, and advocating for the protection of this habitat type from post-fire salvage logging.

Chad Hanson, Ph.D., is the staff Ecologist and Director of the John Muir Project of Earth Island Institute. He has authored and co-authored papers published on topics as diverse as fire history, current fire patterns and trends, post-fire conifer response, and wildlife habitat selection in post-fire forests. Hanson focuses his research in the Sierra Nevada, with a particular emphasis on the Black-backed Woodpecker and the Pacific fisher.

Richard L. Hutto, Ph.D., is Professor of biology at the University of Montana. Hutto has conducted research on migratory landbirds in Mexico, the Southwest, and the Northern Rockies for more than 30 years. In 1990, he developed the USFS Northern Region Landbird Monitoring Program, and he has been studying the ecological effects of fire on bird communities for the last 25 years. He was host of "Birdwatch," a nationally televised PBS series that ran from 1998–2001. Because he is moved by what birds have to teach us about land stewardship, Hutto established the Avian Science Center on the University of Montana campus (http://avianscience.dbs.umt.edu/) to promote ecological awareness and informed decision making by listening to what western birds tell us about the ecological effects of human land-use practices.

Dennis Odion, Ph.D, is a research ecologist with the Department of Environmental Studies at Southern Oregon University and the Earth Research Institute at UC Santa Barbara. His research has focused on the role of variation in fire in shaping patterns of vegetation and biodiversity in forests and chaparral. He has studied mechanisms of non-native species invasions and has authored, or coauthored, numerous papers on these subjects.

Appendix. Bird species present in complex early seral forests in the Sierra Nevada based on comparisons of burned and unburned plots (Raphael et al. 1987: east slopes of Sierra, University of California Sagehen Creek Field Station, pine-fir forests, ridgetop at 2100-m elevation, Burnett et al. 2012: Plumas National Forest, northeastern CA, mixed conifers, elevations 1094–2190 m: Storrie, Moonlight, and Cub mixed-severity fires). Only the Burnett et al. (2012) performed statistical analyses on bird abundances between burned and unburned plots. Taxonomy follows American Ornithologists' Union checklist of North and Middle American birds (http://checklist.aou.org/; active May 20, 2013).

Species	Present in both studies	Difference in abundance burned vs. unburned[2]
Mountain quail[3,4] *Oreortyx pictus*	+	+
American kestrel[3] *Accipiter cooperii*		
Mourning dove[3] *Zenaida macroura*		
Common nighthawk[3] *Chordeiles minor*		
Calliope hummingbird *Selasphorus calliope*	+	NS
Williamson's sapsucker *Sphyrapicus thyroideus*		
Red-breasted sapsucker *Sphyrapicus ruber*		
Hairy woodpecker *Picoides villosus*	+	+
White-headed woodpecker *Picoides albolarvatus*	+	+
Black-backed woodpecker *Picoides arcticus*	+	+
Northern flicker *Colaptes auratus*		
Olive-sided flycatcher[3] *Contopus cooperi*	+	+
Western wood-pewee *Contopus sordidulus*	+	+
Hammond's flycatcher *Empidonax hammondii*		
Dusky flycatcher *Empidonax oberholseri*	+	-
Cassin's vireo *Vireo cassinii*		-
Warbling vireo *Vireo gilvus*		NS
Stellar's jay *Cyanocitta stelleri*	+	NS
Mountain chickadee *Poecile gambeli*	+	-
Red-breasted nuthatch *Sitta canadensis*		-
White-breasted nuthatch *Sitta carolinensis*		

Cont'd.

Appendix. (Continued)

Species	Present in both studies	Difference in abundance burned vs. unburned[2]
Pygmy nuthatch[3] *Sitta pygmaea*		
Brown creeper *Certhia Americana*	+	+
Golden-crowned kinglet *Regulus satrapa*		-
Mountain bluebird[3] *Sialia currucoides*	+	+
Townsend's solitaire *Myadestes townsendii*		
Hermit thrush *Catharus guttatus*		-
American robin *Turdus migratorius*	+	NS
House wren[3] *Troglodytes aedon*	+	+
Nashville warbler *Oreothylypis ruficapilla*	+	-
MacGillivray's warbler *Geothlypis tolmiei*		NS
Yellow warbler[3] *Setophaga petechia*		NS
Yellow-rumped warbler *Setophaga coronata*	+	-
Hermit warbler *Setophaga occidentalis*		-
Green-tailed towhee[3] *Pipilo chlorurus*	+	+
Spotted towhee *Pipilo maculatus*		+
Chipping sparrow *Spizella passerina*	+	+
Brewer's sparrow[3] *Spizella breweri*		
Fox sparrow *Passerella iliaca*	+	+
Dark-eyed junco *Junco hyemalis*	+	+
Western tanager *Piranga ludoviciana*	+	-
Black-headed grosbeak *Pheucticus melanocephalus*		-
Lazuli bunting[3] *Passerina amoena*	+	+

Cont'd.

Appendix. (Continued)

Species	Present in both studies	Difference in abundance burned vs. unburned[2]
Brown-headed cowbird[3] *Molothrus ater*		
Cassin's finch *Carpodacus cassinii*	+	+
Red crossbill *Loxia curvirostra*		
Pine siskin *Carduelis pinus*	+	-
Evening grosbeak *Coccothraustes vespertinus*	+	-

[1] No fire severity estimate was given by Raphael et al. (1987) other than the Donner Ridge fire "consumed about 18,000 ha of pine-fir forests," a "few scattered mature pines and firs survived," and the fire area was "dominated by brush (primarily Ceanothus velutinus) and by regenerating conifers" (thus probably a high severity burn).

[2] (+) indicates species was significantly more abundant in burned, (-) means it was significantly less abundant, and NS means non-significant (P>0.05; Burnett et al. 2012).

s0010
ECOLOGICAL PERSPECTIVES ON MIXED-SEVERITY FIRE

p0090 We have presented compelling evidence of fire's beneficial ecological role mainly in western North America but with relevant case studies in other regions. Even though most people recognize the importance of maintaining fire on the landscape, few realize the myriad ecosystem benefits associated with large fires of mixed severity. Habitat heterogeneity, which may be maximized by mixed-severity fire that includes large patches of high severity, and the successional mosaic such fire creates, is one of the most dependable predictors of species diversity (Odion and Sarr 2007, Sitters et al., 2014). This ecological tenet has yet to be fully realized in management circles. If such fires are operating within historical bounds, then ecosystems will remain resilient to them; indeed, deficits of these fires relative to the natural range of variability, in places such as montane forests of western North America, are degrading to fire-dependent biodiversity (Odion et al., 2014a; Sherriff et al., 2014). This is particularly the case when reductions in fire extent and/or severity occur in combination with forest management practices, such as postfire logging, that undermine development of complex early seral forests (Chapter 11).

The Ecological Importance of Mixed-Severity Fire: Nature's Phoenix.

B978-0-12-802749-3.00013-X, 00013

p0095 Natural heterogeneity in vegetation types, stand structures, and successional age classes at all spatial scales and environmental settings is emerging as a strategy for enhancing forest ecosystem resilience to climate change, at least in North America (Moritz et al., 2014). This will help ensure that there will be enough habitat for species with varying postfire habitat requirements. The fire dynamic is changing in places, however, with climate change now poised in some systems to recalibrate fire behavior (Chapter 9). With the addition of ongoing pre- and postfire logging in forests and other development pressures, particularly in shrublands, this is having a combined negative impact on native biodiversity associated with both complex early seral and old-growth forest and chaparral ecosystems (e.g., Chapters 2–5).

s0015 Beneficial Fire Effects Often Take Time to Become Fully Realized

p0100 In general, for ecological acceptance of postfire landscapes to translate into improved management practices, as a prerequisite fire ecologists, land managers, and the general public all must recognize both pre- and postfire landscapes as irreplaceable habitat for fire-associated biodiversity. To a large extent, this depends on how one views the postfire landscape.

p0105 When considering the effects of fire, patience is clearly a virtue; postfire processes may take years, decades, or longer to unfold. However, land managers often rely on quick indices to assess fire effects, and this can have negative consequences. For instance, in the western United States, the US Forest Service's "burn area emergency response" (http://www.fs.fed.us/eng/rsac/baer/; accessed February 22, 2015) uses satellite images and other geospatial data in real time to classify soil "damages" immediately after fire. Similarly, the US Forest Services' Rapid Assessment of Vegetation Condition (RAVG) after Wildfire (http://www.fs.fed.us/postfirevegcondition/whatis.shtml; accessed February 22, 2015) provides estimates of "basal area losses" in forests 30-45 days following fires >400 ha. We saw in Chapter 11 that these types of rapid assessments can overestimate tree mortality given their immediate timeline compared with the delayed response of fire-affected trees. In forests, particularly pine and mixed conifer, this can lead to premature conclusions about fire "damages" and fire "catastrophes," as well as erroneous notions about high-severity fire patch size, along with a rush to "take action" at any cost and to advance "restoration" or "recovery" approaches that do far more harm than good (Box 13.1; see also DellaSala et al., 2014; Hanson, 2014).

p0110 Notably, differences in whether postfire vegetation is viewed as fuel or habitat (Haslem et al., 2011) most often are at the heart of heated conflicts between natural resource managers and conservationists. Witness these polar opposites: fire suppression (including both mechanical thinning and actions to halt active fires) versus [illegible]rn approaches for wildlife habitat (Chapter 12); postfire logging versus the pulse of biological legacies (Chapter 11); thinning versus habitat for closed-canopy species; and reseeding/replanting and shrub removal versus

Comp. by: GAsokpandian Stage: Revises1 Chapter No.: 13 Title Name: Dellasala

b0010 **BOX 13.1 Rapid Assessment of Vegetation Condition after Wildfire "Treatments" as Defined by the US Forest Service**

p0010 According to the US Forest Service RAVG assessments, the term *treatment* "describes any of a set of management activities that can assist the prompt recovery of forestlands. Management actions include any combination of live, dead, and dying wood removal, or disposal (with or without commercial value) by any feasible method, including but not limited to logging, piling, masticating, and burning, for site preparation. In addition, planting, seeding, and monitoring for natural regeneration without site preparation are appropriate management activities designed to foster the prompt recovery following wildfire. Treatments also include follow up activities to control vegetation that is believed to compete with desired trees during the early establishment period, usually 1 to 5 years after establishment, using any viable method that meets Land and Resource Management Plan direction."

the montane chaparral component of complex early seral forest. Where one stands on this debate can be a matter of principle and perspective, but can also stem from a lack of a comprehensive understanding of the effects of mixed-severity fire and successional processes after fire (see, e.g., Chapters 2–5). Further, while the public may consider fire to be a necessary change agent (see "Understanding the Public's Reaction to Fire," below), this seems to be tempered by whether fire is operating within "safe limits," constrained by prescribed (or "controlled") fire or reduced in intensity by tree thinning and shrub mastication. While prescribed fire is most appropriate for low-severity, high-frequency fire systems, it is not a replacement for the ecosystem benefits produced by large and higher-severity fire because prescribed fire does not mimic the patch mosaics or pulses of biological activity that higher-severity fires provide (Moritz and Odion 2004, DellaSala et al., 2014). Thus, understanding one's perspective is a starting point for potentially settling differences and developing ways to coexist safely and beneficially with fire. Being willing to respond competently to the cognitive dissonance created when perspectives do not align with new scientific information is also vital to the development of successful and ecologically sound fire management strategies (e.g., Chapter 7).

s0020 13.2 UNDERSTANDING THE PUBLIC'S REACTION TO FIRE

p0115 If ecologists and conservationists want a new discourse on fire that improves ecological understanding and fire management practices, then informed and sustained communications with the public, land managers, the media, and decision makers are vital. A common understanding is needed to move the public and land management agencies from a view of fire as the harbinger of death (Kauffman, 2004) to fire as nature's phoenix. Here we provide some insights from a public poll on fire attitudes in the United States that reaffirms our personal experiences about the prevailing attitudes of the public and of land managers when it comes to fire.

B978-0-12-802749-3.00013-X, 00013

s0025 Attitudes Toward Fire

p0120 In 2008 The Wilderness Society and The Nature Conservancy got together to construct a 10-year fire communications framework that was informed by a large national sample of public attitudes ($n = 2000$ respondents), focus groups in six regions of the United States where fire was a concern, and communications experts (Metz and Weigel, 2008). The task was to develop ecological messaging on fires that would "complement Smokey Bear's message" about being careful with fire.

p0125 Based on a summary of the survey findings, important messages on fire can be gleaned from survey data, some of which are remarkably aligned with fire ecology, whereas others are at odds with basic ecological principles. Most notably, the poll demonstrated the public's sophistication regarding the role of fire in ecosystems, but it was clearly tempered by safety concerns (Smokey Bear), notions regarding the importance of "controlled" burns, and a desire to let "some" fires burn in "natural areas." Education (higher levels) was associated with positive attitudes toward fires, and gender was a factor, with men being more risk tolerant and women more risk averse. Some of the poll's most relevant findings are displayed in Box 13.2. We

b0015 BOX 13.2 Key Findings on Public Fire Attitudes from the Study by Metz and Weigel (2008)

- u0010 Some fires can be beneficial, and a history of fire suppression has led to more large and destructive fires. (*Note that dramatic changes in fire behavior actually are associated with very few forest types in western North America* (Odion et al., 2014a)).
- u0015 Strong negative emotional reactions to fire persist based on safety issues (most view fire as "scary").
- u0020 Public understanding of fire's ecological role has increased over time.
- u0025 Public concerns about wildfire rank very low compared with other conservation issues.
- u0030 The most significant fire concerns pertain to effects on people and firefighters rather than ecosystem benefits.
- u0035 Allow fire teams to use "controlled burns" when and where doing so will safely reduce the amount of fuel for fires (*controlled burns are most relevant in low-severity rather than mixed-severity systems*).
- u0040 Cut and remove overgrown brush and trees in natural areas that act as fuel for fires (*this is largely true for low-severity systems, not higher-severity fires that are largely controlled by extreme weather*).
- u0045 Allow naturally started fires that do not threaten homes, people, or the health of natural areas to take their natural course, rather than putting them out.
- u0050 Shift some government funds from putting out practically all fires to proactively cutting and removing overgrown brush and trees and using controlled burns to reduce the amount of fuel for fires (*removing brush/trees and controlled burns are mostly ways to reduce fire severity in low-severity systems*).

also highlight in parentheses those beliefs that seem to be at odds with the ecological literature on mixed-severity fires.

p0130 Communication experts then advised the conservation groups that successful fire messaging should have the following five fundamental communication themes:

o0010 **1.** Protect people, property, and communities
o0015 **2.** Safeguard the health and regeneration of natural areas
o0020 **3.** Safely manage controlled burns to clear fuels (*this management is appropriate in low-severity systems only during the natural fire season*)
o0025 **4.** Save taxpayer money through controlled burns
o0030 **5.** Protect air and water by protecting the health of forests and natural areas and giving plants and wildlife the exposure to fire they need to survive

p0160 From focus groups and polling results, according to communication experts the following cogent messages are likely to reach the public:

u0075 • Safety is always the number one priority when it comes to fire. By putting out every single fire, however, we are actually creating more dangerous conditions (*in western North America, higher-severity fires are operating at an historical deficit*). Using controlled burns to thin out overgrowth and carefully managing natural fires help ensure the safety of neighborhoods in outlying areas.

u0080 • Forests and natural areas are important to our health; they act as natural filters to give us clean air and are the source of clean drinking water. We must ensure the health of forests and natural areas by allowing some fires to take their natural course.

u0085 • Taxpayer money is being wasted putting out fires that are far from people and their property. A far more cost-effective approach is to use controlled burns to prevent large, severe fires from spreading into areas where people live and to allow some fires to take their natural course (*and they are ecologically inappropriate when applied outside the natural fire season*).

p0180 For higher-severity fires, a good portion of this messaging may work to bridge the divide between science and public attitudes, whereas some of the recommendations of the communications experts in 2008 (refer to the italicized text in the parentheses above) do not incorporate the ecological importance of maintaining, and managing for, complex early seral forest created by mixed-severity f[illegible] particular, the poll's findings that fire safety matters most is still very muc[illegible]evant; thus putting out fires that are dangerous to human communities is still of primary importance. From a safety standpoint, Smokey Bear's cautionary fire safety tale needs to be updated so that the focus of fire management is ~~clearly~~ on creating "defensible space" aro[illegible]omes, the home ignition zone (HIZ), and introducing land use zoning to al[illegible]w fire to run its course unimpeded in natural areas under safe conditions (Making Homes Fire Safe, see below). And, while the poll found the public generally agreed that fire is necessary in natural

B978-0-12-802749-3.00013-X, 00013

areas, how far this tolerance would go in relation to large or higher-severity fires is unclear given that the poll's questions were ~~clearly~~ geared toward low-severity fires that can be either "controlled" or suppressed (through thinning or the use of fire retardants). Notably, in Chapter 12 we discussed how runaway expenditures in fire suppression have been ecologically damaging and fiscally irresponsible, and the public seems to agree with these fiscal concerns. In combination with economics, whether public attitudes will change, or are changing, regarding large or higher-severity fires is still unknown; this will require polling that is more specific to these kinds of fires along with enhanced public education (e.g., the videos referenced in the preface) regarding ways to coexist with large fires.

p0185 A core message—and one that will most certainly be difficult for much of the public to accept despite being fact based—is that large fires in any given location each year, at least in western North America, cannot be stopped no matter what we do. We at least need to be honest about that and clearly state the damages that can ensue from large-scale pre- and postfire management that attempts to control large, mainly climate-driven fires that are uncontrollable. We also need to clearly communicate to the public the current state of scientific knowledge regarding the ecological benefits and values of the habitats created by mixed-severity fire. This is especially so given the still all-too-common notions that such areas have been categorically damaged by fire, which in turn leads to misguided assumptions that ~~such areas~~ are in need of "restoration" or "recovery" management actions.

s0030 13.3 SAFE LIVING IN FIRESHEDS

p0190 Based on public attitudes toward fire there ~~clearly~~ are important challenges to coexistence with fire. These can be overcome, however, if we not only increase public education about current fire ecology but also act responsibly in reducing risks where they matter most. We note that by far the biggest challenge to coexistence with fire is the explosion of exurban sprawl in many rural communities triggered by those moving out of congested cities.

p0195 A case in point is Kalispell, Montana, the gateway to Glacier National Park. A November 17, 2014, article in *Greenwire*, the online source of information on the environment ("Where property rights are king, development continues despite growing wildfire threat"), reported that during the 1990s the county's population grew at twice the state's average as more and more people seeking a rural quality of life purchased 16-ha "ranchettes" scattered across Big Sky fire country. They were able to do so as a result of lax and often resisted land use zoning standards. Based on data provided by Headwaters Economics (2014), 11,000 houses in this Montana county lie within the wildland-urban interface (where towns, homes, and other built structures abut fire-prone wildlands)—more than any other county in Montana—and this number is growing at a phenomenal rate. As reported in the online article, public attitudes included the notion that fire will not directly affect them and strong views about private

B978-0-12-802749-3.00013-X, 00013

property rights (i.e., "don't tell me what to do on my land"). Some of the same people vocally oppose government actions in general then demand that public money be spent to remove "fuels" from wildlands. In essence, the lack of homeowner fire risk reductions and inappropriate fuel treatments is setting in motion the perfect storm of land use and fire conflicts.

p0200 To minimize these kinds of conflicts, landowners need to practice fire-safe (also known as "fire-wise" in the United States) planning to protect home structures. We suggest that landowners first declare a common "fireshed" boundary, as they do for watersheds. Firesheds are multidimensional spaces. They begin at the scale of a watershed and encompass the residential community with similar fire risks (Figure 13.1a). Within a fireshed, homeowners can take fire risk reduction measures together (preferably) or on their own (Figure 13.1b).

s0035 Making Homes Fire-Safe

p0205 Probably no research results are as relevant to fire safety science than those of Dr. Jack Cohen, whose seminal fire safe research recommendations are now standard risk reduction measures taken by many homeowners[1] and have caught on with risk-averse insurance companies[2]. The work of Syphard et al. (2012, 2014) on home loss in chaparral systems of southern California is strikingly similar.

p0210 According to Dr. Cohen, fire planning within an HIZ begins with defensible space nearest the home. Notably, research on HIZ risks shows that homes whose owners reduced vegetation and flammables within 10-18 m of the structure and built with nonflammable roof materials had an 86% (Foote, 1996) to 95% (Howard et al., 1973) "survival" rate when fires swept through an area (cf. Syphard et al. (2014) for more recent and similar home structure protection distances). Combined with home fire simulations by the insurance industry (http://www.extension.org/pages/63495/vulnerabilities-of-buildings-to-wildfire-exposures#.VHUr00snRNs; accessed February 15, 2015), Box **13.3** provides measures that are most critical for living safely in firesheds.

p0215 An example from a town in Idaho during an intense 2007 fire is instructive regarding the importance of the HIZ and fireshed management. As the *Idaho Statesman* newspaper reported (Druzin and Barker, 2008):

dq0020 *We spend billions attacking almost every wildfire, but scientists say that's bad for the forest, can put firefighters in unnecessary danger and doesn't protect communities as well—or as cheaply—as we now know how to do. A wall of fire barreled through the forest with a jet-engine roar near Secesh Meadows last August, and local fire chief Chris Bent knew his work was about to be tested.*

f0010 **FIGURE 13.1** (a) Google Earth image of the Anderson Creek watershed and community fireshed in Talent, Oregon, showing a housing development (circled; the center house is depicted in b). Most members of this community reduced lower-strata fuels via thinning small trees in the surroundings, although tree densities are beginning to fill in and require repeat treatments. (b) Two fire-safety zones where the landowner built with fire-resistant material in the inner most zone (home ignition zone 1) and cleared most vegetation within a 10 m radius around the structure (zone 2). Tree crowns are touching in zone 2; however, lower branches were pruned to 3 m, and there are few ladder fuels to carry fire from the ground into tree crowns. Downslope grasses may pose a fire hazard but may not crown out given the precautions taken in zones 1 and 2.

b0020 **BOX 13.3 Prudent Fire Risk Reduction Measures for Homeowners**

u0055
- Build homes with noncombustible roof covering and siding; keep roof and gutters clear of leaves/needles; keep firewood away; keep vegetation adjacent to homes to a minimum; cut overhanging limbs of trees closest to the home; and install ember-resistant attic vents.

u0060
- Clearing vegetation within 5-20 m of a home is the most effective treatment: Carefully space plants, reduce wood plant cover to <40% around the structure, and use varieties that grow low and are free of resins, oils, and waxes that burn easily; mow the lawn regularly and prune trees up to 3 m from ground; space conifer crowns ~3 m apart and remove lower limbs; trim back trees overhanging the house; create a "fire-free" area within 1.5 m of the house using noncombustible landscaping; remove dead vegetation; use fire-resistant furniture; remove firewood and propane tanks; and water plants or use xeriscaping.

u0065
- Additional measures include low-growing, well-irrigated, and relatively noncombustible vegetation in low planting densities; a mix of deciduous and conifer trees; fuel breaks like driveways and gravel walkways and lawns.

u0070
- Treatments >30 m from the home structures offer no additional protection (Syphard et al., 2014).

Flames danced atop lodgepole pines, smoke darkened the sky, and residents of the tiny mountain hamlet north of McCall prepared for the worst. Just a month earlier, a forest fire had burned 254 homes near Lake Tahoe and the 2007 fire season appeared ready to claim its next community. But as the raging East Zone Complex fire reached the cluster of loosely-spaced homes, the flames dropped to the ground, crackling and smoldering. The fire crept right up to doorsteps. But without the intense flames that spurred the fire just moments before, no homes burned—a feat fire managers attributed largely to Bent's push to clear flammable brush from around houses in the community. "It just blew through the area," Bent said. "We were well prepared." The town's ability to withstand a frontal assault by a major wildfire demonstrates what fire behavior experts have been saying for more than a decade. Clearing brush and other flammables and requiring fireproof roofs will protect houses even in an intense wildfire—without risking firefighters' lives. More provocatively, the research suggests that fighting fires on public lands to protect homes is ineffective and, in the long run, counter-productive. It is also far more expensive.

p0225 Importantly, clearing vegetation nearest a home is not enough, as fire risk reduction also needs to include the home structure itself (Figure 13.2). This is often missed in discussions about homeowner fire safety, and it is a crucial step in responsible fire risk reduction, as we illustrate in the following examples.

p0230 In a recent research paper concerning why homes burn in wildfires, Syphard et al. (2014) concluded that geography is key: where the house is located and where houses are placed on the landscape. Syphard and her coauthors gathered data on 700,000 addresses in the Santa Monica Mountains and part of San Diego

B978-0-12-802749-3.00013-X, 00013

f0015 **FIGURE 13.2** Homes burn because they are flammable. Many homes with adequate defensible space still burn in wildland fires because embers land on flammable materials around the home or enter through openings such as attic vents. These two homes burned during the 2014 Poinsettia Fire in Carlsbad, California, despite fire-safe landscaping, a firewall, and thinned wildland vegetation. Focusing exclusively on wildland vegetation clearing ignores the main reasons homes burn: they are flammable. *(Photo credit: Richard W. Halsey.)*

County. They then mapped the structures that had burned in those areas from 2001 to 2010, a time of significant wildfire activity in the region. Buildings on steep slopes, in Santa Ana wind corridors, and in low-density developments intermingled with wildlands were the most likely to have burned. Nearby vegetation was not a major factor in home destruction.

p0235 Looking at vegetation growing within roughly 800 m of structures, Syphard et al. (2014) concluded that the exotic grasses that often sprout in areas cleared of native habitat like chaparral could be more of a fire hazard than shrubs. Interestingly, they found that homes that were surrounded mostly by grass actually ended up burning more than homes with higher fuel volumes such as shrubs.

p0240 Similarly, during the 2007 Witch Creek Fire (San Diego County, CA), houses in Rancho Bernardo started burning by ember contact when the fire front was nearly 6 km away. Two-thirds of the burning homes were set on fire by embers (Maranghides and Mell, 2009).

p0245 During the 2007 Grass Valley Fire near Lake Arrowhead in California's San Bernardino Mountains, approximately 199 homes were destroyed or damaged. This was despite the fact that the US Forest Service had thinned the surrounding forest. The main cause of the losses was that individual homeowners failed to understand that vegetation management is only one part of the fire risk reduction equation. Fire will exploit the weakest link—and it did so in Grass Valley. In the detailed report of the fire, Forest Service researchers (Rogers et al., 2008) concluded: "Post-fire visual examination indicated a lack of substantial fire effects on the vegetation and surface fuels between burned homes. Lack of surface fire evidence in surrounding vegetation provides strong evidence that

Comp. by: GAsokpandian Stage: Revises1 Chapter No.: 13 Title Name: Dellasala

house-to-house ignitions by airborne firebrands were responsible for many of the destroyed homes."

p0250 Investments in making homes and communities fire safe are clearly fiscally prudent and ~~represent~~ responsible homeownership that can save lives and homes by reducing risks to all, especially firefighters. Moreover, proper land use zoning that reduces housing densities in firesheds is key to the survival of home structures over the larger area (Syphard et al., 2014).

p0255 In sum, these recent studies show that overcoming misperceptions about homeowner losses is urgently needed because those misconceptions are a driving factor in many inappropriate fuel reduction projects in wild areas. We hypothesize that with stepped-up planning directed at proper homeowner safety (as demonstrated in the above studies), public attitudes about large and intense fires may begin to shift from fear-based primal responses to more of a neocortex-like awareness of fire as nature's phoenix. This could be tested using before-and-after polling about large, higher-severity fires with and without proper public safety measures in places.

s0040 13.4 TO THIN OR NOT TO THIN?

p0260 One of the most significant challenges involved in changing the way land managers think about fire in the forests is how the US Forest Service views forest fires. The agency is deeply invested in continuing the fire management trajectory of the past—a situation compounded by the budgetary issues associated with the agency's direction of much, and often most, of their tax-based support to selling timber from public lands, and the agency's retention of most of the revenue from such timber sales to fund staff salaries and operations. Though in recent years we have learned much about the ecological benefits of higher-severity fire and the risks to fire-dependent wildlife species from further suppressing these fires, which are deficient in most western US conifer forests (Chapters 1–5), the Forest Service continues to aggressively promote landscape-level mechanical thinning (North, 2012; Stine et al., 2014) and postfire logging (Collins and Roller, 2013) ostensibly to reduce fuels and prevent and mitigate future fire. These forest management policies are promoted based on the assumption that decades of fire suppression have created forests "overloaded with fuel, priming them for unusually severe and extensive wildfires" (Stine et al., 2014; see also North, 2012). The basic concept being articulated by the Forest Service is that, because of decades of fire suppression and "fuel accumulations," we cannot simply allow wildland fires to burn because long-unburned forests will "uncharacteristically" burn almost exclusively at higher severities (North, 2012; Stine et al., 2014). Under this premise, recommendations focus on how to manage forests through logging and fire suppression to further reduce and prevent the significant occurrence of mixed-severity fire (North et al., 2009; North, 2012; Stine et al., 2014). Yet these sources do not include a discussion of the current deficit of these fires in most forests of western North America (Odion et al. 2014a; see also Chapters 1, 2, and 9) or meaningful content on the ecological importance of mixed-severity fire for many rare and imperiled wildlife species (Chapters 2–5). Nor do they explore the validity of the basic premise that long-unburned forests will burn much more severely.

p0265 Studies that empirically investigated the "time-since-fire" issue in the Sierra region of northern California and the Klamath Mountains of Oregon and California tended to find that, contrary to popular assumptions, the most long-unburned forests experience mostly low- and moderate-severity fire and do not have significantly higher levels of higher-severity fire than more recently burned forests (Odion et al., 2004, 2010; Odion and Hanson, 2006, 2008; Miller et al., 2012; van Wagtendonk et al., 2012). One modeling study predicted a modest increase in fire severity with increasing time since fire, but the strength of inference was limited by a lack of data for all but long-unburned stands, especially in the largest forest types, such as mixed-conifer forest. Even the most long-unburned forests were predicted to have ~70-80% low/moderate-severity effects (Steel et al., 2015), well within the range of natural variability (see Chapter 1). In fact, long-unburned forests sometimes have the lowest levels of higher-severity fire; understory vegetation and the lower limbs of conifers self-thin as canopy cover increases and available sunlight in the understory decreases with increasing time since fire (Odion et al., 2010). Therefore the argument that we cannot allow more wildland fires to burn without suppression in natural areas is not valid for many dry montane forests in western North America (Odion et al., 2010).

s0045 Problems with Fuel Models and Fire Liabilities

p0270 Government programs that aim to make forests safe places for people to live are based on theory rather than actual evidence about historical forests. As discussed above, the common argument has been that fuels have unnaturally accumulated from fire exclusion and land uses, and if fuels are restored to low levels, fires will burn primarily at low intensity rather than as high-intensity crown fires (e.g., Agee and Skinner, 2005). Thus forests can be restored while also making them safe places to live—a win-win solution that is appealing to the public. Little evidence about actual historical fuel amounts in forests to support this argument was available, however; instead, evidence is mostly based on the idea that frequent fires would have kept fuels at low levels. When records from land surveys before fire exclusion were examined (Baker, 2012, 2014; Baker and Williams, 2015; Hanson and Odion, in press), understory fuels (shrubs, small trees) that would naturally have promoted intense fires were found to have been common and often abundant in many areas, and small trees were dominant, not rare. This direct evidence suggests that fuel treatments would typically have to artificially remove natural shrubs and small trees and adversely alter habitat for native species in a quest to make forests safer places for people to live.

p0275 Fuel reduction also has been overpromised to be effective, using questionable logic and unvalidated models. First, fire intensity in most forest types is much more strongly affected by wind than by fuel. High fire-line intensity, the primary fire characteristic that promotes crown fires, is the product of the energy released by burning fuel and the rate of spread of fire (Alexander, 1982). Energy release by fuel varies over perhaps a 10-fold range, however, whereas rate of spread can vary over more than a 100-fold range; thus a high rate of spread caused by strong winds can easily overcome the limited reductions in fuel that are feasible (Baker, 2009). This was confirmed by a recent analysis of the 2013 Rim Fire in California, which concludes: "Our results suggest that even in forests with a restored fire regime, wildfires can produce large-scale, high-severity fire effects under the type of weather conditions that often prevail when wildfire escapes initial suppression efforts. . . . During the period when the Rim fire had heightened plume activity. . . [n]o low severity was observed [in thinned areas], regardless of fuel load, forest type, or topographic position" (Lydersen et al., 2014, p. 333). Second, common fire models used to show that forests would be fire-safe after fuel reductions have an underprediction bias and are not validated. These flawed models include NEXUS, FlamMap, FARSITE, FFE-FVS, FMAPlus, and BehavePlus (Cruz and Alexander, 2010; Alexander and Cruz, 2013; Cruz et al., 2014). The underprediction bias means that these models often predict that fuel reductions would reduce or eliminate the potential for crown fires in forests, when in fact fuel reductions do not achieve this effect. Fixing these models would be difficult and has not yet occurred (Alexander and Cruz, 2013). Also, these models have not been sufficiently tested and validated using a suite of actual fires, in which case they would likely be shown to fail (Cruz and Alexander, 2010). Alternative validated models are available and could be further developed, but they are not being used (Cruz and Alexander, 2010). Further, studies of tree mortality in thinned areas following fire do not typically take into account the mortality caused by the logging itself before the fire, leading to further biased results. Au1

p0280 These concerns should raise red flags about the effectiveness of fuel treatments, as well as issues regarding liability and responsibility. Imagine if a company sold airplanes with identified flawed designs and without adequate test flights, which then crashed. There are thus sound scientific reasons to closely scrutinize government wildland fuel-reduction programs. Meanwhile, we need to be honest and warn the public that living within or adjacent to natural forests prone to burn is inherently hazardous. Only treating fuels in the immediate vicinity of the homes themselves can reduce risk to homes, not backcountry fuel reduction projects that divert scarce resources away from true home protection (Cohen, 2000; Gibbons et al., 2012; Calkin et al., 2013; Syphard et al., 2014).

p0285 Finally, another land management liability that is frequently overlooked when assessing fire-related economic losses is the role of silviculture. For instance, before the 2013 Rim Fire, a significant portion of the Stanislaus National Forest in central California's Sierra Nevada Mountains consisted of even-aged monoculture tree plantations (following past clearcuts) distributed across large landscapes (Figure 13.3). Land managers often claim that clearcutting over large landscapes

B978-0-12-802749-3.00013-X, 00013

f0020 **FIGURE 13.3** Google image of the Stanislaus National Forest, central Sierra Nevada, taken on July 8, 2012, before the August 25, 2013, Rim Fire. The red boundary is where the Rim fire burned. Note numerous clearcuts within the burn area, where the fire later burned intensely. Figure provided by J. Keeley.

like this reduces fire spread, yet based on preliminary findings from the Rim Fire, clearcutting did nothing to stop the fire. In fact, the area with the most clearcutting had the largest contiguous area of high-severity fire of any portion of the Rim Fire (see Figure 13.3 and compare with Figure 11.11). In other areas with large portions of the landscape in tree plantations [illegible] past clearcutting, fires have a tendency to burn uncharacteristically severely, presumably because of homogenized fuel loads (e.g., Odion et al., 2004). Despite these observations, in postfire assessments land managers rarely discuss this effect or the liabilities it creates for economic losses related to intense burns.

s0050 13.5 FIRE SAFETY AND ECOLOGICAL USE OF WILDLAND FIRE RECOMMENDATIONS

p0290 Based on the ecological importance of higher-severity forest fires (e.g., Reinhardt et al., 2008; DellaSala et al., 2014; Hanson, 2014; Moritz et al., 2014) and home safety concerns (e.g., Cohen, 2000; Headwaters Economics, 2014), there are ways for people to live safely in firesheds and still allow fire to perform its vital ecosystem service. Below we provide some summary recommendations that, if widely implemented, would allow fire to take its natural course (i.e., ecological use of wildland fire) while reducing risks to people.

s0055 Fire Safety Recommendations

u0090
- Prepare to live safely with fire so that it can perform its ecologically beneficial functions. (The bulk of fire risk reduction should occur immediately adjacent to homes.)

- u0095 Develop negative financial consequences for landowners who increase fire risk within firesheds by not taking precautionary measures versus providing financial incentives for those who reduce risks (e.g., cost sharing for fire safety). As an example, mortgage and/or insurance rates could be increased for high risks from lack of fire safety and discounted for those who practice fire risk management principles. In this manner, planning for home fire safety would become as routine as taking out a mortgage to buy a home.
- u0100 Include HIZ and fire-safe principles in rural land use planning, including zoning restrictions that limit housing densities in firesheds deemed too risky for development.
- u0105 Require mandatory disclosure of fire risks to homebuyers.
- u0110 Have local and state governments contribute to firefighting costs to create a powerful incentive for improved land use planning, including zoning restrictions, which reduce fire suppression needs.
- u0115 Offer technology transfer to local governments and financial assistance to plan communities that are fire safe.
- u0120 Map high-risk areas where fire-safe standards are most prudent within a local county or other land use unit.
- u0125 Discourage rebuilding in the same high-risk place or require that building occurs with risk management conditions.
- u0130 Redirect funding away from backcountry fire suppression and fuel reduction programs and toward aiding willing homeowners in creating defensible space and reducing the ability of homes to ignite.
- u0135 Initiate strategies to reduce human-caused fire ignitions, especially along roadsides. Many wildland fires start along highways and streets.

s0060 Wildland Fire Recommendations

- u0140 Postfire "salvage" logging is especially damaging to complex early seral Au2 forests. If such forests were ecologically valuable or protected before fire, then they should also be recognized as uniquely valuable and protected after fire.
- u0145 Wildlands cannot be fireproofed by suppression (mechanical thinning or aerial retardants) or clearcutting; fuel treatments (thinning) are more likely to work in low-severity frequent fire systems and much less so in mixed- and higher-severity fire systems that tend to burn under extreme conditions, when suppression is least effective.
- u0150 Large fires, including high-severity patches, are the most efficient means of restoring fire-dependent ecosystems and natural heterogeneity where fire has been excluded for decades. When a fire burns under these conditions, fire-dependent communities are therefore restored. This should be encouraged, with public safety assured.
- u0155 The best way to buffer fire-dependent ecosystems from climate change is to increase ecological resilience, particularly in areas where a fire deficit

B978-0-12-802749-3.00013-X, 00013

exists, by allowing fires to burn naturally under safe conditions. This will require relatively large protected landscapes with proper land use zoning and logging restrictions.

u0160 • Implement strategies to reduce human-caused fires in ecosystems with excessive fire frequencies, such as the chaparral in southern California.

s0065 13.6 LESSONS FROM AROUND THE GLOBE

s0070 Africa

p0380 Of the five communication themes that arose from the polling in North America, the one most applicable to attitudes in sub-Saharan Africa is number 5, a broad statement to protect natural resources for the ecosystems services they provide (see Chapter 8). The public in South Africa, for example, assumes number 3, safety in controlled burns, because the public is already attuned to the widespread use of fire for habitat management, and when accessible, fuel wood is collected for heat and cooking. Of course, the South African public is not deluged by media reports of catastrophic losses caused by wildfire, so items 1, 2 and 4 are not part of a daily discourse in countries where wildfires in large forests are rare and most of the managed habitat is the much thinner type of woodland associated with savanna (see Chapter 8).

p0385 In terms of such issues as woodland thinning (directed silviculture or ad hoc management), in African savanna the public and policy makers are more concerned with maintaining herbivore populations as part of ecotourism and for the love of Africa's "big five" megafauna wildlife species. South Africa practices extensive silviculture, and it often is blended into wilderness areas (Tsitsikama National Forest lies adjacent to extensive tracts of forest plantation, where fire suppression is practiced because of economics of the wood industry). It seems the "fear" of fire so prevalent in North America is absent from rural areas of Africa for multiple reasons, but this results in a more sane approach to fire ecology. In Kruger Park managers learned over time that allowing wildfire is acceptable, and it is now a tool (although not frequent) integrated with controlled burns. They even seek to achieve as hot a fire as they can in certain habitat conditions to clear the invasive vegetation or just to suppress woody growth. The lesson learned in South Africa over 50 years of "experimenting," and from many decades of following the Serengeti system, is that monitoring is critical, and adapting to those results (adaptive management) is imperative.

s0075 Australia

p0390 In Australia prescribed burning is considered a staple part of the land management tool kit and is routinely applied with the aim of reducing the risk of large, unplanned wildfires to property and infrastructure (Clarke, 2008). In some cases fire is applied to the landscape in efforts to "restore" ecosystems or to create fine-scaled fire mosaics of mixed successional stages to encourage greater faunal and floral diversity (Bradstock et al., 2005). In response to the perceived need to apply fuel-reduction burns, the Victorian state government implemented a policy that mandated that 5% of the total land area under state jurisdiction be burned each year. This policy did not discriminate fire prescriptions between ecosystems and has been subject to widespread criticism from fire ecologists in Australia; it is currently under review (DELWP, 2015a). Although appropriate fire regimes have positive ecological outcomes in many systems, application of prescribed burning can lead to species declines and in some cases can cause irreversible changes in ecosystem state (Pardon et al., 2003, Pennman et al. 2011, Pastro et al., 2011).

p0395 Recent large wildfires in Australia have spurred new policies to address the growing public concern over the dangers presented by these fires (McLennan and Handmer, 2012; Whittaker et al., 2013). The royal commission that followed the 2009 "Black Saturday" fires suggested the implementation of new policies to encourage clearing around homes and to shift public perceptions toward recognition of bushfires as defensible events (i.e., homes can be effectively protected) that require early planning and avoidance actions (Teague et al., 2010). Residents in areas of high fire risk are now able to clear all vegetation within 50 m of their homes. These new measures, coupled with the 5% burn target, aim to reduce the potential of a repeat of the 2009 fires. This home protection approach is partially supported by science. Gibbons et al. (2012) highlighted that houses with vegetation cleared within 50 m were 70% more likely to survive a fire than those with no clearing. They revealed, however, that there was no effect of fuel reduction burning in nearby state forest or ecological reserves on house preservation following the 2009 fires in Victoria, Australia. Furthermore, in some of the most potentially pyrogenic systems, such as mountain ash forests, fuel reduction burns are rarely applied because moisture levels are normally high, and risk of fire spread is considered unacceptable when conditions are dry (DELWP, 2015b). A growing body of literature indicates that inappropriate fire regimes are contributing to species declines globally (Driscoll et al., 2010). In response to the increased fire risk caused by climate change, policy makers should seek to implement strategies with a proven ability to protect homes, while avoiding ineffective actions that detrimentally impact biodiversity.

s0080 Central Europe

p0400 In central Europe forest fires are relatively infrequent and mainly limited to regions with pine forest plantations growing on sands, gravel-sands and sandstone rocks. Any burned areas are mandatorily reclaimed within just 2 years of their formation; exceptions are possible in forests protected as national parks or nature reserves. The option to request avoidance of logging and replanting is used only rarely, however, and nearly all forests affected by fires are quickly logged and replanted.

p0405 Available evidence suggests that fire-induced bare soil patches, charred trunks, and dead wood resulting from the postfire dieback represent unique nesting resources for numerous species. The areas subject to mixed- and high-severity fires are associated with dynamic assemblages of plant and animal species, many of which are rare or even absent in the surrounding landscape. The burned forests serve as key habitats, particularly for aculeate Hymenoptera associated with cavities in dead wood (such as *Dipogon vechti*). Such cavities are considered limiting nesting resources, and their absence (and targeted removal of any newly emerging snags, which is mandatory by law) causes numerous specialized cavity adopters to be red-listed or extinct. Mounting evidence suggests that specific groups of organisms are strictly dependent on the occurrence of repeated fires. As long as sites of natural disturbances become extremely rare in the intensively cultivated landscape of central Europe, bare soil specialists and species that specialize in cavities of decaying wood will be completely absent where forests are subject to intense cultivation and rigorous dead wood removal. Dead wood thus should be considered an important habitat resource deserving conservation measures. Mosaic management of burned forest sites and retaining charred trunks are suggested as management measures supporting biodiversity at the sites of recent forest fires (Bogusch et al., 2015).

s0085 Canadian Boreal

p0410 There is emerging a new paradigm about the role of fire in the Canadian boreal forest. Historically, it was perceived as a simple system where "catastrophic" fire created landscapes of young, even-aged stands and where species diversity was poor. The reality is much more complex. There is an impressive range of fire cycle estimates—some as long as several centuries—suggesting that for at least part of the boreal forest region the abundance of old-growth forests in preindustrial times was much greater than expected (see Chapter 8). Associated with these old-growth forests is high understory diversity in black spruce (*Picea mariana*) stands and a number of rare species of nonvascular plants associated with balsam fir (*Abies balsamea*) stands. Similar findings have been made in boreal forests of Europe and Asia.

p0415 At the other end of the disturbance spectrum, there is now compelling evidence showing the importance of early seral burned habitats for the pyrocommunity, led by saproxylic insects (dependent on dead or decaying wood) and followed by primary cavity nesting birds (see Chapter 8). The retention of a wide range of burn conditions enhances saproxylic insect diversity. A link between this saproxylic community and nutrient cycling has been found, indicating a connection between biodiversity and ecosystem function in Canadian boreal forests. Large fires produce significant pulses of dead wood, which drive biodiversity and ecosystem processes through natural succession over time. Fire skips, or remnants left after large burns, also are critically important for biodiversity, species persistence, and recolonization and ecosystem recovery.

B978-0-12-802749-3.00013-X, 00013

p0420 For a long time, forest management was driven with a strong focus on timber extraction and developed a jargon that infiltrated the dialect of forestry, with words like "decadent" for old-growth forests, "waste wood" for trees that had been killed by natural disturbances, and "salvage" as the practice used to recover that "wasted" timber. Today, management in the boreal forest is increasingly driven by themes like ecosystem-based management and sustainable development. The new era will require conservation of boreal forests at different ends of the disturbance spectrum from newly created, postfire habitat to multicentury, old-growth forests.

s0090 13.7 ADDRESSING UNCERTAINTIES

p0425 Even though most people recognize the importance of maintaining fire on the landscape, there remain important questions about what might be the optimal postfire conditions for the broad suite of species with varying fire tolerances. For instance, we do not know whether there is a certain amount of burned forest or spatial distribution of burned forest patches, patch sizes, and fire frequencies necessary to maintain species at polar ends of the successional gradient. However, we hypothesize that in large, intact forested landscapes where fire is allowed to burn and logging is restricted (e.g., wilderness areas, large national parks, and other protected ecosystems) there should be ample habitat for all seral species over the long term and the best opportunities for coexistence with fire as a process (see Chapters 3–5). By contrast, in highly degraded landscapes, particularly those close to towns and homes, an optimal condition of recently burned and long-unburned patches is more difficult to ascertain because it may involve tradeoffs for public safety reasons (DellaSala et al. 2004).

p0430 Currently, megafires in western North American forested landscapes burn in mixed-severity patterns and seem to provide the necessary patch mosaics for a broad array of species (Chapters 2–6). Fire-related change of late seral habitat to complex early seral forest (Swanson et al., 2011; DellaSala et al., 2014; Hanson, 2014) has not been a threat to species dependent on such mature forest habitat, particularly given that there is generally much less high-severity fire in mixed-conifer and pine forests of western North America than there was historically (Odion et al., 2014a). Rates of old forest recruitment, as a result of growth, also outpace rates of high-severity fire in old forest by several times (Hanson et al., 2009; Odion and Hanson, 2013; Odion et al., 2014b). The situation is less clear in portions of Australia, however, where fewer vertebrate species have thus far been found to be fire dependent (see Chapters 3 and 4) and there are more species associated with late seral conditions that are especially at risk (Kelly et al., 2015). By contrast, other Australian research found bird species richness to be highest where there is the most successional diversity from higher-severity fire (Sitters et al., 2014) (see Chapter 8). Human-caused fires in North American chaparral, the Great Basin, and many desert ecosystems, which mostly replace stands, have exceeded historical bounds, adversely affecting this diverse shrubland

Comp. by: GAsokpandian Stage: Revises1 Chapter No.: 13 Title Name: Dellasala

B978-0-12-802749-3.00013-X, 00013

community (Chapter 7). Thus, whether or not fire mosaics are correlated with high levels of biodiversity (cf. Martin and Sapsis, 1991 versus Parr and Andersen, 2006; Taylor et al., 2012; Kelly et al., 2015) depends on differences in biogeography, fire histories, land use histories, and life history requirements (including fire tolerances and dependencies) of species over long time lines and large landscapes (e.g., Scott et al., 2014; see Chapters 3–5).

p0435 In addition, climate change introduces uncertainty in how forests will respond to changes in fire extent, longer fire seasons, higher severities in places, how soon the current fire deficit in places will remain that way before exceeding historical bounds, and whether existing deficits will be exacerbated in some forests with increasing precipitation driven by climate change (see Chapter 9). Nonetheless, at least for mixed-severity fire systems there is no magic thinning or suppression bullet to forestall climate-mediated fire changes. Changes in fire behavior are a consequence of human-caused climate change. It is best to treat the cause—climate change—rather than the symptom (fire behavior) if we are truly concerned about climate effects on ecosystems and people.

s0095 13.8 CLOSING REMARKS

p0440 When viewing the natural world, as a matter of perspective, we are reminded of discussions we have often had with foresters regarding how we each see the value of postfire landscapes. Clearly, we see the world differently depending on our professional judgment and value system.

p0445 A professional forester views the fruits of his or her labor, imagining what the future "production" forest will look like after decades of growing wood fiber, and then being frustrated by nature run amuck when the forest goes up in flames.

p0450 For the fire-trained ecologist, the initiating fire is but a glimpse into a vibrant community that begins with a pulse of biological activity and ensures successional events, just one of the many important links to follow in a long chain of ecosystem changes. Even the most charred forest is transformed by fire on one of nature's grandest stages. Among the first actors to arrive on the postfire stage are the biological legacies that provide the supporting foundation for other postfire actors to enter with the passage of time. If we imagine what the stage will look like years after a severe burn (often only 1 year), we see a floral phoenix arising from the ashes, we hear a cacophony of songbirds and drumming woodpeckers, and the rhythmic buzzing of bees and other insects as they go about their business of pollinating the next explosion of flowering plants. Up close and personal, we see tiny native beetle larvae tucked neatly into galleries beneath the outer charred tree bark, wood-boring scorpion wasps recoiling long abdomens after depositing eggs into open crevices in tree bark, centipedes and millipedes working charred humus, and ravenous insect-loving bats and fly-catching birds feasting on all the buzz.

p0455 The postfire landscape is indeed a transformative place if we humans are willing to have the patience to look beyond the brief snapshot in time right after

the initiating event. Only then will the postfire esthetic become apparent. Our human world of instant gratification pales in comparison to nature's seemingly infinite horizon. Meticulous observations by trained ecologists too often are drowned out by the noise of a fast-paced society preoccupied with one-size-fits-all solutions, do something at any cost, myopic economic benefits, and a fear-based media blitz of fire catastrophe reporting. But if we wait for the ecosystem actors to emerge in synchronicity, the postfire habitat unveiled is remarkably resilient, brilliant like the mythical phoenix, and even musical if we know how to listen. We hope that we have sufficiently portrayed an ecological awareness for this postfire symphony in the chapters of this book.

p0460 In this closing chapter we also have discussed the importance of education and outreach for a communications framework and improved ecological understanding of fire that follows fundamental ecological and safety principles.

p0465 From a communications standpoint, fire operates very much like an apex predator, thinning out and culling its prey, sometimes in large numbers, sometimes not. Apex predators are indeed vital to fully functioning ecosystems, yet they are either loved or hated based on one's perspective, which simply boils down to either an appreciation for wild things or a fear of being attacked or of losing a commodity. People view fire in much the same way. Decades of public outreach and campaigns in many places (most notably Europe and North America) have shifted public opinion to be more accepting of predators, and even to relish them in national parks and other protected landscapes where predators roam free and tourists flock to witness nature primeval. Clearly, fires, like apex predators, cannot be restricted to inside national parks, as the parks are not big enough to sustain them.

p0470 There is a lesson to be learned regarding the message of fear in both instances: As with predators, the risks of losses to people and property can be successfully mitigated by taking precautionary measures (e.g., just don't feed the bears, and remember to make loud noises while hiking in grizzly bear country!). In the case of fire, public safety of those living in firesheds is based on prudent fire risk reduction that with stepped-up outreach one day may become common knowledge. With a shift in this direction, we envision a move toward fire tolerance, and eventually coexistence, so that fire, in all its severities and forms, can continue to shape ecosystems into the next millennium. This will take a concerted effort of sophisticated and sustained message framing, an infusion of funds for stepped-up education that at least rivals predator-friendly campaigns, a commitment from land management agencies and the media to become more ecologically literate (including replacing Smokey Bear with nature's phoenix), conservation groups to see the value in mixed-severity and not just low-severity fire, and politicians to see the big picture that the postfire landscape has irreplaceable ecological value and is not just a money tree to be ravaged for short-term profit. Then nature's phoenix will truly take flight, reborn out of the ashes of a postfire landscape mosaic that is alive and well!

Abstract

Throughout this book we present a compelling case for the ecological importance of mixed-severity wildfires in forests (though some chaparral systems currently experience too much fire), including, in many cases, megafires from western North America. Stand-replacing fire disturbances are underappreciated natural events that have been shaping fire-dependent ecosystems for millennia, and their ecosystem benefits are being compromised by management actions that carry unintended consequences. Mimicking the spatial, temporal, and structural heterogeneity of these fire effects through management is not possible. Moreover, fire management actions such as forest thinning, mastication, and postfire logging are creating novel fire regimes at the expense of historical ones. Dramatic improvements in fire management and public perceptions of wildfire are needed to accommodate wildfires where they are beneficial. We provide several closing recommendations for addressing public safety concerns and ecological use of fire in natural areas.

ABSTRACT

Existing fire policy encourages the maintenance of ecosystem integrity in fire management, yet this is difficult to implement on lands managed for competing economic, human safety, and air quality concerns. We discuss a fire management approach in the mid-elevations of the Sierra Nevada, California, USA, that may exemplify similar challenges in other fire-adapted regions of the western USA. We also discuss how managing for pyro-

RESUMEN

La política de fuego actual fomenta la permanencia de la integridad del ecosistema en el manejo del fuego. Sin embargo esto es difícil de implementar en tierras manejadas con multiplicidad de objetivos (económicos, de seguridad humana, o relacionados con la calidad del aire). Nosotros debatimos un enfoque sobre el manejo del fuego en las elevaciones medias de la Sierra Nevada en California, EEUU, que podría extenderse a casos similares que ocurren en otras regiones adaptadas al fuego en el oeste de los EEUU. También discutimos como el manediversity through mixed-severity fires can promote ecosystem integrity in Sierran mixed conifer and ponderosa pine (*Pinus ponderosa* Laws) forests. To illustrate, we show how coarse-filter (landscape-level) and complementary fine-filter (species-level) approaches can enhance forest management and conservation biology objectives as related to wildfire management. At the coarse-filter level, pyrodiverse mixed-severity fires provide landscape heterogeneity. Species and ecosystem characteristics associated with pyrodiversity can be maintained or enhanced by accommodating moderately severe fires, which hasten restoration by recreating a complex vegetation mosaic otherwise at risk from suppression. At the fine-filter level, managers can select focal species and species of conservation concern based on the degree to which those species depend on fire and accommodate their specific conservation needs. The black-backed woodpecker (*Picoides arcticus* [Swainson, 1832]) is an ideal focal species for monitoring the ecological integrity of forests restored through mixed-severity fire, and the California spotted owl (*Strix occidentalis occidentalis* [Xantus de Vesey, 1860]) is a species of conservation concern that uses post-fire habitat mosaics and is particularly vulnerable to logging. We suggest a comprehensive approach that integrates wildland fire for ecosystem integrity and species viability with strategic deployment of fire suppression and ecologically based restoration of pyrodiverse landscapes. Our approach would accomplish fire management goals while simultaneously maintaining biodiversity.

jo para lograr la pirodiversidad a través de fuegos de severidad mixta podrían promover la integridad del ecosistema boscoso de coníferas mixtas de estas Sierras y de bosques de pino ponderosa (*Pinus ponderosa* Laws). Para ilustrarlo, mostramos cómo los enfoques a gran escala (a nivel de paisaje) y complementariamente a pequeña escala (a nivel de especie), pueden favorecer los objetivos del manejo forestal y de la conservación biológica en relación al manejo del fuego. A nivel de gran escala, la pirodiversidad de los fuegos de severidad mixta resultó en la heterogeneidad del paisaje. Las características de las especies y del ecosistema asociadas a la pirodiversidad pueden ser mantenidas o favorecidas cuando se admite la ocurrencia de algunos fuegos moderadamente severos, los cuales aceleran la restauración recreando un mosaico complejo de la vegetación, lo que no ocurriría en caso de ser suprimidos. A nivel de pequeña escala, los gestores pueden seleccionar especies focales y especies relacionadas con la conservación, basados en el grado sobre el cual esas especies dependen del fuego y se adaptan a sus necesidades de conservación específicas. El pájaro carpintero negro (*Picoides arcticus* [Swainson, 1832]) es una especie focal ideal para monitorear la integridad ecológica de los bosques restaurados a través de fuegos de severidad mixta, y la lechuza moteada de California (*Strix occidentalis occidentalis* [Xantus de Vesey, 1860]) es una especie de interés para la conservación que utiliza mosaicos de hábitat post fuego y es particularmente vulnerable al aprovechamiento forestal. Nosotros sugerimos un enfoque comprensivo que integre los fuegos naturales para la integridad del ecosistema y la viabilidad de las especies, con la implementación estratégica de la supresión del fuego y la restauración de paisajes pirodiversos basada en principios ecológicos. Nuestro enfoque podría cumplir con los objetivos de manejo del fuego, manteniendo simultáneamente la biodiversidad.

Accommodating mixed-severity fire to restore and maintain ecosystem integrity with a focus on the Sierra Nevada of California, USA. Fire Ecology 13(2): 148–171. doi: 10.4996/fireecology.13014817

INTRODUCTION

Pyrodiversity, the mean spatial variability in wildfire effects, results in complex post-fire vegetation mosaics that are associated with high levels of biodiversity. Large fires that produce a variety of severities (i.e., mixed-severity fires) in ponderosa pine (*Pinus ponderosa* Laws) and mixed-conifer forests of the western USA are increasingly recognized for their importance in generating pyrodiverse landscapes (e.g., Perry *et al.* 2011, Williams and Baker 2012, Odion *et al.* 2014, Marcoux *et al.* 2015). Top-down processes such as extreme fire weather, regional climate (which influences fuel moisture and ignitions), and bottom-up processes such as topographic relief, vegetation, and disturbance history govern the distribution and size of fire patches in mixed-severity fires (Perry *et al.* 2011, Dunn and Bailey 2016). Regional drought, high winds and temperatures, and other factors (e.g., surface fuel loading, crown base height, and crown bulk density; Cruz and Alexander 2010) drive crown fire behavior in these systems, producing small and large patches of high tree mortality within a predominantly surface-fire matrix of mostly surviving trees. Mixed-severity fires therefore generate complex stand structures and landscape heterogeneity—characteristics not typically produced by low-severity fire (Table 1). Low-severity fire, while also important ecologically, is preferred by many managers due to lower risks to economic values. Here, we focus on mixed-severity fires because they have received less attention by managers, but they result in pyrodiverse landscapes (DellaSala and Hanson

Table 1. Pyrodiversity attributes produced by mixed-severity fires associated with high levels of biodiversity and ecosystem functions.

Mixed-severity fire attribute	Ecological importance
Landscape heterogeneity	Habitat for wide array of species—early to late seral associates Mixture of foraging and nesting habitat for spotted owls
Complex stand structures	Biological legacies: large snags, down wood, shrubs, flowering plants Habitat for black-backed woodpeckers
Food web dynamics	Complex trophic structure connected across seral stages with abundant food for certain taxa (e.g., beetle larvae for woodpeckers) Pulsed nutrient inputs (aquatic and terrestrial)
Ecosystem processes	Nutrient cycling and soil nutrient exchange, energy transfer from live to dead material, pollination, predator-prey (owls-mice)
Species composition	Rich and varied, compared to old growth

2015). We demonstrate how ecosystem integrity can be met by managing for pyrodiverse landscapes mediated by mixed-severity fires in the biodiverse region of the Sierra Nevada, California, USA.

Although it is the subject of ongoing research and debate (Odion *et al.* 2016), it has been suggested that mixed conifer, ponderosa pine, and Jeffrey pine (*Pinus jeffreyi* Grev. & Balf.) forests in this region historically experienced a mix of fire severities, including areas of high overstory tree mortality (DellaSala *et al*. 2014, Stevens *et al.* 2016). There is considerable variability in reported proportions and sizes of high-severity fire patches, with the greatest differences found in relatively smaller study areas or studies in which shorter time periods were analyzed (Table 2). High-severity patches commonly ranged from 0.4 ha to >50 ha, but the historical frequency of patches >1000 ha is still debated (e.g., Baker 2014, Stevens *et al.* 2016). While uncertainty remains on some issues, there is general agreement that most forests of the Sierra Nevada currently have less high-severity fire, in terms of annual or decadal area burned, than they did historically, prior to fire suppression (Mallek *et al.* 2013, Odion *et al.* 2014, Baker 2015). Additionally, drier low-elevation pine forests burned most frequently at low to moderate severity (Stephens *et al.* 2015), but those fires also contained variably sized high-severity patches (Leiberg 1902, Baker 2014, Hanson and Odion 2016*a, b*). Douglas-fir (*Pseudotsuga menziesii* Mirbel) (Odion *et al.* 2014) and Sierra lodgepole pine (*Pinus contorta* var. *murrayana* Grev. & Balf.) forests experienced mixed-severity fires as well (Caprio 2008).

Tree mortality is also an important component of mixed-severity fire effects characterized mostly by low-mortality levels (0% to 20% tree basal area), highly variable moderate-mortality levels (20% to 70%), and high-mortality levels (>70% tree mortality) (Perry *et al.* 2011; Figure 1). Agee (2005) noted that mixed-severity fires are not merely an intermediate state between low and high severity but, rather, are a unique type of disturbance that warrants careful study by ecologists.

While there are winners and losers in the immediate aftermath of any disturbance event, the net effect of mixed-severity fire is that it

Table 2. Historical fire severity proportions and maximum high-severity fire patch sizes in mixed-conifer and ponderosa pine forests, Sierra Nevada management region.

Study	Study area size (ha)	Fire severity (%)			Time period (yr)	Maximum high-severity patch size (ha)
		Low	Moderate	High		
Beaty and Taylor (2001)[1]	1587	1 to 60	14 to 47	6 to 86	43	no data
Bekker and Taylor (2001)	2042	2 to 4	35 to 44	52 to 63	75	no data

Hanson and Odion (2016*a,b*)	65296	no data	no data	22	60	697
Leiberg (1902)[2]	1193166	no data	no data	20	100	~16000
Stephens *et al.* (2015)	11500	no data	no data	1 to 6	~20 to 30	no data

[1] Fire severity percentages vary by slope position and aspect.
[2] Does not include high-severity fire patches <32.4 ha, so actual percent high-severity fire would be higher, if patches <32.4 ha had been mapped. Historical high-severity fire mapped polygons are from Leiberg (1902), and analysis of high-severity fire percent by forest type is from Hanson (2007), based on Leiberg (1902).

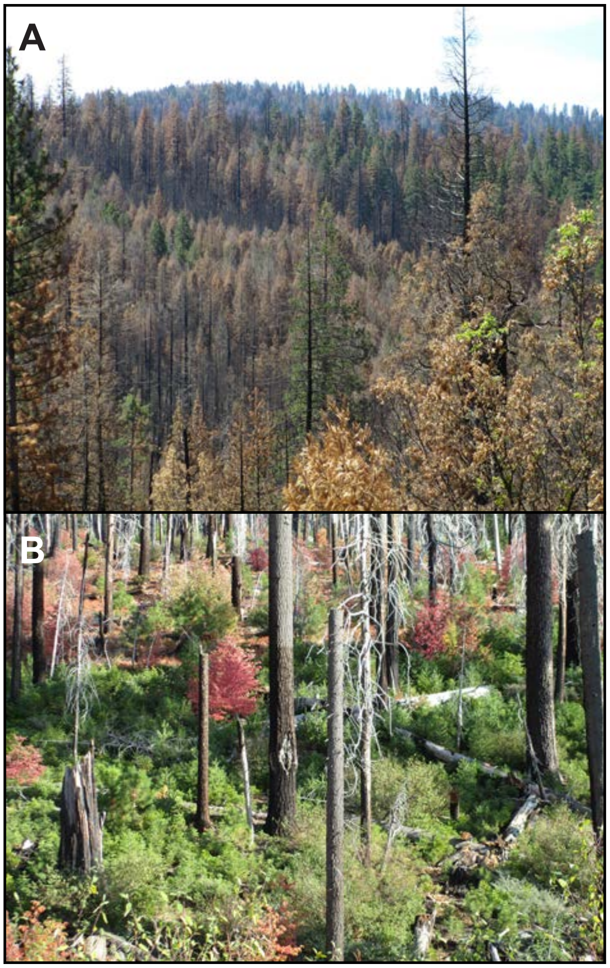

Figure 1. (A) Landscape view of mixed-severity fire effects in the Rim Fire 1 year post fire. The spatial pattern of fire severity patches and patch sizes results in a pyrodiverse landscape that provides habitat for wildlife across a post-fire vegetation gradient of low or unburned vegetation patches to severely burned vegetation patches. (B) Close-up of large patch of complex early seral forest created by high-severity fire in juxtaposition with abundant and varied "biological legacy" trees (complex structures, such as snags, logs, and shrubs that survive fire). Photos by C. Hanson.

provides a mosaic of habitat for a broad suite of species. For instance, songbirds have high levels of species richness and abundance in post-fire vegetation at mid elevations (Fontaine *et al.* 2009, Tingley *et al.* 2016). Black-backed woodpeckers (*Picoides arcticus* [Swainson, 1832]), mountain bluebirds (*Sialia currucoides* [Bechstein, 1798]), tree swallows (*Tachycineta bicolor* [Vieillot, 1808]), and numerous shrub-nesting birds preferentially use recently burned forests in the Sierra Nevada and other regions, presumably due to increased shrub cover and presence of snags (Fontaine *et al.* 2009, DellaSala *et al.* 2014, Hutto *et al.* 2015, Tingley *et al.* 2016). California spotted owls (*Strix occidentalis occidentalis* [Xantus de Vesey, 1860]) and olive-sided flycatchers (*Contopus cooperi* [Nuttall, 1831]) forage in severely burned patches where prey are abundant, and nest in unburned to moderately burned portions of the same fire mosaic (Bond *et al.* 2009, 2016; Hutto *et al.* 2015; Comfort *et al.* 2016). Bats make use of high snag densities (Buchalski *et al.* 2013) and fire-recruiting plants are associated with severely burned patches (Donato *et al.* 2009). Even mature-forest carnivores such as the Pacific fisher (*Pekania pennanti* [Erxleben, 1777]) actively forage in severely burned patches (Hanson 2015).

The high-severity patches within the mixed-severity mosaic provide a unique pulse of biological legacies—complex structures such as snags, downed logs, and native shrub patches from seed that survive fire and that are important in connecting seral stages through time (Franklin *et al.* 2000, Fontaine *et al.* 2009, Donato *et al.* 2012, DellaSala *et al.* 2014). The economic value of large dead and live trees within these patches means that commercial trees are most often targeted for harvest soon after fire. In addition, nursery-grown young trees are planted soon after fire and, to promote the crop of young trees, herbicides are often sprayed to kill competing vegetation (Lindenmayer *et al.* 2008, 2017). Logging slash from post-fire logging may contribute to subsequent fire behavior (Donato *et al.* 2006, Thompson *et al.* 2007), as can the fuel array of densely planted even-aged trees (Odion *et al.* 2004).

On public lands, current fire policy promotes thinning over large landscapes (e.g., USDA Forest Service 2002, US Congress 2003, USDA Forest Service 2009, US Congress 2015), which is costly (Schoennagel and Nelson 2011), infeasible over large areas (Calkin *et al.* 2013, North *et al.* 2015*a*, Parks *et al.* 2015), and largely ineffective under extreme fire weather conditions (Lydersen *et al.* 2014, Cary *et al.* 2016). For instance, from 2001 to 2008, over 11 million hectares were thinned on national forests (mostly in the western USA) at a cost of more than \$6 billion (Schoennagel and Nelson 2011). Mechanical vegetation treatments can cost over \$3700 per hectare for each round of thinning (Kline 2004), which would need to be repeated at least every 15 to 20 years to keep flammable vegetation at low levels. Additionally, from 1985 to 2015, suppression costs were more than \$25 billion to fight approximately 2 million fires on over 83 million hectares, mostly spent by the Forest Service (Ingalsbee and Raja 2015).

Thus, we concur with others that active management approaches could include more natural fire ignitions (Calkin 2013, Meyer 2015, North *et al.* 2015*b*) or resource objective wildfires (Meyer 2015) in which fire is put back on the landscape to hasten the process of forest restoration (Moritz *et al.* 2014, Moritz and Knowles 2016). This would also help to meet fire and fuels objectives and allow managers to better accommodate mixed-severity fire effects for ecosystem integrity (Meyer 2015, Dunn and Bailey 2016). We suggest that an ecosystem integrity approach is not inconsistent with current active fuel management on federal lands and may be a cost-effective way to achieve biodiversity goals (North *et al.* 2015*b*), while reducing some of the conflicts associated with extensive fuels-focused approaches—particularly impacts to imperiled species and at-risk ecosystems. We use the definition of ecosystem integrity common in the literature (e.g., Pimentel *et al.* 2000), also adopted by the USDA Forest Service (2012), as the ability of an ecological system to support and maintain a community of organisms that has a species composition, diversity, and functional organization comparable to those of natural habitats within a region.

Our focus is the Sierra Nevada region because of national attention given to so many recent fires therein. We include an example of a fire-adapted species (black-backed woodpecker) that uses high-severity patches, and an imperiled species (California spotted owl) known to decline within intensively managed post-fire landscapes. The Sierra Nevada is one of the most diverse temperate conifer forest regions on Earth and has exceptional levels of plant endemism (Ricketts *et al.* 1999). Approximately half of California's 7000 vascular plant species occur in this region, with 400 considered endemic and 200 rare. High levels of vertebrate richness and endemism also occur. Species composition varies across north-south, east-west, and elevational gradients, resulting in high levels of beta diversity.

Importantly, the 2012 forest planning rule (USDA Forest Service 2012) includes specific provisions for managing public resources to maintain or restore: (1) structure, function, composition, and landscape connectivity; (2) ecological conditions for recovery of imperiled and focal species; and (3) rare and unique habitat types (USDA Forest Service 2012). The National Cohesive Wildland Fire Management Strategy (USDI and USDA 2014) and Sierra national parks (e.g., Yosemite, Sequoia and Kings Canyon) also include multi-faceted approaches that promote greater wildfire ignitions. Though national forest lands compose most of the forested area in California, and are thus our focus herein, significant areas of federal forest in California are managed by the National Park Service (NPS), and a state agency, California Department of Forestry and Fire Protection (CAL FIRE), responsible for decisions and operations pertaining to fire suppression on private and state lands. NPS, like the Forest Service, is required to protect species listed under the Endangered Species Act (ESA), and CAL FIRE is subject to the California state ESA. Thus, our approach to wildfire management can be applied to these agencies and land ownerships regarding decisions about fire suppression and forest management that might impact imperiled or ESA-listed species associated with post-fire landscapes.

STUDY AREA

The Sierra Nevada management region is a 750 km long, north-south oriented mountain range in California composed of granitic rock, and distributed across three ecoregions: Sierra Nevada proper; portions of the Modoc Plateau; and the eastern portion of the southern Cascades (Bailey 1995; Figure 2). The regional climate is mediterranean with cool, wet winters, and warm, dry summers; precipitation generally decreases west to east and north to south (Millar1996).

There are 11 national forests totaling about 4.6 million hectares: Modoc, Lassen, Plumas, Tahoe, Eldorado, Stanislaus, Sequoia, Sierra, Inyo, Humboldt-Toiyabe (western portion), and Tahoe Lake Basin Management Unit. Forest planning is governed by the Sierra Nevada Framework (USDA Forest Service 2004), but the Forest Service is currently revising its forest plans for the Inyo, Sequoia, and Sierra national forests as "early adopters" (i.e., first national forests to test the planning rule) of the 2012 forest-planning rule (USDA Forest Service 2012). Three national parks—Lassen, Sequoia and Kings Canyon, and Yosemite—and several large wilderness and inventoried roadless areas >2000 ha also occur in the region.

Coarse-Filter and Fine-Filter Approaches to Ecosystem Integrity in Mixed-Severity Systems

Managers wishing to maintain ecosystem integrity via naturally ignited fires can do so using a combination of coarse- and fine-filter conservation approaches (Noon *et al.* 2003, USDA Forest Service 2012). Coarse filters invariably include relatively few indicators associated with the larger ecosystem of interest (e.g., major vegetation types or, in this case, different categories of burn severity). Their presence is meant to indicate that essential components of the whole system are intact, and they operate at broad spatial scales such as those associated with large fires (hundreds of square kilometers). Coarse filters are typically used to guide reserve design based on fundamental principles of conservation biology, including spatially redundant reserve complexes representative of the major forest types and fire severities interconnected across large landscapes. To achieve a pyrodiverse landscape, perhaps the best coarse filter would include high-severity fire patches interspersed with fire refugia (unburned areas) and low- to moderate-severity patches.

Fine-filter considerations complement coarse filters by adding site-specific or habitat elements associated with focal species, guilds, or other species groupings (USDA Forest Service 2012). Application of this kind of filter allows managers to evaluate whether habitat and special conservation needs are met through a given management plan, and ground-truth the utility of burn severity maps by linking mapped fire severities to habitat needs of target species. In addition, the approach allows managers to meet national forest planning requirements to monitor and evaluate a small suite of focal species selected to assess the degree to which ecological conditions are supporting the diversity of plant and animal communities within a given planning area (USDA Forest Service 2012). Focal species can, therefore, be used to monitor the integrity of the larger system to which they belong, and researchers (e.g., Seavy and Alexander 2014, Stephens *et al.* 2015, Siegel *et al.* 2016) have suggested using patterns of plant and animal distributions as a passive management strategy to accommodate mixed-severity systems. The Forest Service also now considers species of conservation concern as "a species, other than federally recognized threat-

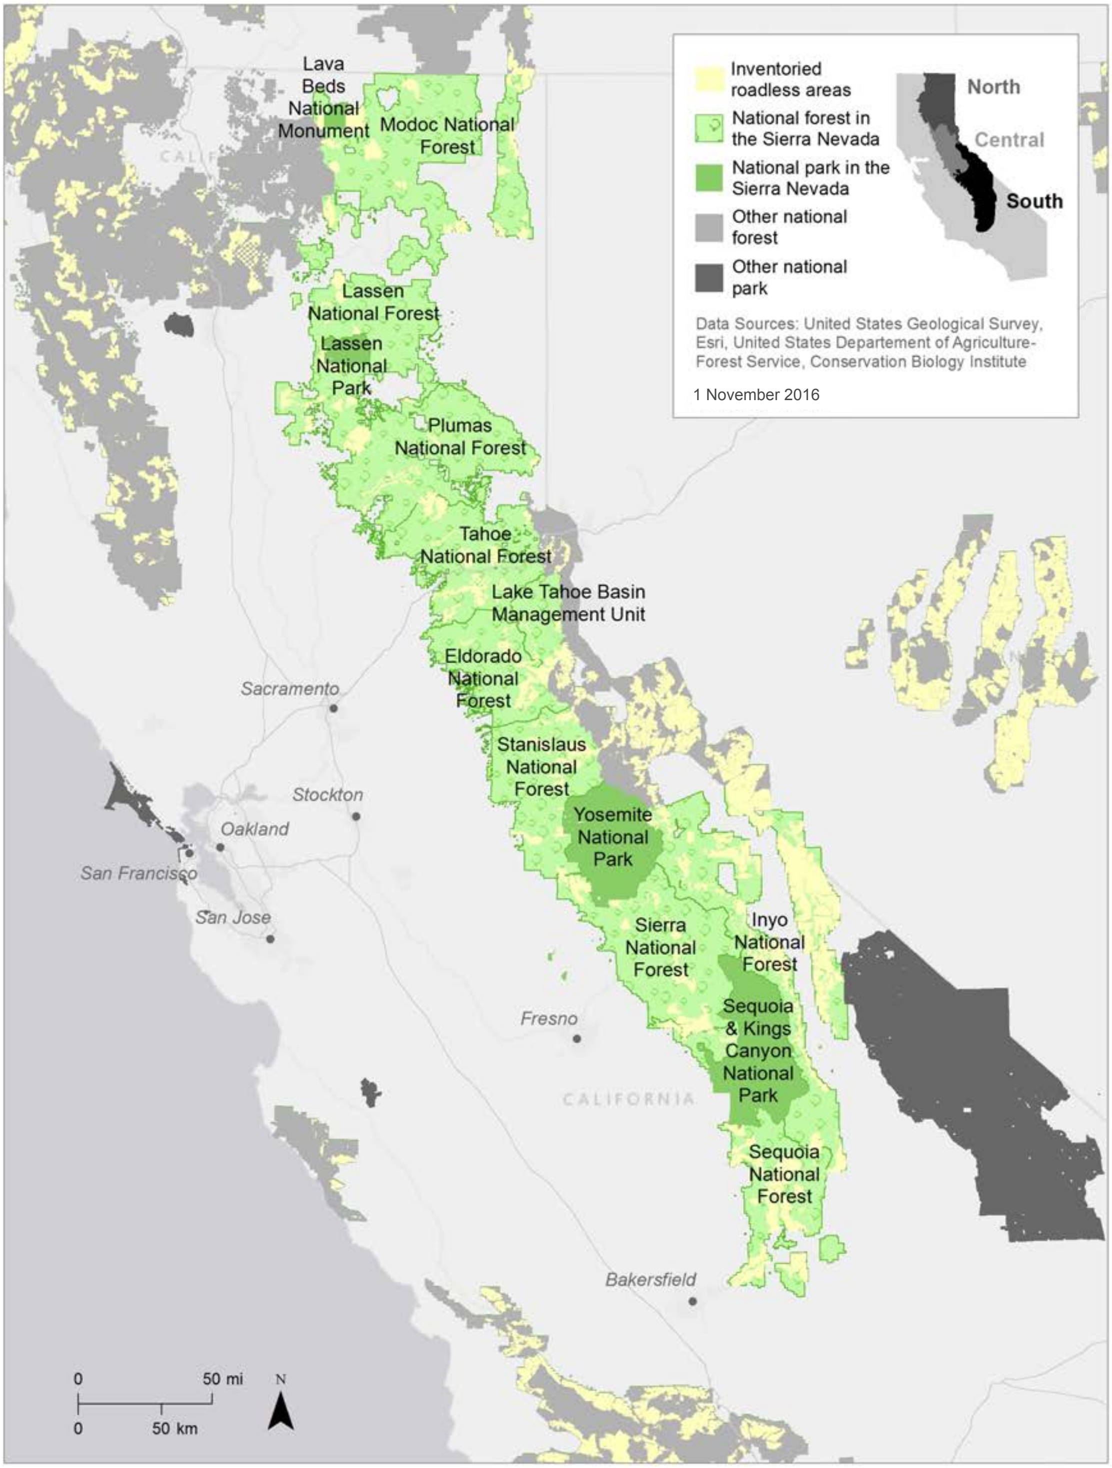

Figure 2. Sierra Nevada study region showing national forests, national parks, and inventoried roadless areas.

ened, endangered, proposed, or candidate species, that is known to occur in the plan area and for which the regional forester has determined that the best available scientific information indicates substantial concern about the species' capability to persist over the long-term in the plan area" (36 CFR 219.9(c); https://www.fs.usda.gov/Internet/FSE_DOCUMENTS/stelprdb5359595.pdf, accessed 12 May 2017). The agency is required to maintain suitable habitat for these species to ensure viable populations are present in the planning area (USDA Forest Service 2012).

Comprehensive Wildland Fire Management

We recognize that land managers face many constraints (legal and social) and often competing regulatory and management objectives that limit wildfire management options. However, the Planning Rule and the National Cohesive Wildland Fire Management Strategy (USDI and USDA 2014) offer opportunities to put more fire back on the landscape whether through prescribed burning or managed wildfires. We provide some general concepts that managers might apply with pyrodiversity outcomes realized through mixed-severity fires that meet ecosystem integrity objectives.

Integrating Wildland Fire and Targeted Fire Suppression (Coarse Filter)

Mixed-severity fire effects for ecosystem benefits can be integrated with targeted suppression and fire-risk reduction efforts near towns using this coarse-filter approach. While we acknowledge that there was concern about the size and severity of the 2013 Rim Fire (Lydersen *et al.* 2014), the largest fire in recent Sierra Nevada history, we note that even this fire produced mostly low- to moderate-severity effects (i.e., ~20% of the burn was high severity based on Monitoring Trends in Burn Severity [MTBS]; http://mtbs.gov/MTBS_Uploads/data/2013/maps/ca3785712008620130817_map.pdf, accessed 23 April 2017), and a wide range of high-severity patch sizes, which contributed to significant heterogeneity at landscape scales. Thus, we concur with others (e.g., Moritz *et al.* 2014, Ingalsbee and Raja 2015, Dunn and Bailey 2016, Moritz and Knowles 2016, Schoennagel *et al.* 2017) that suppression could be focused narrowly to lands surrounding towns and used in combination with defensible space management nearest homes (Cohen 2000, 2004) so that more wildland fires can burn safely in the backcountry.

Notably, one way to safely modify fire suppression activity would be to restrict large fire crews and heavy equipment to protect homes and communities within the Wildland Urban Interface (WUI). The WUI is usually considered to extend to ~2 km from an at-risk community (US Congress 2003, USDA Forest Service 2004), even though most vegetation treatments are conducted farther from communities (Schoennagel *et al.* 2009). Beyond the WUI, point protection strategies would be used to keep fire away from isolated structures and infrastructures like cabins, communication towers, bridges, or other human assets that could be destroyed by fire. Relatively small, mobile fire crews would also use minimum impact suppression tactics (i.e., Minimum Impact Suppression Tactics [MIST]; https://www.nifc.gov/PUBLICATIONS/redbook/2003/AppendixU.pdf, accessed 12 May 2107) in backcountry areas, primarily monitoring fire spread but, when necessary, actively managing it (rather than containing and controlling wildfire as in traditional full-suppression strategies) by steering fire away from threatened social assets (Donovan and Brown 2005, 2008; Ingalsbee and Raja 2015). In municipal watersheds where fire management plans may want to avoid high-severity fires burning near water sources, more fires could be allowed to burn during moderate weather conditions. Wildfire management should be a useful tool for managing fuel loads in municipal watersheds where the use of chemicals or heavy equipment for either thinning or suppression would cause unacceptable impacts to water quality and soils. MIST could also be employed where fires in wilderness and roadless complexes, national parks, and even in roaded areas many kilometers from the nearest town pose low risk to residential areas. In sum, this approach would shift wildfire operations from limiting fire spread, size, or duration in backcountry areas to working with fire for ecosystem benefits while still effectively providing for community wildfire protection.

Sierra Nevada national forests and parks are large enough to accommodate most large fires over thousands or even tens of thousands of hectares (Appendix 1). For instance, many (>50%) of the largest forest fires from 1984 to 2014 were primarily contained within an individual national forest or national park boundary. In general, federal lands offer unique opportunities in which the maintenance of pyrodiversity for biodiversity could be emphasized in large protected areas (wilderness and roadless area complexes; Appendix 2). Coordination among agencies with similar objectives may allow for more naturally ignited fires over mixed ownerships having similar objectives (e.g., wilderness or roadless areas, other remote forests, conservation areas juxtaposed with parks) using an all-lands approach. If reserves were too small to accommodate large fires or patches of different fire severities, then complexes of multiple reserves widely distributed across a region in redundant locations would collectively help maintain the full complement of post-fire stages using the coarse-filter approach.

In the Sierra Nevada, the draft revised forest plans for the three early-adopter national forests in the southern portion of the range have included a fire-management-zoning approach similar to what we suggest here, allowing more naturally ignited fire in remote areas and suppressing fires close to communities (USDA Forest Service 2016). However, the focus in the draft plans remains on mechanical thinning and post-fire logging (USDA Forest Service 2016). We submit that an approach that allows more natural fire ignitions is advisable and warranted from the standpoint of both ecosystem integrity and public safety, as discussed herein.

Focal Species and Species of Conservation Concern (Fine Filter)

By way of example, we consider two species that could be used to monitor mixed-severity effects. The black-backed woodpecker would be an ideal focal species given its very close association with high-severity fire patches, as would the California spotted owl, a species of conservation concern. Both species are complementary to mixed-severity fire management, given that the woodpecker is mainly associated with the high-severity component, and spotted owls use a broad gradient of fire severity patches. Moreover, while there is some overlap in geographic ranges, spotted owls generally occupy low- to mid-montane forests, while the black-backed woodpecker lives in mid- to high-elevation mixed-conifer forests up to subalpine forests.

Black-backed woodpecker as focal species of high-severity fire patches. In the Sierra Nevada, black-backed woodpeckers occur across mid- to upper-montane and subalpine conifer forests from ~1200 m to 2800 m, depending on latitude. While still uncommon even in burned areas, the greatest concentrations occur in severely burned, mixed-conifer and upper montane forests with high basal area of snags (Hanson and North 2008, Saracco *et al.* 2011) where wood-boring beetle larvae are abundant (Saab *et al.* 2007). Burned areas also typically harbor high densities of medium to large dead trees >30 cm dbh (Cahall and Hayes 2009, Saab *et al.* 2009, Tingley *et al.* 2014). Black-backed woodpeckers also occur (albeit much more rarely) in dense, mature unburned forests (Bonnot *et al.* 2009, Fogg *et al.* 2014) where they have relatively larger home ranges, presumably reflecting conditions that are less than optimal (Tingley *et al.* 2014). Nevertheless, unburned forests with high levels of dead trees from drought and native bark beetles might at least slow the rate of population decline during interludes between severe fires (Rota *et al.* 2014). Only a small fraction of fires burn suitable woodpecker habitat, due to the narrow convergence of conditions that include recent (generally ≤8 years post-fire) higher-severity fire effects in dense, mature, middle- to high-elevation conifer forest (Casas *et al.* 2016). Often a single pair of birds uses hundreds of hectares (Dudley and Saab 2007, Tingley *et al.* 2014).

Black-backed woodpeckers are vulnerable to even partial post-fire logging (Hutto and Gallo 2006, Koivula and Schmiegelow 2007, Saab *et al.* 2009, Rost *et al.* 2013). Radio-telemetry studies in the Lassen and Plumas national forests of California showed that home-range sizes were significantly larger in forests in which some post-fire logging occurred, and post-fire logged patches in the Sierra Nevada were avoided (Tingley *et al.* 2014). For example, even though post-fire logging was proposed for what seems like a minor portion of the King Fire, logging was especially concentrated within the highest quality woodpecker habitat (Figure 3), where a high density of medium to large snags occurred. Notably, on national forests of the Sierra Nevada, post-fire logging decisions have typically authorized removal of 40% to 60% of high-severity patches, displacing complex early seral forest with tree plantations (e.g., USDA Forest Service 2014, 2015, 2016). Retention of dead trees in logging units generally averages ~10 trees per hectare >38 cm dbh (USDA Forest Service 2004). By comparison, to maintain habitat for this focal species, generally hundreds of medium to large snags per hectare (>30 cm dbh to 40 cm dbh, and especially snags >50 cm dbh) are needed (Hanson and North 2008, Saab *et al.* 2009, Tingley *et al.* 2014) in patches consistent with home-range size, along with an ample supply of dense, mature or old conifer forest to facilitate conditions for high quality habitat when fires do occur (DellaSala *et al.* 2014).

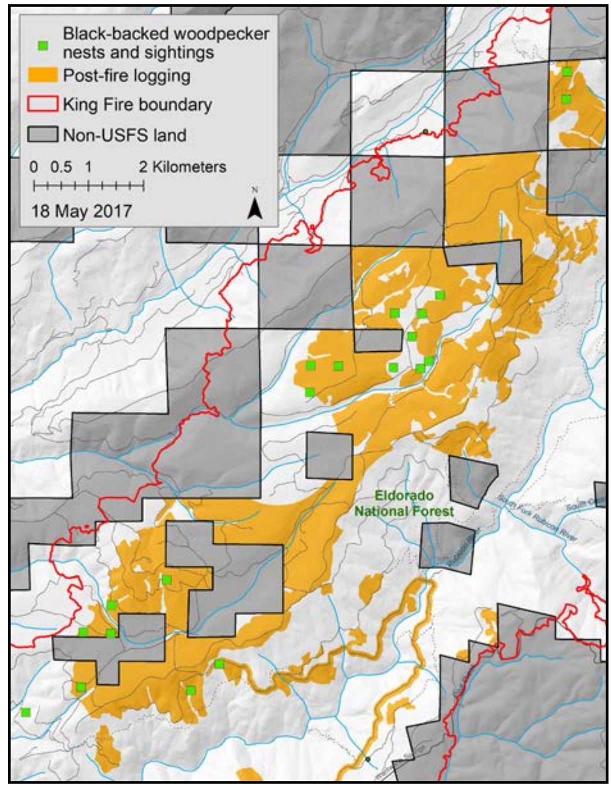

Figure 3. King Fire logging units on the Eldorado National Forest and black-backed woodpecker nests and sightings. After extensive surveys for black-backed woodpeckers were conducted for the US Forest Service throughout the fire area one year post fire, using playback recordings to detect the birds, all but one of the detections was in a relatively small area of dense, mature mid-montane conifer forest in a very large high-severity fire patch in the northern portion of the fire area (shown above). The Forest Service's decision authorized post-fire logging of ~80% of these locations.

California spotted owl as species of conservation concern. Early studies on habitat associations and reproductive success of spotted owls in the Sierra Nevada were conducted in long-unburned forests, and "non-suitable" owl habitat was typically the result of logging (e.g., Moen and Gutiérrez 1997, Blakesley *et al.* 2005). Because spotted owls are usually associated with older, dense forests, it was assumed that effects of high-severity wildfires were similar to logging (Weatherspoon *et al.* 1992). However, recent studies have demonstrated that occupancy (Roberts *et al.* 2011, Lee *et al.* 2012, Lee and Bond 2015*a*) and reproductive success (Roberts 2008, Lee and Bond 2015*b*) were similar or higher in forests burned with a mixture of fire severities compared to long-unburned forests for up to at least 15 years post fire (longer-term studies have not been conducted). Lee and Bond (2015*a*) reported higher occupancy rates than any Sierra Nevada study area for historical owl breeding sites one year after the Rim Fire. The amount of high-severity fire within an owl pair's 120 ha protected activity center, as defined by the Forest Service, had no effect on occupancy, although occupancy by single owls declined slightly as the extent of severe-fire patches increased.

Thus, even though spotted owls are not considered a fire-dependent species, they do persist after mixed-severity fires when both unburned and severely burned patches occur within historical territories (Lee *et al.* 2012; Lee and Bond 2015*a, b*). Owls foraged preferentially in high-severity patches within mature forest in the southern Sierra Nevada (Bond *et al.* 2009) and used high- and moderate-severity patches in the San Bernardino Mountains in proportion to availability (Bond *et al.* 2016). Notably, structural complexity (including high density of dead trees) is important for spotted owl foraging habitat. Bond *et al.* (2009) found that dead tree basal area and shrub cover were highest in high-severity fire patches in which owls preferentially foraged. The owls found a rich food source, in the form of small mammal prey, in post-fire habitat (Bond *et al.* 2016). California spotted owls also selected high-severity patches for foraging more than any other fire severity condition or than long-unburned forests when within 1.5 km of the nest or roost (Figures 4 and 5). Although there are reports of California spotted owls nesting in moderate-severity patches, these raptors mostly nest and roost in long-unburned or lower-severity areas within a burned landscape (Bond *et al.* 2009), underscoring the importance of the mixed-severity mosaic. In contrast, Jones *et al.* (2016) found higher rates of territory extirpation and lower rates of colonization of owl sites that experienced >50 % high-severity fire in the King Fire on the Eldorado National Forest, and reported avoidance of high-severity patches for foraging. The circumstances of their study differed greatly from others (Lee and Bond 2015*a, b*), presumably due to pre- and post-fire logging within owl territories, as well as extensive high-severity fire in pre-fire clearcuts with young plantations.

Long-term occupancy monitoring without the confounding influence of post-fire logging is especially important to understanding fire effects on spotted owls. Hence, Bond *et al.* (2009) recommend that, if managers want to maintain spotted owl habitat after fire, they should prohibit post-fire logging and pesticide and herbicide applications within at least 1.5 km of historical spotted owl nest and roost sites. Even larger areas may be needed given that owl breeding-season home ranges can extend upwards of 700 ha (Bond *et al.* 2016), and some birds expand their range or migrate during the non-breeding season (Bond *et al.* 2010). Therefore, a reasonable protected area might be within 2.4 km of nest and roost sites, which corresponds to interim spotted owl management guidelines of the Forest Service's Pacific Southwest Research Station (http://www.fs.usda.gov/Internet/FSE_DOCUMENTS/fseprd504726.pdf).

Restoration of Degraded Forests

Land-use stressors that degrade or impair ecosystem processes are fundamentally at odds with ecosystem integrity approaches (Pimentel *et al.* 2000, USDA Forest Service 2012). Thus, restoration treatments can be used to reverse the causative agents of ecosystem degradation. One example is to limit human-set fires via: (1) seasonal closure and decommissioning of roads, or convert roads not considered essential in firefighting within the

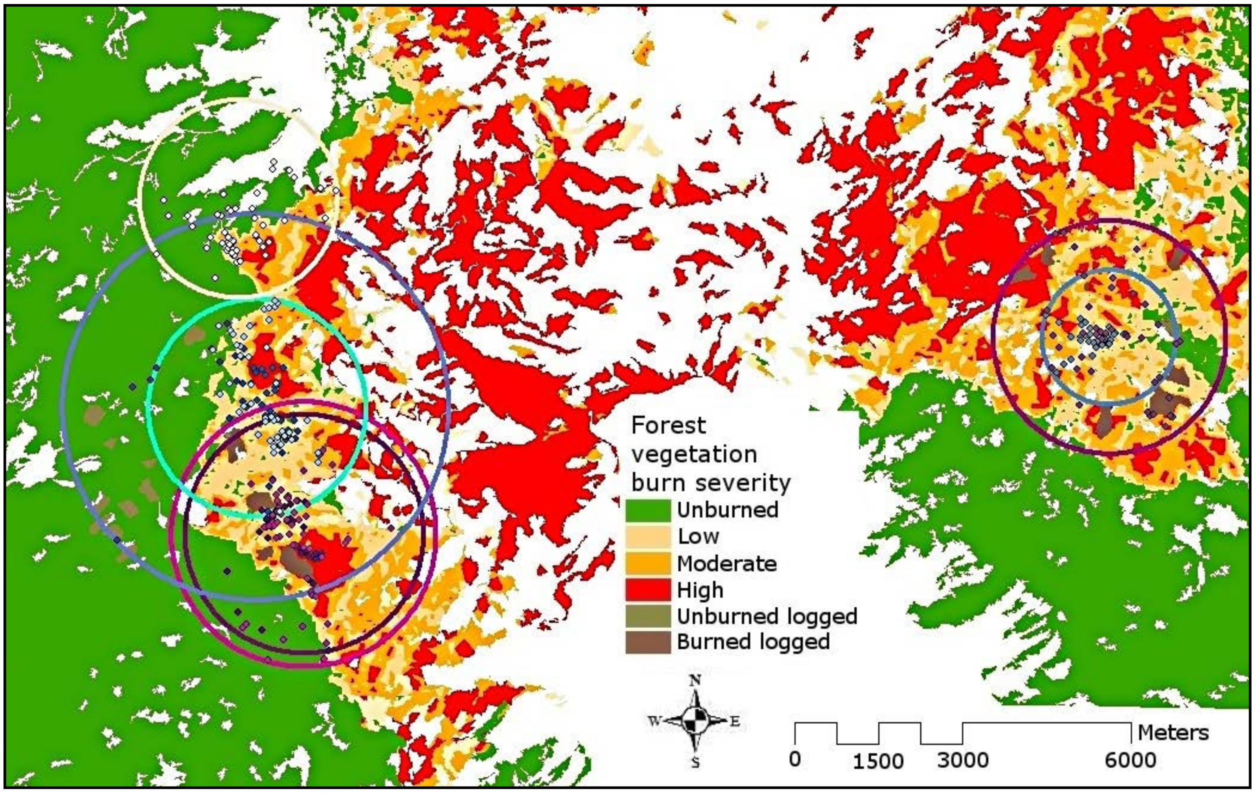

Figure 4. (A) Estimated foraging locations (obtained in 2006) of seven radio-marked California spotted owls in the 2002 McNally Fire, Sequoia National Forest, Sierra Nevada, USA. Different colored points represent each individual owl's estimated foraging location. Circles represent foraging ranges: each circle is centered on the nest with its radius extending to the farthest estimated foraging location for each individual owl. White areas are non-suitable for owls (e.g., foothill chaparral vegetation).

WUI to indefinitely closed; and (2) focused thinning and prescribed burning nearest homes, around campgrounds and other facilities, and along narrowly defined road prisms close to towns to avoid fire spread from anthropogenic ignitions. Managers could also concentrate thinning of small trees (shaded fuel breaks) along with prescribed burning nearest critical evacuation routes for communities with only one means of ingress or egress, redesign traveler stopping points along roads to avoid fire-prone settings, and concentrate visitation in fire-safe locations. Importantly, because tree plantations create unnaturally homogenized forests that lack complex structures, managers could integrate thinning with mixed-intensity prescribed burning, or naturally ignited fires, and create snags and downed logs to introduce structural complexity. Thinning small trees combined with prescribed fire (Kalies and Kent 2016) may reduce fire intensity in densely stocked tree plantations (Odion *et al.* 2004).

CONCLUSIONS

The 2012 Planning Rule provides the Forest Service with new direction for restoring and maintaining integrity and for managing focal species and species of conservation concern that can be integrated with fuels management approaches. The National Cohesive Wildland Fire Management Strategy (USDI and USDA 2014) allows managing wildfire for ecosystem benefits; hence, our findings can be applied to Department of Interior lands as well.

Figure 5. (A) General location of a California spotted owl nest territory in the 2002 McNally Fire (circle not to scale). Nest site was in a low-severity patch directly adjacent to high-severity patch (severity defined using Miller and Thode 2007). (B) Zoom-in (center snag) of general location of California spotted owl nest tree within McNally Fire burn patch shown in (A). Photos by M. Bond.

We suggest that managing for ecosystem integrity using both a coarse- and fine-filter approach centered on pyrodiverse fire effects can inform forest management in a biodiversity context. Our approach would have the added benefit of likely reducing suppression costs and some of the negative effects of mechanical vegetation removal over large areas (Dale 2006, Donovan and Brown 2008, Dunn and Bailey 2016). The complementary nature of conservation filters would allow managers to check burn severity maps with habitat associations of focal species to assess management efficacy.

Managers face substantial political and public pressure to suppress fires through the use of aggressive firefighting tactics, but such tactics do little to contain fires under extreme weather conditions (Lydersen *et al.* 2014, Moritz *et al.* 2014, Ingalsbee and Raja 2015, Carey *et al.* 2016). Instead, managers could be encouraged to use prescribed and naturally ignited fires that yield both cost savings and ecosystem benefits. Unfortunately, federal fire suppression budgets are dominated by suppression costs, causing siphoning of funds away from other essential programs (Ingalsbee and Raja 2015). To support managers in using more natural fire ignitions, conditions and certain trigger points could be more clearly defined and integrated with forest planning. This would allow flexibility to use several approaches to managing a fire, even on the same incident. Thus, in theory, a large fire could be managed in one area with general containment strategies that employ MIST (backcountry), while simultaneously in another area (near towns) with direct attack methods.

Accommodating mixed-severity fires for ecosystem benefits pertains to both ends of the fire continuum: large fires with high-severity effects that generate unique biological pulses (e.g., complex structures), and lower-severity systems that may have been homogenized through management and suppression. This suggests an important opportunity for expanding fire management beyond traditional kinds of prescribed burning to include prescriptions that benefit a broader suite of species associated with pyrodiverse landscapes (Moritz *et al.*

2014, DellaSala and Hanson 2015, Moritz and Knowles 2016). We note the conundrum of natural fire ignitions creating greater smoke emissions that may conflict with air quality objectives. Importantly, the Environmental Protection Agency (2016) recently revised policies to provide special regulatory exemptions and provisions that allow for more managed wildfires.

With proper planning and use of modern smoke management techniques, adverse effects of emissions on public health can be mitigated and fire restoration goals better accommodated. However, smoke emissions must be viewed as an unavoidable trade-off to be weighed against other potentially worse effects from attempted fire exclusion (that will eventually burn in a wildfire) or other chemical and mechanical methods for managing fuel loads that have ecosystem consequences.

There is clearly a need for research on whether natural fire ignitions can primarily provide desired mixed-severity fire effects. We suggest that studies are needed to determine the following.

(1) Specific locations and forest types best suited for mixed-severity fire effects, particularly in relation to ecological mechanisms by which pyrodiversity influences biodiversity.
(2) Current versus historical sizes and proportions of fire-severity patches and how those might be affected by climate change.
(3) Additional species that may be affected by suppression such as declining shrub-nesting birds associated with complex early-seral forests (Hanson 2014).
(4) Importance of other disturbance events (e.g., native insect outbreaks, drought) in maintaining ecosystem integrity.
(5) Effects of mechanical treatments before and after fire on the integrity and quality of mixed-severity patches including species of conservation concern and focal species.
(6) Kinds of education efforts required to implement this type of integrated disturbance ecology approach.
(7) Decision-support tools to help managers assess the costs and benefits of natural fire ignitions, along with conditions under which fires should be suppressed for human safety.

We argue that expanding natural fire ignitions for ecosystem benefits in combination with strategic use of defensible space, directed suppression, and active fuels management in appropriate areas provide untapped potential to enhance ecosystem integrity while protecting people and infrastructure with the potential for lower financial costs. Our approach is based on an ecological understanding of the importance of mixed-severity fires (DellaSala and Hanson 2015), and the need to reconsider "catastrophe" biases regarding natural disturbance processes (Lindenmayer *et al.* 2017).

ACKNOWLEDGEMENTS

We thank the editors and anonymous reviewers for making improvements to early drafts. Special thanks to C. Bradley (Center for Biological Diversity), J. Leonard (Geos Institute), and T. Sinnot (New England GreenInfo Network) for data analysis and map preparations. T his work was supported by a grant to D. DellaSala from Environment Now. R.L. Hutto thanks National Geographic Society, Glacier National Park, US Forest Service Rocky Mountain Research Station, and Joint Fire Science Program for supporting his fire research.

Tech. Rep. RMRS-GTR-310. Fort Collins, CO: U.S. Department of Agriculture, Forest Service, Rocky Mountain Research Station. 76 p.

Abstract

Ponderosa pine and dry mixed-conifer forests in the Southwest United States are experiencing, or have become increasingly susceptible to, large-scale severe wildfire, insect, and disease episodes resulting in altered plant and animal demographics, reduced productivity and biodiversity, and impaired ecosystem processes and functions. We present a management framework based on a synthesis of science on forest ecology and management, reference conditions, and lessons learned during implementations of our restoration framework. Our framework focuses on the restoration of key elements similar to the historical composition and structure of vegetation in these forests: (1) species composition; (2) groups of trees; (3) scattered individual trees; (4) grass-forb-shrub interspaces; (5) snags, logs, and woody debris; and (6) variation in the arrangements of these elements in space and time. Our framework informs management strategies that can improve the resiliency of frequent-fire forests and facilitate the resumption of characteristic ecosystem processes and functions by restoring the composition, structure, and spatial patterns of vegetation. We believe restoration of key compositional and structural elements on a per-site basis will restore resiliency of frequent-fire forests in the Southwest, and thereby position them to better resist, and adapt to, future disturbances and climates.

Keywords: dry-mixed conifer, ecosystem services, ecosystem processes and functions, frequent-fire forests, forest structure, ponderosa pine, restoration, species composition, spatial patterns

Authors

Richard T. Reynolds is Research Wildlife Biologist with the U.S. Department of Agriculture, Forest Service, Rocky Mountain Research Station, in Fort Collins, Colorado. He has investigated the relationship between the composition and structure of habitats and the demographic performance of apex avian predators in forested ecosystems for over 40 years. His recent research focuses on relationships between individual and population demographics of northern goshawks and the structure and composition of their habitats in ponderosa pine and dry mixed-conifer forests on the Kaibab Plateau, Arizona. He and his colleagues have written management recommendations for restoring the native biodiversity, food webs, and goshawk habitat in ponderosa pine and dry mixed-conifer forests. He received his B.S. degree in Life Science and M.S. degree and Ph.D. in Wildlife Ecology from Oregon State University.

Andrew J. Sánchez Meador is the Program Director of Biometrics and Forest Management with the Ecological Restoration Institute and Assistant Professor of Biostatistics and Quantitative Ecology in the School of Forestry at Northern Arizona University in Flagstaff, Arizona. Andrew's most recent research focused on: (1) quantifying how natural and anthropogenic disturbances shape forested ecosystems; (2) application of spatial statistics to characterize individual tree-, stand-, and landscape-scale patterns; (3) using state-transition-modeling to examine factors influencing treatment effectiveness and longevity; and (4) applications of remote sensing and computer vision techniques to quantify vegetation structure. He received his B.S. and M.S. degrees in Forestry from Mississippi State University and his Ph.D. in Forest Science from Northern Arizona University.

James A. Youtz is Regional Silviculturist with the U.S. Forest Service, Southwestern Region, in Albuquerque, New Mexico. He has been involved with the practice of silviculture and fire management in Southwestern forests since 1983. His program management responsibilities include training and certification of silviculturists in forest ecology and silvicultural practices and transfer of best available science to other managers to develop and incorporate strategies for ecological restoration of forest resiliency into program and project plans for National Forests in the Southwestern United States. He also has extensive experience serving with the U.S. Department of Interior in post-fire emergency stabilization and rehabilitation throughout the continental United States. He received a B.S. degree in Forest Management from Northern Arizona University.

Tessa Nicolet is the Regional Fire Ecologist with the U.S. Forest Service, Southwestern Region, in Payson, Arizona. She has been involved with fire ecology and fire management in the Southwestern Region since 2005. Her responsibilities include training, analysis, and transfer of best available science relating to fire and fuels management, fire ecology, fire regimes, fire analysis modeling, and restoring fire to fire adapted ecosystems for fire professionals across the Southwest. She received an M.F. degree in Forestry with emphasis in Fire Ecology from Northern Arizona University.

Megan S. Matonis is a Ph.D. student with the Graduate Degree Program in Ecology at Colorado State University. She is also a Graduate Student Cooperator with the Science Integration and Application program at the U.S. Forest Service, Rocky Mountain Research Station, in Fort Collins, Colorado. Her dissertation research focuses on collaborative landscape-scale restoration of ponderosa pine and dry mixed-conifer forests along the Colorado Front Range and Uncompahgre Plateau. She received a B.S. degree in Natural Resource Management from Colorado State University and an M.S. degree in Forestry from Michigan State University.

Patrick L. Jackson is Chief of Staff with the U.S. Forest Service, Southwestern Region, in Albuquerque, New Mexico. He led a Forest Service Team in the development of Desired Conditions for frequent-fire forests in the Southwestern United States that is being utilized in the Forest Plan Revision process. He also led the Regional Landscape-Scale Restoration efforts resulting in an ecological restoration strategy and program based on Desired Condition. He received a B.S. degree in Forestry and Range Management from Colorado State University and an M.S. degree in Watershed Management from the University of Arizona.

Donald G. DeLorenzo is Director of the Wildlife, Fish, and Rare Plant program with the U.S. Forest Service, Southwestern Region, in Albuquerque, New Mexico. Don has over 35 years of natural resource management experience with the U.S. Forest Service. He is a certified Wildlife Biologist and has held the positions of Research Associate at New Mexico State University and Assistant Professor at Oregon State University. He received a B.S. degree in Agriculture (Wildlife Science emphasis), and an M.S. degree in Wildlife Science from New Mexico State University.

Andrew D. Graves is a Forest Entomologist with the U.S. Forest Service, Forest Health, New Mexico Zone, Southwestern Region, in Albuquerque, New Mexico. He has worked in the forests of the upper Midwest, Alaska, and California primarily focusing on bark beetles in these systems. He has worked in the region as an Entomologist since 2010. His responsibilities include providing expertise for the Forest Health, Prevention, and Suppression Program; providing hazard tree training; and assisting public land managers with forest insect detection, identification, and disturbance mitigation. He received a B.S. degree in Forest Management and a Ph.D. in Forest Entomology from the University of Minnesota.

Executive Summary

Many forest landscapes in the Southwestern United States (Arizona, New Mexico, southwest Colorado, and southern Utah) have become increasingly susceptible to large-scale, severe wildfire, insect, and disease episodes. As a result, these areas are experiencing altered plant and animal demographics, reduced structural and spatial heterogeneity of vegetation, reduced productivity and biodiversity, and impaired ecosystem processes, functions, and services. Increased susceptibilities are most evident in frequent-fire forests—forests that historically experienced frequent, low-severity fire, which in the Southwest include ponderosa pine and dry mixed-conifer forests. Changes to these frequent-fire forests largely resulted from unregulated livestock grazing around the turn of the 20th Century, logging, and human activities such as fire suppression, resource use, and infrastructure development.

We present a management framework for improving the resistance and resiliency of frequent-fire forest ecosystems to severe disturbances. This is accomplished by restoring the characteristic vegetation composition and structure in these forests. Frequent-fire forests had a characteristic uneven-aged structure consisting of a temporally shifting mosaic of different aged tree groups and scattered individual trees in an open grass-forb-shrub matrix—a spatial and temporal pattern that provided and sustained plant and animal habitat adjacency, local biodiversity, and food webs. Hence, the key compositional and structural elements of our restoration framework are: (1) species composition (tree and understory vegetation); (2) groups of trees; (3) scattered individual trees; (4) open grass-forb-shrub interspaces between tree groups and individual trees; (5) snags, logs, and woody debris; and (6) variation in arrangements of these elements in space and time. Our framework is informed by:

- reference conditions (conditions of ecosystems before significant industrial human disturbance),
- natural ranges of variability (ranges of reference conditions for a specific ecosystem and time period),
- observed changes in disturbance regimes, and
- lessons learned during applications of our framework in frequent-fire forests in the Southwest.

The types, frequencies, and severities of disturbances (e.g., fires, insects, and diseases) played an important role in shaping the historical composition, structure, and function of frequent-fire forests. Therefore, where forest composition and its structure allow, the framework recommends that fire, the primary historical disturbance agent in these forests, play a prominent role in their restoration. The framework also emphasizes that mechanical treatments may be necessary to initiate suitable compositions and structures before reintroducing fire. Where use of fire is limited, mechanical treatments may be the only available tool to create and maintain restored forests. Conversely, fire may be the only tool in some areas. Restoration provides opportunities for the re-establishment of the characteristic disturbance regimes as well as the spatial and temporal links between pattern and process (e.g., the feedback relationship between forest structure and fire) that sustained the characteristic composition and structure of these forests. Implementation of our framework should improve overall ecosystem productivity and function and enhance ecosystem services such as soil productivity, biodiversity, wildlife habitat, clean air, water quality and quantity, wood products, and recreation.

Natural ranges of variability are considered a “best” estimate of a resilient and functioning ecosystem because they reflect the evolutionary and historical ecology of forests. Natural ranges of variability are thereby a powerful template for improving the resiliency of frequent-fire forests. Natural variability in the composition and structure across sites in these forests results from and drives spatial differences in fire effects, plant species compositions, tree establishment patterns and densities, and numbers and distribution of snags, logs, and woody debris. Managers are encouraged to recognize the natural variability in ponderosa pine and dry mixed-conifer forests and to use historical evidence, such as old trees, stumps, and logs, and biophysical site attributes (e.g., soils, slopes, aspects, and climate) to guide the restoration of variability in these forests. Studies of reference conditions in Southwestern ponderosa pine and dry mixed-conifer showed that trees occurred in a range of spatial patterns, most often aggregated but with a random distribution on certain soils. Tree groups were separated by open grass-forb-shrub interspaces of variable sizes and shapes that often contained scattered individual trees. In areas exhibiting strong tree aggregation, openness was typically higher, but on sites with less tree aggregation, openness may have been lower depending on the arrangement of trees, their sizes, and crown widths (Table 1). The distribution and abundance of snags and logs varied with site and likely coincided with the type, severity, and scale of historical disturbance (Table 1). While reference condition literature on the fine-scale (<10 acres) composition and structure in dry mixed-conifer is more limited than for ponderosa pine, studies showed many similarities—the consequence of their characteristic frequent, low-severity fire regimes. Nonetheless, ranges of reference conditions at small spatial scales showed that mean tree densities and basal areas were slightly greater in dry mixed-conifer forests than ponderosa pine, and snag and log abundances appeared similar to or slightly greater in dry mixed-conifer than in ponderosa pine forests. Compared to today's forests, characteristic dry mixed-conifer forests had higher proportions of fire-resistant/shade-intolerant tree species; lower tree densities; a more open structure comprised of higher proportions of large, old trees; and more spatial heterogeneity (groups and patches of trees).

To illustrate implementation of our framework, we describe a restoration treatment in a ponderosa pine stand in New Mexico that had experienced incidental tree cutting and no fire since the 1880s. While the stand had a characteristic component of old trees, there was a preponderance of mid-aged trees. Fire behavior modeling of pre-treatment conditions showed that 11 percent of the stand could support torching and active crown fire under dry conditions and moderate wind speeds. Our restoration treatment moved the composition and structure of the stand towards characteristic conditions—distinct tree groups, scattered single trees, and open interspaces between tree groups. Implementation of the framework resulted in predicted crown fire behavior on only 1 percent of the stand. Post-treatment abundance of logs and snags was lower than desired, but these elements will accumulate over time.

Our framework incorporates knowledge of the historical compositions, structures, functions, and processes in Southwest frequent-fire forests and how these operated through feedback mechanisms to sustain their characteristic compositions and structures. Current forest conditions are reviewed in light of historical conditions and how human-caused changes to these forests lowered their resistance and resilience to disturbance agents, which have become more intense and frequent. Our framework offers management recommendations for achieving the key compositional and structural elements for restoring frequent-fire forests. Once restored, these forests comprise a temporally shifting mosaic of groups of trees with interlocking crowns; scattered single trees; open grass-forb-shrub interspaces between tree groups; and dispersed snags, logs, and woody debris. It may not always be feasible or even desirable to restore exact reference compositions and structures. Instead, our framework's objective is to increase forest resiliency by managing forest composition and structure toward reference conditions. We believe restoration of key compositional and structural elements on a per-site basis will enhance the resiliency of frequent-fire forests in the Southwest, thereby positioning them to better adapt to future disturbances and climates. It is our intent that application of this framework be flexible and adaptive (i.e., learn-as-you-go), that it will evolve with accumulation of knowledge, and that its conceptual approach will provide a blueprint against which management plans and practices can be evaluated.

Table 1. Ranges of reference conditions for ponderosa pine and dry mixed-conifer forests in the Southwestern United States from studies detailed in Tables 3, 6, 7, and 9.

	Reference conditions by forest type	
Forest attribute	**Ponderosa pine**	**Dry mixed-conifer**
Trees / acre	11.7-124	20.9-99.4
Basal area (ft^2 / acre)	22.1-89.3	39.6-124
Openness (%)[a]	52-90	78.5-87.1
Openness on sites with strong tree aggregation (%)[a]	70-90	79-87
Spatial patterns	Grouped or random	Grouped or random
Number of trees / group	2-72	Insufficient data
Size of groups (acres)	0.003-0.72	Insufficient data
Number of groups / acre	6-7	Insufficient data
Snags / acre	1-10	≥ Ponderosa pine forests
Logs / acre	2-20	≥ Ponderosa pine forests

[a]Openness is the proportion of area not covered by tree crowns, estimated as the inverse of canopy cover. Openness data for dry mixed-conifer is limited; range of reference condition openness will likely change with additional studies.

Table 2. Characteristic fire regimes of Southwestern forest types. Fire frequency refers to the mean number of years between fires, and fire severity relates to the effect of the fire on dominant overstory vegetation. Infrequent-fire forests (wet mixed-conifer and spruce-fir) are included for comparison to frequent-fire forests.

Forest type (subtype)	Fire regime[a]		Fire type[b]	Forest structure	Seral species[c]	Climax species
	Fire frequency	Fire severity				
Ponderosa pine (all subtypes)	Regime I					
	0-35 years	Low	Surface	Uneven-aged, grouped, open	**Dominant:** ponderosa pine	**Dominant:** ponderosa pine Shade-intolerant species.
Dry mixed-conifer	Regime I (common)					
	0-35 years	Low	Surface	Uneven-aged, grouped, open	**Dominant:** ponderosa pine **Subdominant:** aspen, oak, Douglas-fir, Southwestern white pine, and limber pine	**Dominant:** ponderosa pine **Subdominant:** Douglas-fir and Southwestern white pine or limber pine Shade-intolerant species.
	Regime III (rare)					
	35-100+ years	Mixed	Mixed	Uneven-aged, patched, open		
Wet mixed-conifer	Regime III (common)					
	35-100+ years	Mixed	Mixed	Uneven-aged, patched, closed	**Dominant** (depending on plant association): aspen or Douglas-fir	**Dominant** (depending on plant association): white fir and/or blue spruce Shade-tolerant species.
	Regime IV (rare)					
	35-100+ years	High	Stand-replacing	Even-aged, closed		
Spruce-fir (mixed, lower subalpine)	Regime III and/or IV					
	35-100+ years	Mixed / High	Mixed/ stand-replacing	Even-aged, closed	**Dominant** (depending on plant association): aspen or Douglas-fir	**Dominant** (depending on plant association): Engelmann spruce and/or white fir Shade-tolerant species.
Spruce-fir (upper subalpine)	Regime V					
	200+ years	High	Stand-replacing	Even-aged, closed	**Dominant** (depending on plant association): aspen, Douglas-fir, or Engelmann spruce	**Dominant:** Engelmann spruce and corkbark fir or subalpine fir Shade-tolerant species.

[c]USDA Forest Service (1997)

Introduction

There is increasing recognition that frequent-fire forests, defined as forests with fire return intervals <35 years (Table 2), have become progressively more susceptible to large-scale, severe wildfire (Covington and Moore 1994b; Steele and others 1986; Westerling and others 2006). These forests, which in the Southwestern United States include ponderosa pine and dry mixed-conifer forests (see Appendix 1 for scientific names of species referred to herein), are also increasingly prone to insect and disease epidemics and altered plant and animal habitats, all leading to reduced biodiversity, ecological function, resilience, and sustainability (Allen and others 2002; Benayas and others 2009; Carey and others 1992; Carey and others 1999; Colgan and others 1999; Covington and Moore 1994a; Kalies and others 2012; Lynch and others 2010). Reduced ecosystem resilience to disturbances is more evident in frequent-fire forests where the composition, structure (age, size, density, and spatial patterns of vegetation), processes (e.g., disturbances), and functions (e.g., food webs) have changed to a greater degree due to reductions in fire frequency than in forest types where fire was historically less frequent (Agee 2003; Covington and Moore 1994a; Crist and others 2009; Hessburg and others 1999). This reduction in fire frequency is, in part, a result of more than a century of intensive human activities, including fire suppression, livestock grazing, and logging. Important compositional and structural changes in these forests resulting from human activities, especially those that changed historical fire regimes, include:

- increased tree densities,
- reduced structural and spatial heterogeneity of vegetation,
- declines in grass-forb-shrub vegetation,
- loss of old trees, and
- reductions in the diversity and quality of plant and animal habitats and food webs (Abella 2009; Arnold 1950; Covington and others 1997; Kalies and others 2012; Larson and Churchill 2012).

In addition to increasingly frequent and uncharacteristic disturbances such as large-scale severe fire events (Allen 2007; Covington and Moore 1994b; Fitzgerald 2005; Graham and others 2004; Swetnam and others 1999) and insect epidemics (Ferry and others 1995; Hessburg and others 2005; Kolb and others 1998; Negrón 1997), these changes resulted in environments that differed from those in which the native fauna and flora evolved (Carey 2003; Carey and others 1992, 1999; Colgan and others 1999; Covington and Moore 1994b; Kalies and others 2012; Reynolds and others 1992, 2006a). Furthermore, ecosystem services such as clean air and water, water yield, wood products, recreation, aesthetic and spiritual experiences, old-growth, nutrient cycling, pollination, and carbon sequestration have been altered and are now more vulnerable to rapid degradation by uncharacteristic fire and insect epidemics (Benayas and others 2009; Ferry and others 1995; Finkral and Evans 2008; Hessburg and others 2005; Kolb and others 1998; Negrón 1997; reviewed in Evans and others 2011 and Hunter and others 2007).

Prior to human-influenced changes to the characteristic fire regime, the composition, structure, and spatial pattern in frequent-fire forests were maintained by frequent, low-severity fire through a functional relationship between pattern and process; that is, frequent low-severity fires resulted in forest structures that facilitated continued low-severity fire (Fitzgerald 2005; Graham and others 2004; Hiers and others 2009; Mitchell and others 2009; Thaxton and Platt 2006). Over time, shifting mosaics of tree groups and individual trees of varying ages were maintained within a grass-forb-shrub matrix by relationships among the severity and frequency of fire, presence of surface fuels (fuels on or near the surface of the ground), and tree regeneration sites that escaped fire (Larson and Churchill 2012). Some dry mixed-conifer forests and ponderosa pine-shrub communities experienced mixed-severity fires, which included combinations of surface and crown fires (see Table 2), sometimes resulting in larger patches of tree aggregation (Agee 1993; Arno and others 1995; Kaufmann and others 2007; Larson and Churchill 2012).

Forest restoration guided by reference conditions (conditions that characterized the status of ecosystems before significant industrial human disturbance; *sensu* Kaufmann and others 1994) provides for the approximation of the historical (i.e., natural) effects of characteristic disturbances. Restoration is the process of assisting the recovery of degraded, damaged, or destroyed ecosystems (SER 2004). Restoration initiates or accelerates ecosystem recovery with respect to ecological health (productivity), integrity (species composition, community and ecosystem structure), and sustainability (resistance and resilience to disturbance)

(SER 2004). Ecosystem resiliency is the ability of an ecosystem to absorb and recover from disturbances without altering its inherent function (SER 2004). A functioning ecosystem provides opportunities for sustaining plant and animal habitats and populations, increased biodiversity, nutrient cycling, carbon sequestration, air quality, water quality and quantity, wood products, forage, recreation, and aesthetic and spiritual experiences (Aronson and others 2007; Benayas and others 2009). Restoring forest composition and structure improves ecosystem function and resiliency (Bradshaw 1984; Cortina and others 2006).

A holistic approach to forest restoration based on appropriate science can also help meet multiple management objectives, including fuels reduction; reintroduction of characteristic disturbances; and the return of wildlife habitats, native biodiversity, and food webs (Covington and Moore 1994b; Kalies and others 2012; Reynolds and others 1992, 2006a). Management informed by reference conditions and natural ranges of variability (the range of ecological and evolutionary conditions appropriate for an area; *sensu* Landres and others 1999) allow for the restoration of the characteristic composition, structure, spatial pattern, processes, and functions of ecosystems. Managing forests guided by historical conditions also restores the evolutionary environment (Kalies and others 2012; Moore and others 1999), enhancing the capacity of organisms in ecosystems to adapt to stressors such as fire, insects, disease, and climatic variability and change.

We describe a framework, including assumptions, principles, values, concepts, and procedures, for restoring the composition, structure, and spatial pattern of ponderosa pine and dry mixed-conifer forests in the Southwest. Our framework is a science-based approach to restoration that will prove useful for developing strategic plans and management applications. The framework emphasizes vegetation composition and structure, describes expected outcomes, and presents management recommendations for implementation. Expected outcomes include: increased biodiversity, plant and animal habitats, and ecosystem services; increased resilience to insects, disease, and climate change; and reduced fuel loads and fire hazards. Key compositional and structural elements of our restoration framework are:

(1) species composition (tree and understory vegetation);

(2) groups of trees;

(3) scattered individual trees;

(4) open grass-forb-shrub interspaces;

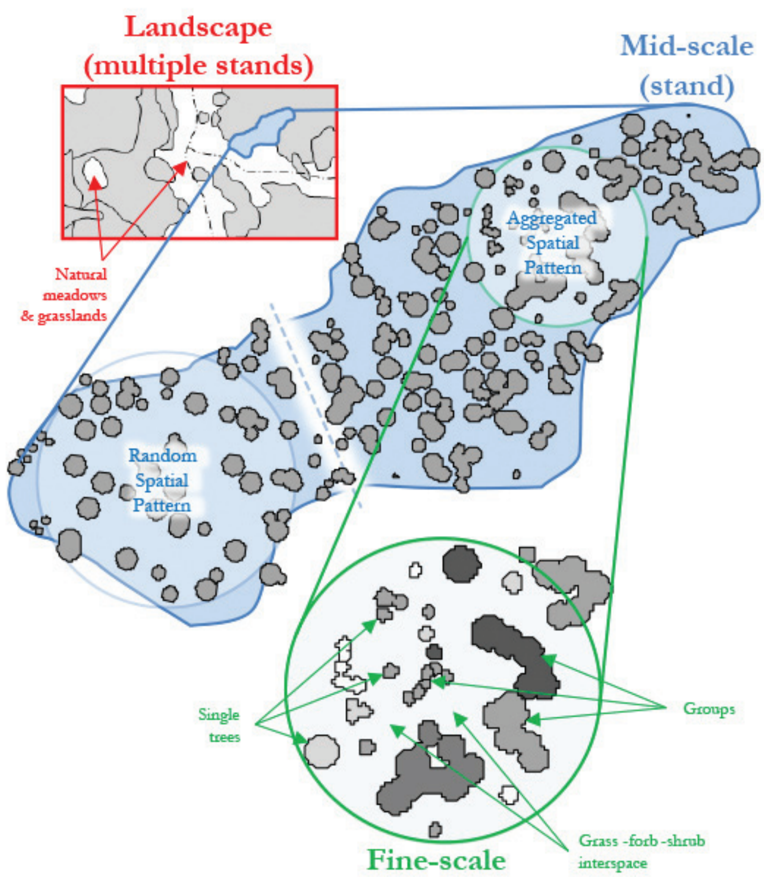

Figure 1. Characteristic vegetation patterns at three spatial scales for frequent-fire forests in the Southwest. The landscape-scale illustrates the importance of multiple stands (patches), meadows, and grasslands. The mid- and fine-scales illustrate grass-forb-shrub interspaces and uneven-aged stand conditions consisting of single, random, and grouped trees of different vegetation structural stages (from young to old) represented by different shades and sizes at the fine-scale. Also depicted are two different tree spatial patterns at the mid-scale (separated by the dashed line): trees are randomly spaced on the left side of the dashed line and are aggregated on the right (given the definition of stand as a homogenous area, both patterns could not actually be present).

(5) snags, logs, and woody debris; and

(6) variation in arrangements of these elements in space and time (Fig. 1).

Ecosystems are structured hierarchically and their composition, structure, processes, and functions are temporally and spatially dynamic. Therefore, we characterize the key compositional and structural elements at three spatial scales: fine (<10 acres), mid (10-1000 acres), and landscape (1000-10,000+ acres) (Fig. 1). These scales generally correspond with structural features in frequent-fire forests. The fine scale is an area in which the species composition—age, structure, and spatial distribution of trees (single and grouped)—and grass-forb-shrub interspaces are expressed. Aggregates of fine-scale units comprise mid-scale patches or stands, which are relatively homogeneous in vegetation composition and structure. The landscape scale is composed of aggregates of mid-scale units and usually has variable elevations, slopes, aspects, soil types, plant associations, disturbance processes, and land uses. Understanding and incorporating temporal scales (e.g., seasonal, annual, decadal, and centuries) in a restoration framework is required to sustain vegetation dynamics of forests that result from growth, succession, senescence, and the historical and anthropogenic disturbances that periodically reset the dynamics.

Management recommendations for implementing our framework are tempered by our management and research experience in frequent-fire forests, as well as by lessons learned during implementations of the framework in the Southwest. The intent of our framework is to inform management strategies that will facilitate the resumption of historical processes and functions. Managing for the framework's key elements should increase the resilience of the forests and facilitate opportunities for the resumption of characteristic function and disturbance regimes. The spatial and temporal aspects of these elements reflect the reciprocal interactions between pattern and process in these forests and are an ecological basis (Turner 1989) for incorporating spatial information in forest restoration (Larson and Churchill 2012).

Mechanisms Influencing Forest Composition

Plant species composition of a forest ecosystem is influenced by both deterministic and stochastic factors, including complex interactions among species' life histories, disturbance regimes, and chance events. The establishment, growth, and survival of under- and over-story species are affected by competition for space, light, nutrients, and moisture. For example, tree regeneration and growth is affected by species-specific shade tolerance (Fig. 2); open stand conditions favor the regeneration of shade-intolerant species while closed stands favor shade-tolerant species (Langsaeter 1944; Long 1985; USDA Forest Service 1990). Biophysical conditions, such as soils, temperature, and moisture regimes, also influence the establishment, development, and abundance of under- and over-story plant species. Disturbances (e.g., fire, insects, pathogens, drought, and wind) often interact with biophysical site characteristics to further influence composition and structure of forest ecosystems. Such disturbances have variable temporal and spatial effects on vegetation depending on their type, frequency, intensity, seasonality, and spatial scale, which collectively define a characteristic disturbance regime of an ecosystem. Species in a forest ecosystem evolved under its characteristic disturbance regime, resulting in a natural range of variability or the range of ecological and evolutionary conditions appropriate to an ecosystem (Landres and others 1999).

Fire is the primary disturbance agent in many Southwestern forests, and fire regimes are central to understanding an ecosystem's reference conditions and natural range of variability (Fig. 3; Table 2) (Fulé and others 2003). The species composition, as well as the structure and spatial pattern of vegetation in Southwestern frequent-fire forests developed in a feedback relationship with fire. Ponderosa pine and dry mixed-conifer forests are characterized by a frequent low-severity fire regime (Swetnam and Baisan 1996; Swetnam and Betancourt 1990) with historic mean fire return intervals ranging from 2-24 years (Brown and others 2001; Brown and Wu 2005; Evans and others 2011; Hunter and others 2007; Swetnam and Baisan 1996). Frequent low-severity fire favors shade intolerant and fire-resistant tree species (Fig. 2) and open forest conditions with discontinuous crowns and minimal fuels build-up, often with tree groups separated by open interspaces with grass-forb-shrub communities. In contrast, longer fire return intervals permit seedling development to larger, more fire-resistant tree sizes and favor survival of less fire-resistant species (Fig. 2) (Fulé and Laughlin 2007; Laacke 1990; Taylor and Skinner 2003).

Endemic forest insects and pathogens are important disturbance agents that do not threaten long-term

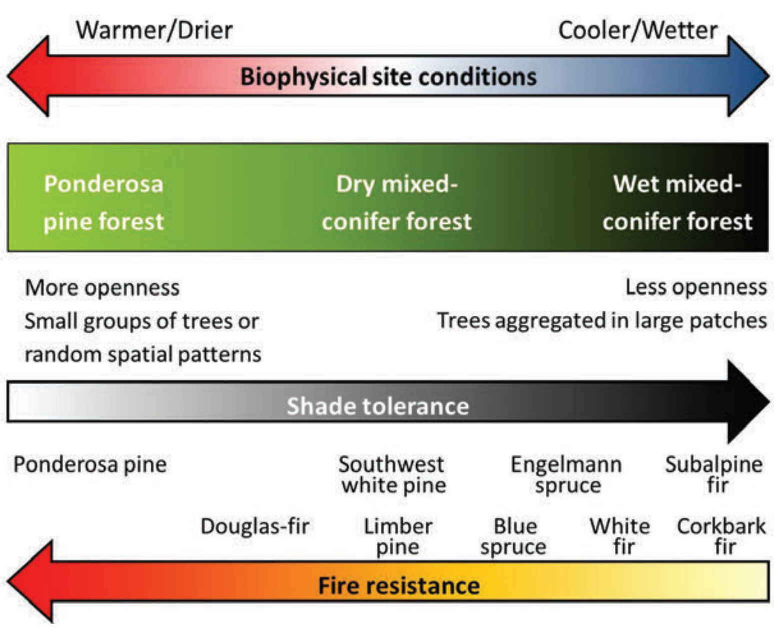

Figure 2. Dry mixed-conifer forests occupy the ecological gradient from warm/dry to cool/wet biophysical site conditions. Dry mixed-conifer is not a homogenous type, intergrading with ponderosa pine forest on warm/dry sites and wet mixed-conifer forests on cool/wet sites. Its structure and composition become more similar as it intergrades with adjacent forest. Common tree species in ponderosa pine and mixed-conifer forests also vary in their relative shade and fire tolerance.

Figure 3. Prescribed, low-severity surface fire carried by needles, cones, dried grass, and forbs on the Lincoln National Forest, 2010.

stability and productivity of forests under endemic conditions due to moderation by millions of years of evolution (Goheen and Hansen 1993). When large or uncharacteristic insect and disease outbreaks occur, profound changes to the composition, structure, processes, and functions of forests often take place. Insects and diseases affect nearly all aspects of forest stand dynamics, from seed viability to seedling survival, from bud, shoot, and leaf production to growth and maintenance, and, ultimately, the survival and distribution of mature trees (Castello and others 1995; Tainter and Baker 1996). Bark beetles, in particular, are considered primary sources of mortality in Southwestern ponderosa pine forests. In 2011 alone, bark beetles caused varying rates of ponderosa pine mortality on more than 144,000 acres in Arizona and New Mexico (USDA Forest Service 2012). Unlike bark beetles in ponderosa pine, the primary sources of mortality attributed to insects in mixed-conifer forests are typically defoliating insects. Damage from defoliators can range from large areas of widespread growth losses and infrequent mortality, as with the spruce budworm, to more localized, high levels of mortality caused by the Douglas-fir tussock moth (Wickman 1963).

While numerous species of dwarf mistletoe occur in frequent-fire forests, Southwestern (ponderosa pine) dwarf mistletoe and Douglas-fir dwarf mistletoe are the most prevalent. Dwarf mistletoes may be the most damaging of pathogens in Southwest forests with estimates of current infection being 30 percent or greater in ponderosa pine forests (Andrews and Daniels 1960; Maffei and Beatty 1988) and around 50 percent in mixed-conifer forests (Conklin and Fairweather 2010; Drummond 1982). Additionally, the presence and intensity of Southwestern dwarf mistletoe infection in ponderosa pine stands has been implicated as a source of mortality or as an exacerbating factor in bark beetle outbreaks (Negrón 1997; Stevens and Hawksworth 1984). Endemic soil fungi that cause root disease (e.g., armillaria and black-stain root diseases) also influence forest composition and structure (Rippy and others 2005). Root diseases are known to affect the ponderosa pine forests of the Southwest, with observations of mortality associated with root disease, mistletoe, and bark beetles as high as 25 percent (Wood 1983). In some locations, conifers killed by root disease are replaced by less susceptible conifers, hardwood species, or grass-forb-shrub interspaces. In the case of armillaria and related wood decay fungi, this shift in species composition can be maintained for decades due to remnant fungi in stumps and root systems (Roth and others 1980). In most situations, native root diseases do not cause irreplaceable loss of entire stands over large areas, nor do they threaten the existence of any host species. However, shifts in stand composition and other natural and human-caused disturbances have frequently resulted in increased damage from root diseases (Edmonds and others 2000).

Mechanisms Influencing Forest Structure

Frequent-fire forests typically comprise a mosaic pattern of groups of trees, scattered single trees, grass-forb-shrub interspaces, snags, logs, and woody debris (Cooper 1960; Larson and Churchill 2012; Pearson 1950; White 1985). Structural heterogeneity

Table 3. Historical spatial patterns and tree group characteristics in frequent-fire forests of the Southwest, arranged by forest type (PP: ponderosa pine, PO: pine-oak, DMC: dry mixed-conifer).

[a]Values should be not interpreted as "strict" densities of trees within groups as authors used different definitions and methods to define and characterize "groups." We suspect that as the number of species and site productivity increase the metric of "tree group" becomes less useful than this metric at the mid- to landscape-scale. For example, when tree density is fixed and numbers of tree species varies (i.e., compare ponderosa pine vs. ponderosa-pine Gambel oak vs. dry-mixed conifer forests), the area available to a "tree group" will likely decrease.

[b]Data based on 2.47-acre plots reconstructed prior to Euro-American settlement (1876-1890) in Arizona (n = 17 plots) and New Mexico (n = 7 plots) using the same methods as Sánchez Meador and others (2010, 2011). Historical and contemporary field methods, as well as contemporary conditions, are detailed in Sánchez Meador and others (2010) and Moore and others (2004) who reported forest structural reference conditions (size distributions, tree density ranges, spatial patterns, etc.) on a subset of these same plots. In brief, all live and dead tree structures were measured, including stumps, snags, and wind-fallen trees, that grew to at least breast height (4.5 ft). All tree structures were located using historical stem-maps and measured spatial coordinates, and dendrochronological reconstructions were used to quantify structural and spatial reference conditions (Baker and others 2008; Sánchez Meador and others 2010). Spatial attributes (e.g., group size and density) were quantified using methods described in Sánchez Meador and others (2011).

Figure 4. A group of ponderosa pine trees comprised of two clumps of trees.

in these forests is a consequence of interactions among biophysical site conditions (e.g., topography, soils, climate); disturbance types, frequencies, intensities, and extent; levels of competition among species; and tree demographic rates. Variability in biophysical site conditions is a primary source of spatial and temporal variation in vegetation structure. Of studies that investigated the origin, distribution, and mortality of ponderosa pine forests, most reported uneven-aged reference conditions at the stand scale (Sánchez Meador and others 2010), but three different within-group age structures were identified. Cooper (1960) reported relatively even-aged tree groups, White (1985) and Abella (2008) reported groups of multi-aged trees, and Sánchez Meador and others (unpublished data; see Table 3 footnote) found mixtures of both types. Variation of tree ages within groups likely reflects the establishment and growth of a single, grouped cohort of trees and perhaps seedling establishment and growth of trees under, or adjacent to, tree groups (see Spatial Patterns: Formation and Maintenance) (Sánchez Meador and others 2009).

Heterogeneity of within-group tree sizes can generate from processes related to growth, competition, and disturbances and may result in a range of tree sizes irrespective of age (Mast and Veblen 1999; Pearson 1950; Sánchez Meador and others 2011; Taylor 2010; Woodall 2000). Trees on the perimeter of groups tend to have higher growth rates, attain larger sizes, lean away from the group center, and have asymmetrical crowns with larger lower limbs than interior trees (Pearson 1950). Heterogeneity in tree sizes and spacing within groups may decline over time due to mortality resulting in a gradual transition from dense to more uniform spacing of trees (Cooper 1961; Mast and Veblen 1999; Mast and Wolf 2004, 2006; Pielou 1960). However, tight clumps of trees sharing the same root ball often persist within groups (Fig. 4) (Larson and Churchill 2012). Mortality over time may also gradually reduce within-group tree density, resulting in increased variation in tree densities and ages within and among groups.

Like composition, the structure of forest vegetation is also affected by disturbances such as fire, insects, disease, wind, and drought (Brown and others 2001; Ehle and Baker 2003; Mast and others 1998, 1999). Numerous abiotic and biotic disturbances affect the composition, amount, arrangement, spatial continuity, and volatility of surface and canopy fuels (Franklin and others 2012), which in turn effects fire behavior (Van Wagner 1977). Dense forest structures can facilitate crown fire by providing a potential path for fire through tree crowns (Cruz and others 2003; Fulé and others 2001; Graham and others 2004; Stratton 2004; Van Wagner 1977, 1993). Forest density further influences surface and canopy fuels through interactions with insects and diseases. The effects of bark beetles in ponderosa pine stands are more pronounced during and following extended droughts and under dense stand conditions; both of which are conducive to the survival and reproduction of beetle populations. Negrón (1997) showed a link between roundheaded pine beetle attacks and higher densities of smaller, pole-sized trees in relatively homogenous stands of ponderosa pine in the Sacramento Mountains of New Mexico. Additionally, trees with heavy mistletoe infection are more susceptible to severe crown scorch and death from fires (Harrington and Hawksworth 1990; Hoffman and others 2007). Hawksworth and Wiens (1996) suggested that mistletoes have been important species in frequent-fire forests since fire first appeared on these landscapes.

The density and arrangement of forest canopies affects the penetration of sunlight, precipitation, humidity, and wind. In fact, dense forest structures can maintain relatively high fuel moistures and ameliorate wind effects. Forest canopies also influence the composition and abundance of surface fuels, which are essential to facilitate fire as a disturbance agent. Surface fuels also offer nutrients to soils, help reduce erosion, and influence understory vegetation productivity, density, and diversity (Kalies and others 2012; Kerns and others 2003; Moore and others 1999). In general, more fuel accumulates and persists in forests with longer fire return intervals than in those with more frequent surface fire (Brewer 2008; Minnich and others 2000). Fine fuels (grass, needles, cones, and woody material less than 0.25 inches in diameter) and small branches accumulate more rapidly under tree groups than in interspaces between tree groups (Fig. 5). This accumulation facilitates fire, in turn restricting the establishment and persistence of trees and shrubs under tree groups. The amount and composition of surface fuels interact with weather conditions to influence fire behavior. Herbaceous fuels respond quickly to relative humidity and thus carry fire less readily when humidity is high, whereas pine needles will readily carry fire under these conditions (see moisture of extinction in Anderson 1982; Scott and Burgan 2005). Furthermore, needle and twig litter will burn with higher intensity than herbaceous fuel under similar weather conditions.

Forest structure affects the distribution, density, and composition of surface and canopy fuels, which affects the behavior of fire and, ultimately, post-fire forest structure. Historically, seedling establishment was more frequent in fire-created areas of bare mineral soil where competition with other vegetation and the abundance of surface fuels were reduced (Agee 1993; Cooper 1960; Stephens and others 2008). However, regeneration is less affected by the availability of bare mineral soil in some plant associations and soil types (Hanks and others 1983; USDA Forest Service 1997). A study in the Southwest showed a high density of tree regeneration on sites with one or more of the following: fine-textured soils, understories where screwleaf muhly was the dominant graminoid, and sites with high annual precipitation (Puhlick and others 2012). Depending on seed availability, some individuals and small groups of seedlings may establish throughout the stand, including under

Figure 5. (a) Fine fuels (grasses, forbs, needles, branches, cones) beneath the crown of an individual tree and **(b)** under the canopy of a tree group.

Figure 6. A group of ponderosa pine saplings in a grass-forb interspace between mature tree groups that experienced faster growth and survived a prescribed fire. Shade-suppressed saplings in heavier fine fuel loadings under a mature group of pine did not survive the fire.

tree groups (Abella 2008; Sánchez Meador and others 2009; White 1985).

Tree seedlings that established in small forest openings are subsequently thinned by later fires and/or other sources of mortality (Fig. 6) (Cooper 1960, 1961; Sánchez Meador and others 2010; Stephens and Fry 2005; White 1985). Young tree groups in open areas reach fire-resistant sizes more rapidly than those beneath closed canopies (Fitzgerald 2005; Sackett and Hasse 1998; York and others 2004). Fire-caused thinning of young tree groups was more substantial if the group was overtopped by older trees due to suppressed seedling growth and increased litter accumulation (Agee 1993; Cooper 1960). Fire-spread through young tree groups may also be influenced by microclimate and fuel moisture in these groups (Harrington 1982). As trees grow, increasing needle and twig accumulations facilitate the spread of surface fire. Seedlings that establish some distance away from mature older trees are also more likely to survive fires due to less rapid accumulation of fine fuels and small branches from overstory trees (Fig. 5, 6), likely leading to less intense and severe fire (Cooper 1960) and variable spacing of tree groups. The seasonality and burning conditions of fire occurrence also result in variable outcomes.

Spatial Patterns: Formation and Maintenance

Spatial patterns of vegetation are a component of forest structure. The historical spatial mosaic of tree groups, scattered individual trees, and openings in frequent-fire forests was maintained by interactions among the locations and types of fuels, the frequency and severity of fire, and tree regeneration and mortality patterns. A landscape mosaic of tree groups and scattered individual trees within an open grass-forb-shrub matrix, along with snags, logs, and woody debris, provides for the predominance of surface fire mixed with small-scale, variable fire behavior (e.g., torching). An open or grouped spatial structure reduces canopy continuity, decreasing a stand's vulnerability to active crown fire (Fitzgerald 2005; Fulé and others 2004; Roccaforte and others 2008; Stephens and others 2009). These interactions were mediated by small-scale variability in fire behavior and effects and often resulted in sites with aggregated tree regeneration that were temporarily "free" or "safe" from fire (Larson and Churchill 2012). The location of some safe-sites for tree regeneration appeared to be related to local areas of previously more intense fire associated with accumulations of coarse woody debris (logs and other dead woody material greater than 3 inches in diameter) originating from the death of individual trees (Sánchez Meador and Moore 2010; West 1969; White 1985) or tree groups (Cooper 1960; Stephens and Fry 2005; Taylor 2010; West 1969). Death of individuals or groups of old trees create new snags and logs that, when consumed by fire, result in "safe" sites for tree regeneration. Extended fire-free periods may allow tree regeneration in areas not typically fire "safe" (Fig. 7) (Fulé and others 2009), resulting in temporal shifting of tree locations where new cohorts develop to fire-resistant sizes. The cyclic repetition of forest vegetation dynamics stemming from disturbances and tree regeneration perpetuates a shifting mosaic of tree groups and individual trees in different stages of development in a grass-forb-shrub matrix (Fig. 8).

Figure 7. Ponderosa pine regeneration under a group of snags. This site is not currently fire "safe" due to the accumulation of surface fuels over an extended fire-free period. In the absence of fire, these seedlings could grow to fire-resistant sizes. If fire occurs prior to the trees attaining fire-resistant size, the seedlings would likely not survive. However, the reduction of surface fuels post-fire may create a temporary fire-safe site for future regeneration.

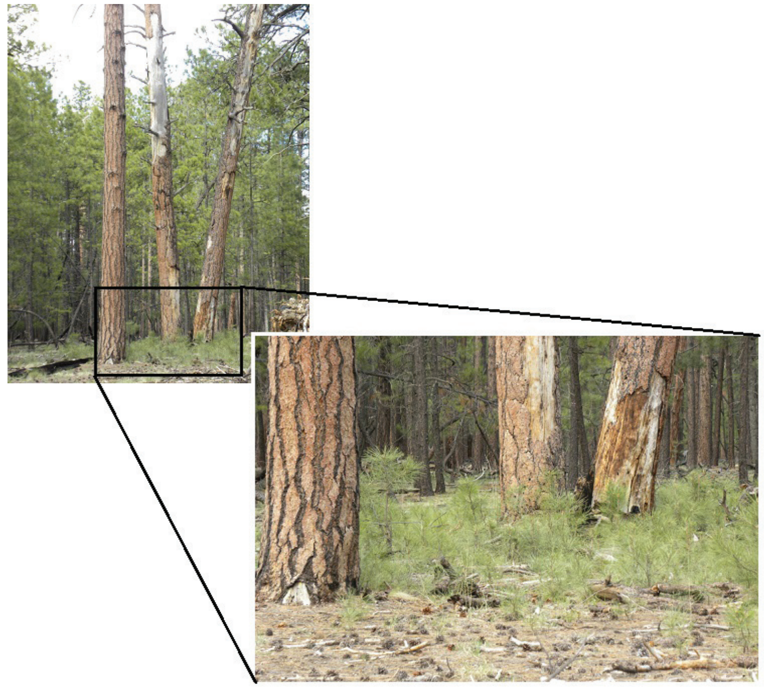

Figure 8. Tree groups and a single individual tree on the right in a grass-forb-shrub interspace.

Insects and diseases also shape spatial patterns of forested landscapes. Due to the slow spread of infection, it has been suggested that the current distribution of mistletoe throughout the Southwest is likely similar to its historical distribution, although spatial continuity and levels of infection may have changed (Conklin and Fairweather 2010). Under historical forest conditions, it is likely that large-scale, contiguous insect and disease outbreaks would have been rare. It is more likely that mistletoe would have thrived in denser multistoried portions of stands that escaped fire pruning and thinning (see Conklin and Geils 2008 for additional discussion). In such portions, periodic tree deaths would have occurred directly from mistletoe, or infected trees would have had increased the likelyhood of succumbing to bark beetles or root disease. Localized mistletoe infections would have created pockets of tree death that could eventually serve as regeneration sites. In cases where regeneration occurred in larger openings between trees, trees may have escaped mistletoe infection altogether. Other scenarios can be envisioned. For instance, in cases of stands with relatively homogenous age and spacing, bark beetles may have had periodic population increases, causing high rates of local mortality. Localized beetle outbreaks likely occurred in stands with severe crown damage following fire (Breece and others 2008), and these infestations may have spilled over into undamaged trees nearby, creating larger openings. Root diseases also create scattered mortality, small openings, and increased volume of snags and downed large woody debris (Rippy and others 2005).

An understanding of forest processes and their effects at different spatial scales is important because landscapes are spatially dependent (Turner 1989). Inferences about patterns and processes in forests are contingent upon the scale at which they are investigated. For example, a fine-scale model for ponderosa pine regeneration showed that the majority of the variance (76 percent) in seedling density was explained by properties such as soil texture and pH, precipitation, seed tree proximity, and composition of the plant community (Puhlick and others 2012). However, at the mid- to landscape-scale, models including abiotic conditions and tree density at this broader scale accounted for less of the variability in observed seedling densities (only 13 percent) (Puhlick and others 2012). Fire further shapes tree spatial patterns at varying scales through its influence on seedling survival, with variability in the severity, seasonality, and frequency of fire (Cooper 1960; Pearson 1950; Stephens and Fry 2005; Taylor 2010; West 1969; White 1985). An overall aggregated (grouped) historical tree pattern separated by openings has been frequently reported in Southwestern frequent-fire forests (Fig. 8) (Larson and Churchill 2012). However, Abella (2008), Binkley and others (2008), and Sánchez Meador and others (unpublished data, see Table 3 footnote) observed grouped and random (no aggregation) historical tree spatial patterns (Fig. 9). Schneider (2012) observed only random historical tree spatial patterns in Southwestern ponderosa pine.

Spatial heterogeneity can exist at any scale, and the value of metrics used to assess forest conditions varies in usefulness with scale. At mid- and landscape scales, elements such as single tree and group density become less useful as a metric and elements such as patches, the grass-forb-shrub matrix, stand density, canopy cover, and basal area become more appropriate. Patches are roughly synonymous with stands, being defined as an area of relatively homogeneous vegetation composition and structure differing from its surroundings (Forman 1995). Patches are the basic unit of the landscape, and their sources of variability are attributed to scale-appropriate factors such as elevation, topography, climate, and land use. Our restoration framework describes forest composition, structure, and spatial patterns at fine-, mid-, and landscape-scales (Fig. 1).

Figure 9. Random (i.e., not aggregated) distribution of ponderosa pine trees in a patch of old trees. Also displayed are snags, logs, and coarse woody debris.

Southwestern Frequent-Fire Forests

The natural range of variability is a "best" estimate of a resilient and functioning ecosystem because it reflects the evolutionary ecology of these forests. Natural range of variability is therefore a powerful science-based foundation for developing a framework for restoring the composition and structure of forests (Kaufmann and others 1994; Keane and others 2009; Moore and others 1999). The natural range of variability can be estimated by pooling reference conditions across sites within a forest type. Reference conditions for a forest type typically vary from site to site due to differences in factors such as soil, elevation, slope, aspect, and micro-climate and manifests as differences in fire effects, tree densities, patterns of tree establishment and persistence, and numbers and dispersion of snags and logs. When pooled, these sources of variability comprise the natural range of variability of a site or forest type.

Our estimates of natural ranges of variability are derived from multiple lines of evidence based on historical ecology techniques (Egan and Howell 2001) such as written and oral historical records, historical photographs, early forest inventories, and dendrochronological studies (Table 4). While cultural accounts and early inventories provide a general context of historical conditions, they do not fully characterize forest structure by today's statistical standards. More recently, dendrochronological techniques for quantifying historical conditions, including spatial and temporal variation, have been developed (e.g., Covington and Moore 1994a; Covington and others 1997; Fulé and others 1997; Mast and others 1999; Sánchez Meador and others 2010; White 1985). Nonetheless, there is a clear need for additional reference condition data sets, including sites from a wider spectrum across environmental gradients (e.g., soils, moisture, elevations, slopes, aspects) occupied by frequent-fire forests in the Southwest, especially in dry mixed-conifer. While the quantity of reference data sets is increasing, existing data represent a largely unbalanced sampling across gradients (e.g., most data sets are from basaltic soils and on dry to typic plant associations), and there have been few studies quantitatively examining and reporting spatial patterns of trees and the sizes and shapes of grass-forb-shrub interspaces.

Ponderosa Pine

Woolsey (1911) described Southwestern ponderosa pine forests as having "…pure park-like stand(s) made up of scattered groups of 2-20 trees, usually connected by scattering individuals. Openings are frequent and vary in size. Because of the open character of the stand and the fire-resisting bark, often 3 inches thick, the actual loss in yellow (ponderosa) pine by fire is less than with other more gregarious species." Others also described historical ponderosa pine forests as having low density, open stands consisting of groups of pine trees interspersed with grassy or shrubby openings (Dutton 1882; Lang and Stewart 1910; Pearson 1923; White 1985).

Tree density, structure, spatial pattern, and ecological functions in today's ponderosa pine forests of the Southwest are greatly altered from their historical conditions. Most Southwest ponderosa pine forests are at much greater risk of high-intensity, severe fire than they were prior to Euro-American settlement (Covington 1993; Fulé and others 2004; Moore and others 1999; Roccaforte and others 2008). Historical ponderosa pine forests had widely spaced, large trees, typically occurring in small groups with scattered single trees, and open forest conditions with a productive grass-forb-shrub understory (Cooper 1960; Dutton 1882; Lang and Stewart 1910; Pearson 1923, 1950; Sánchez Meador and others 2009, 2011; White 1985). The grass-forb-shrub vegetation and other fine fuels and branches carried fires started by lightning and, to an uncertain extent, by Native Americans (Allen and others 2002; Kaye and Swetnam 1999). Forest composition, structure, and spatial patterns were maintained by low-severity surface fires that occurred every 2-26 years (Fig. 3), rarely killing large trees, thinning regeneration, and maintaining an open forest structure (Dieterich 1980; Fiedler and others 1996; Fitzgerald 2005; Pearson 1950; Swetnam and Dieterich 1985; Weaver 1951; Woolsey 1911). Fire chronologies in Western U.S. frequent-fire forests are

reviewed in Evans and others (2011), Hunter and others (2007), Smith (2006b), and Swetnam and Baisan (1996).

Bark beetles also influenced pre-Euro-American ponderosa pine structure. Various sources indicate that bark beetle outbreaks occurred periodically in the Western United States since at least the 1750s (Bentz and others 2009) and likely much longer. Current forested landscapes are experiencing outbreaks that are larger and more frequent than previously recorded (Lynch and others 2010). For example, bark beetles caused variable amounts of mortality on more than 700,000 acres in Arizona and New Mexico in 2003 (Fettig and others 2007; USDA Forest Service 2004). Although there is no direct evidence linking the effects of bark beetles to the structure of pre-Euro-American frequent-fire forests, evidence from today's beetle population dynamics suggests that homogenous, dense, even-aged stands are highly susceptible to beetle outbreaks (Fettig and others 2007; Negrón 1997). However, historical observations suggest that high-density, even-aged stand structures were infrequent or rare in frequent-fire forests (Woolsey 1911; reviewed in Covington and Moore 1994a, 1994b). Alternatively, spatial heterogeneity would have been promoted and maintained at the fine scale by bark beetle attacks on single or small groups of trees, or perhaps in high density groups or patches, which would have created growing space for regeneration or surviving trees (Fettig 2012; Lundquist 1995; Von Schrenck 1903). During droughts, it was likely that many more trees would have succumbed to bark beetles (Bentz and others 2010; Negrón and others 2009). Bark beetles evolved under the range of natural variability where there would have been sufficient hosts (e.g., fire-stressed, lightning struck, and broken top trees) to maintain endemic beetle populations (reviewed in Jenkins and others 2008 and Moeck and others 1981).

Ponderosa Pine: Species Composition: Ponderosa pine is the dominant seral and climax tree species in Southwest ponderosa pine forests. Depending on locale, ponderosa pine forests may also have a mix of Gamble oak, evergreen oaks, junipers, pinyon pines (DeVelice and others 1986), with occasional presence of quaking aspen, New Mexico locust, Douglas-fir, or southwestern white pine. Ponderosa pine is one of the most fire-adapted conifer species in the West, and its resistance to surface fire increases as trees age (Miller 2000).

Composition of the grass-forb-shrub community in ponderosa pine forests is typically diverse, especially in open interspaces between trees (e.g., Fig. 8) (Abella and others 2011; Laughlin and others 2006; Moir 1966; Naumburg and DeWald 1999). Ponderosa pine plant associations (classified by understory plant assemblages, plant succession, and co-dominant tree species) are variable and are reflective of local biophysical site and climate conditions that both influence the type of disturbances and vegetation responses to disturbances (Table 5) (USDA Forest Service 1997). Southwestern ponderosa pine plant associations range from pure ponderosa pine to mixed tree species overstories with understories ranging from bunchgrass/forb to shrub-dominated types, and these can be broadly grouped into four forest subtypes: (1) ponderosa pine-bunchgrass, (2) ponderosa pine-Gambel oak, (3) ponderosa pine-evergreen oak, and (4) ponderosa pine-shrub (Appendix 2). The most mesic sites are the ponderosa pine-Gambel oak and some ponderosa pine-bunchgrass plant associations; the most xeric sites are the ponderosa pine-evergreen oak and some ponderosa pine-shrub plant associations. Bunchgrass plant associations generally occupy the mid-range of the moisture gradient for ponderosa pine forests in the Southwest.

Understory composition includes various combinations of grasses, forbs, shrubs, ferns, and cacti depending upon plant associations (Korb and Springer 2003; USDA Forest Service 1997), all of which contribute to the biodiversity found in frequent-fire forests (Laughlin and others 2006). The growth habit (e.g., bunchgrass, sod, or shrub) and spatial patterns of the understory influence the establishment and growth of trees (Biondi 1996; Boyden and others 2005; Sánchez Meador and others 2009; Youngblood and others 2004) and provide wildlife habitats (Dodd and others 2006; Reynolds and others 1992; Waltz and Covington 2003; Wightman and Germaine 2006; USDA Forest Service 1997). Variation in species composition among plant associations within forest subtypes influences forest dynamics. For example, within the ponderosa pine bunchgrass subtype, tree regeneration establishes rapidly following disturbance on sites with screwleaf muhly plant associations (the most mesic associations in the bunchgrass subtype), episodically on Arizona fescue plant associations (the typic associations in the bunchgrass subtype), and sparsely on blue grama plant associations (the most xeric associations in the bunchgrass subtype) (USDA Forest Service 1997). Tree establishment often occurs differently in shrub-dominated plant associations than in bunchgrass types, where rapid re-sprouting of shrub species (e.g., shrub live oak) following disturbances may inhibit pine regeneration. Other re-sprouting shrubs (e.g., New Mexico locust) are nitrogen-fixers and have been shown to facilitate pine seedling establishment (Fisher and

Table 5. Plant associations for the ponderosa pine series in the Southwestern United States sorted by ponderosa pine subtype, temperature-moisture gradient, dominant season of precipitation, and parent material type (USDA Forest Service 1997).

[a]Typic refers to modal, mid-gradient temperature-moisture types.
[b]Climate refers to mean annual soil temperatures, with cold climates having frigid soils (mean annual soil temperatures <8 °C) and mild climates having mesic soils (mean annual soil temperatures >8 °C).
[c]Dominant season of precipitation refers to the 6-month period (winter = October-March, summer = April-September) that typically has higher average precipitation levels. Most ponderosa pine and dry mixed-conifer sites in the Southwestern United States receive bimodal precipitation, but the season listed in the table experiences higher average precipitation levels.
[d]Variable = multiple parent materials; sed. = sedimentary; rhy. = rhyolites; gran. = granites

Fulé 2004; USDA Forest Service 1997). Fire may also facilitate establishment of tree regeneration on sites with non-sprouting shrub species (e.g., black or big sagebrush species) by removing competition. Together, trees and the grass-forb-shrub community affect below- and aboveground microclimates (i.e., soil moisture, nutrients, etc.) as well as ecological processes and functions such as biodiversity, trophic interactions, food webs, disturbances, and hydrology (Abella 2009; Arnold 1950; Barth 1980; Covington and others 1997; Kalies and others 2012; Moir 1966; Parker and Muller 1982; Scholes and Archer 1997) (see Expected Outcomes of Framework Implementation). Environmental variables such as light intensity, soil pH, soil and litter depth, and percent litter cover are directly influenced by the presence of tree canopy cover (Evenson and others 1980). For example, Abella (2009) reported that understory species richness was greater and plant cover was up to eight times greater in openings than under tree canopies in a ponderosa pine/Gamble oak forest.

Mycorrhizal fungi are important species in ponderosa pine and play an important role in plant nutrition, nutrient cycling, soil structure, and food webs (Carey 2003; Johnson and others 1997). Two Arizona studies reported higher densities of mycorrhizal propagules in areas where grass cover was greater and tree cover was less, such as in areas following mechanical treatments and burning, and that increased light and soil moisture in restored stands likely increased photosynthesis and mycorrhizal infection (Korb and others 2003; Korb and Springer 2003). Other studies show that abundant arbuscular mycorrhizae can increase plant diversity and overall community structure (Klironomos and others 2000; van der Heijden and others 1998). Arbuscular mycorrhizae are particularly important in grass-dominated ecosystems (Dhillion and Anderson 1993; Koske and Gemma 1997), but little is known of their status in the grass-forb-shrub community in ponderosa forests (Korb and Springer 2003).

Ponderosa Pine: Forest Structure: Structure in ponderosa pine forests emanates from the vertical and horizontal arrangement of trees and grass-forb-shrub species. Specifically, the vertical and horizontal architecture of a forest arises from variations in tree and grass-forb-shrub species and their ages, heights, crown spreads, densities, and spatial heterogeneity. Human activities since the late 19th Century resulted in changes to forest structure due to a reduction in fire frequency causing tree density and surface fuel load increases (Moore and others 2004; Naficy and others 2010; Parsons and DeBenedetti 1979; Scholl and Taylor 2010). For example, Moore and others (2004) reported a mean tree density increase by a factor of almost 7 (32-208 trees per acre) between 1909 and the 1990s. Tree encroachment into grass-forb-shrub forest openings has resulted in a decline in percent cover, abundance, and biodiversity of open grass-forb-shrub communities (Abella 2009; Bogan and others 1998; Clary 1975; Covington and Moore 1994b; Moore and others 2006; Moore and Deiter 1992; Swetnam and others 1999).

Differences in reference conditions for tree densities have been reported for fine- versus coarse-textured soils (Abella and Denton 2009; Puhlick 2011). Average plot-level reference conditions in ponderosa pine on basalt soils ranged between 0-220 trees per acre and 33-83 square ft per acre of basal area while sites on coarse-textured soils (primarily limestone) ranged between 8 and 262 trees per acre and 22 and 89 square ft per acre of basal area (Table 6; Fig. 10). In general, ranges reported for reference tree densities on coarse-textured soils were higher than those reported on fine-textured soils (Table 6). The minimum diameters reported in Table 6 may also result in a source of error that can lead to small underestimates of historical tree densities reported in studies. Additional error may result from missing fully decomposed structures at time of measurement and reconstruction (Fulé and others 1997; Mast and others 1999; Moore and others 2004).

To date, only six studies report tree spatial reference conditions in the Southwestern ponderosa pine forests. Based on these studies, the historical conditions in ponderosa pine exhibited as many as 67 tree groups per acre. Tree groups ranged between 0.003 and 0.72 acres in size and were composed of 2-72 trees (Table 3; Fig. 4). Tree groups were separated by grass-forb-shrub openings of variable sizes and shapes that contained scattered individual trees (Fig. 8). The proportion of the stand or mid-scale area not covered by vertical projections of tree crowns (referred to as "openness") has received little attention. However, several studies have reported the inverse of openness—canopy cover (Table 7); White (1985), Covington and Sackett (1986), and Covington and others (1997) reported 21.9, 19.0, and 17.3 percent canopy cover for ponderosa pine stand reference conditions on the Fort Valley Experimental Forest, Arizona, respectively. A nearby study of a reconstructed ponderosa pine/Gambel oak site on the Coconino National Forest, Arizona, reported a range of 10.2-18.8 percent canopy cover (Sánchez Meador and others 2011). Fulé and others (2002) reported an average canopy cover of 48.3 percent for the Rainbow Plateau, an area in the Grand Canyon National Park-North Rim

[a]Openness is the proportion of area not covered by tree crowns, estimated as the inverse of canopy cover.
[b]Forest Vegetation Simulator

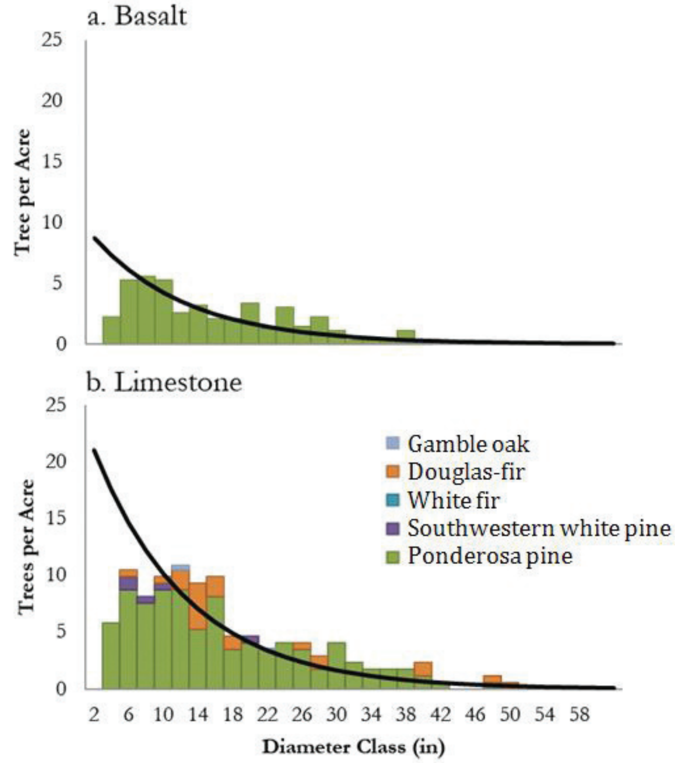

Figure 10. Theoretical diameter distributions representing reference conditions illustrating a superimposed basal area-diameter distribution (BDq) (where q = 1.2); (a) pure ponderosa pine present on basalt soils, (b) dry mixed-conifer on limestone soils. Seedling and sapling-sized tree distribution (i.e., trees in the 2-inch DBH class) on both sites may not be fully represented.

where the authors suggested that contemporary conditions were statistically similar to historical reference conditions as determined by basal area comparisons. A reference condition study conducted in ponderosa pine near Cheeseman Lake, Colorado, reported a range of 12.9-21.5 percent canopy cover (Fornwalt and others 2002). Overall, the range of canopy cover for ponderosa pine for these studies was about 10-50 percent, giving reference conditions for openness (i.e., inverse of canopy cover) of 50-90 percent. If areas with strong tree aggregation (i.e., with interlocking crowns; Fig. 11) exhibit lower mid-scale canopy cover (10.2-21.9 percent; Table 7), then it stands to reason that sites with less tree aggregation would have higher mid-scale canopy cover due to tree arrangement and reduced crown overlap (Christopher and Goodburn 2008).

Snags, logs, and woody debris are important structural and functional elements in frequent-fire forests (Figs. 12 and 13), yet little is known about volumes of coarse woody debris under historical fire regimes. Nonetheless, studies using extensive, historical stem-maps and/or locations of historical evidences (e.g., logs,

Figure 11. Interlocking or nearly interlocking crowns are components of groups of mid-aged to old trees.

Figure 12. Snags, logs, and woody debris are important components of frequent-fire forests. They provide structural diversity, nutrient cycling, and wildlife habitat.

stumps, and snags) reported a mean of 2.3 snags and 2.7 logs per acre (Moore and others 2004), 1-8 snags and 3-23 logs per acre (Sánchez Meador and others 2010), and 10 snags and 20 logs per acre as reference conditions for southwestern ponderosa pine (Abella 2008). These densities suggest that the distribution and

Figure 13. Litter, logs, and coarse woody debris contribute to fire spread and intensity. Old logs also provide local evidence of historical forest composition and structure. The excessive quantity of litter is a result of the lack of fire in this frequent-fire forest.

abundance of snags and logs varied with site and likely coincided with the type, severity, and scale of historical disturbance.

Dry Mixed-Conifer

Mixed conifer forests can be divided into two subtypes: a warm-dry (dry mixed-conifer) type and a cool-moist (wet mixed-conifer) type. Dry mixed-conifer forests are similar to ponderosa pine forests in general stand structure, but Douglas fir, white fir, white pines, and, occasionally, blue spruce are also important components of these forests (Fig. 14). Wet mixed-conifer forests typically lack ponderosa pine, have a greater abundance of Douglas-fir and white fir, and, on some sites, include other fire-intolerant and shade-tolerant species such as blue spruce, subalpine/corkbark fir, and Engelmann spruce (Fig. 2). Dry mixed-conifer forests typically occupy the lower, warmer, and drier end of the elevation zone occupied by mixed-conifer forests. They intergrade with the cool/moist ponderosa pine types on warmer/drier sites at the lower end of the mixed-conifer zone and with wet mixed-conifer forests on cooler/moister sites at the upper end of the zone (Korb and others 2013; Romme and others 2009; Smith and others 2008).

Dry mixed-conifer forests intergrade with or are adjacent to pure ponderosa pine forests and experience similar site conditions and ecological disturbances (types and frequencies) (Grissino-Mayer and others 1995). Romme and others (2009) suggested that the stand structure of dry mixed-conifer was maintained in part by recurrent fires of relatively low to moderate

Figure 14. Groups of dry mixed-conifer are similar to groups in ponderosa pine forests but often have more diverse assemblages of species and higher tree densities.

severity, although small areas of higher-severity crown fire were likely. While only a few studies report the extent of mixed-severity fires (Romme and others 2009), Fulé and others (2009) found no areas of high-severity fire larger than 158 acres as inferred by the current extent and presence of even-aged structures or early seral species.

Dry mixed-conifer forests occur on relatively warm sites at lower elevations or on southerly aspects at higher elevations and are characterized by historical frequent surface-fires synchronized by climate (approximately 9-30 years) (Brown and others 2001; Brown and Wu 2005; Fulé and others 2003, 2009; Grissino-Mayer and others 2004; Heinlein and others 2005). In contrast, wet mixed-conifer is typified by mixed-severity fire regime (Fulé and others 2003). Many studies based on fire-scarred trees show that dry mixed-conifer forests had frequent but variable fire return intervals. Some studies report fire return intervals that were similar to ponderosa pine, as frequently as every 4-14 years (Brown and others 2001; Touchan and others 1996; reviewed in Evans and others 2011), whereas other dry mixed-conifer forests experienced fires as infrequently as every 18-32 years (Fulé and others 2003; Korb and others 2013; Touchan and others 1996; reviewed in Evans and others 2011). A recent study in Southwestern Colorado warm/dry mixed conifer forests found a mean fire return interval ranging from 9-30 years on three different sites at similar latitude and elevation. Korb and others (2013) also showed significant influence of local site factors (e.g., topography, forest structure, and species composition) on fire frequency and severity. Departures from historical compositions, structures, and spatial patterns are likely greater on the warmer/drier than the cooler/wetter portion of the mixed-conifer environmental gradient due to a more severe disruption of the characteristic fire regime (Fulé and others 2002).

When direct evidence of historical fire regime is lacking (i.e., fire scars not present), plant associations that classify seral and climax species composition relative to the shade and fire tolerance of tree species and biophysical site conditions may assist in making inferences regarding fire regimes (see Tables 2 and 8). Openings in dry mixed-conifer include grasses, forbs, shrubs, ferns, and cacti (Korb and Springer 2003), but the specific assemblage of understory plants varies greatly by plant association, being broadly grouped as dominated by bunchgrasses or by forbs/shrubs (Table 8). Bunchgrass-dominated plant associations in dry mixed-conifer forests generally occur in warmer/drier conditions than sites dominated by forbs and shrub understories (e.g. white fir/Arizona fescue [warm/dry] compared to white fir/forest fleabane [cool/moist]; Table 8). For example, the U.S. Forest Service, Southwestern Region utilizes plant association classifications for mapping the spatial extent of dry and wet mixed-conifer forests on National Forest Lands.

Dry Mixed-Conifer: Species Composition: Due to a predominance of frequent, low-severity fire, historical species composition in dry mixed-conifer forests was dominated by fire-resistant, shade-intolerant conifers such as ponderosa pine, Southwestern white pine, and Douglas-fir (Fig. 2) (Evans and others 2011; Fulé and others 2003). Dry mixed-conifer forests occur in environments that are wet enough to support trees such as white fir and aspen. However, these species are also more susceptible to death from fire than fire-resistant pines and Douglas-fir (Fig. 2) (Evans and others 2011; Fulé and others 2003). Consequently, species composition in dry mixed-conifer forests was historically regulated by the balance between climate and disturbance agents such as fire. Periods of frequent fire in mixed-conifer gave fire-resistant species a competitive advantage, allowing them to establish dominance. During "fire-free" or less frequent-fire periods, ponderosa pine persisted

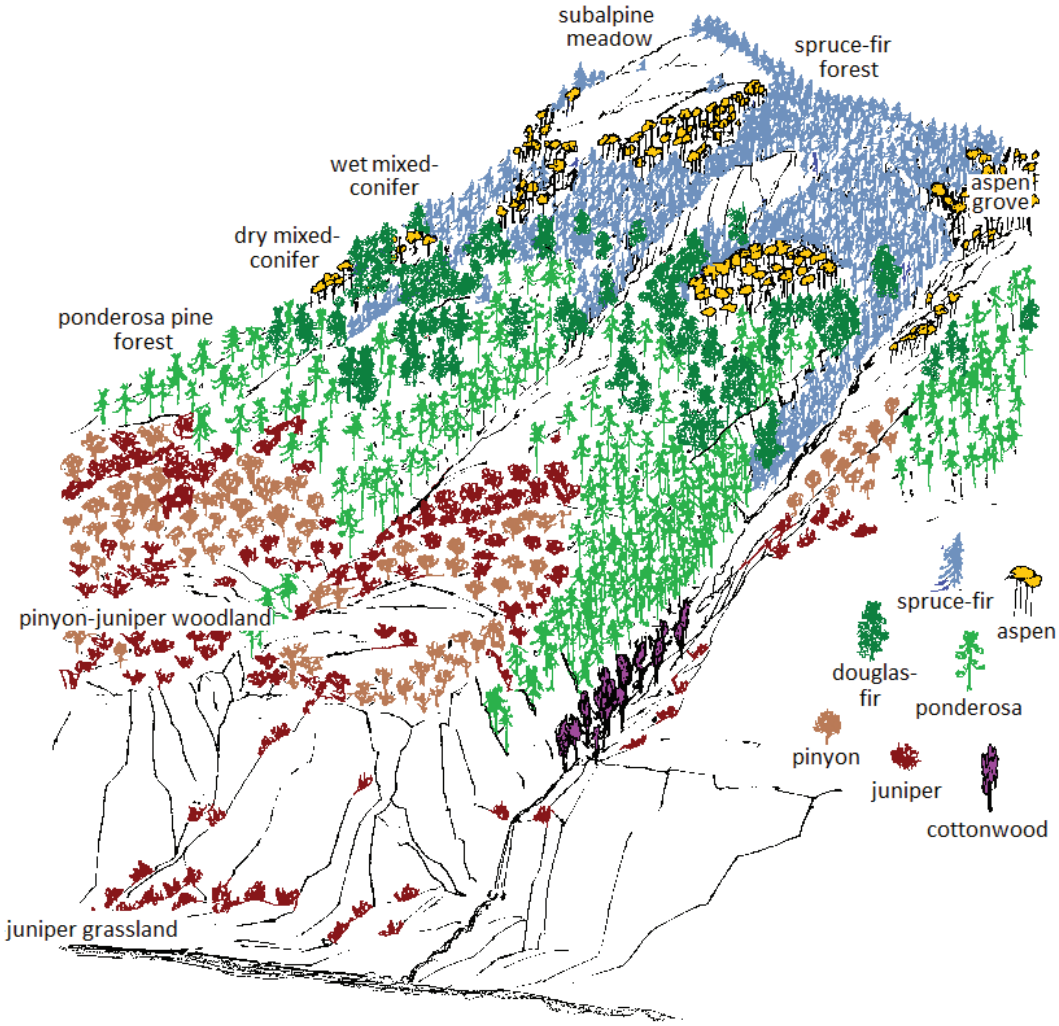

Figure 15. Illustration of changes in forest type by elevation and aspect (adapted from LANL 2011).

due to its dominant positions in the forest canopy (Fulé and others 2009). As a result, shade-tolerant, less fire-resistant species were historically minor components on drier sites, such as ridge tops and southwest-facing slopes, and likely more frequent on cooler and/or more mesic sites in frequent-fire forests, such as drainages and north-facing slopes (Fig. 15) (Romme and others 2009).

Compared to early 1900s Southwestern forest inventories, the current species composition of dry mixed-conifer forests has shifted toward more shade-tolerant, less fire-resistant species (Fulé and others 2009; Johnson 1994; Romme and others 2009). For example, one study in northern Arizona found that ponderosa pine represented an average 64 percent of basal area in the 1870 forest (range 54-69 percent) but only 36 percent in the same forest in 2003 (range 27-46 percent) (Fulé and others 2009). A recent study in Southwestern Colorado found that species composition prior to the last fire record on two different sites (1861 and 1878) was dominated by ponderosa pine, but white fir and Douglas-fir increased in dominance since the cessation of fire (Korb and others 2013). Other studies similarly concluded that extended fire exclusion in dry mixed-conifer forests resulted in substantial increases in stand-level tree density, especially by shade-tolerant white fir and Douglas-fir (Fulé and others 2004; Heinlein and others 2005). These increases resulted in forests with greater homogeneity in species composition across landscapes (Cocke and others 2005; White and Vankat 1993). Furthermore, early selective logging of ponderosa pine and intensive grazing exacerbated the compositional shift toward mesic species (Cocke and others 2005). The combination of fire exclusion, grazing, selective logging, and favorable climatic conditions for young tree establishment in the early 20th Century has created atypical stand compositions and structures in many of today's dry mixed-conifer forests

Table 8. Plant associations for dry mixed-conifer forests in the Southwestern United States sorted by plant association series, dry mixed-conifer subtype, temperature-moisture gradient, dominant season of precipitation, and parent material type (USDA Forest Service 1997).

Plant association (common name)	Dry mixed-conifer subtype	Temperature-moisture gradient[a]	Climate[b]	Dominant season of precipitation[c]	Parent material type[d]

[a]Gradient based on all mixed conifer forests (dry and wet mixed-conifer types). Typic refers to modal, mid-gradient temperature-moisture types.
[b]Climate refers to mean annual soil temperatures, with cold climates having frigid soils (mean annual soil temperatures <8 ˚C) and mild climates having mesic soils (mean annual soil temperatures >8 ˚C).
[c]Dominant season of precipitation refers to the 6-month period (winter = October-March, summer = April-September) that typically has higher average precipitation levels. Most ponderosa pine and dry mixed-conifer sites in the Southwestern United States receive bimodal precipitation, but the season listed in the table experiences higher average precipitation levels.
[d]Variable = multiple parent materials; sed. = sedimentary; rhy.= rhyolites; cong. = conglomerate; and. = andesite

(Moore and others 2004). In many locations, large, dominant ponderosa pine and Douglas-fir trees have been reduced to few or none, leaving today's stands dominated by young ponderosa pine, Douglas-fir, and white fir (Fulé and others 2003).

Dry mixed-conifer plant associations are highly variable and reflective of local biophysical site conditions that influence the type of disturbances and vegetation responses to disturbances (Table 8) (USDA Forest Service 1997). These plant associations are classified by forest series representing the most shade-tolerant conifer species that can establish and grow on a given site, absent disturbance. However, ponderosa pine typically dominates the species mix in dry mixed-conifer forest series under the characteristic fire regime. Dry mixed-conifer forest series include: (1) Douglas-fir, (2) white fir, and (3) those blue spruce plant associations that do not classify as wet mixed-conifer. These series can be subdivided by understory plant composition into the general subtypes of bunchgrass and forb-shrub. The most mesic dry mixed-conifer sites are the forb-shrub plant associations, and the most xeric are the bunchgrass plant associations. These subtypes differ in their relative fire frequencies; bunchgrass understories support more frequent surface fire, while forb-shrub understories facilitate less frequent surface fire and greater fuel accumulation (Anderson 1982; LANDFIRE 2007; Scott and Burgan 2005; USDA Forest Service 1997).

Dry Mixed-Conifer: Forest Structure: Compared to ponderosa pine, there is considerably less literature on fine-scale forest structure and spatial pattern reference conditions in dry mixed-conifer forests. However, there are some historical references to similarities between structure and spatial pattern of these two forest types. Due to its frequent fire regime, the historical fine-scale structure and spatial pattern of dry mixed-conifer forests were similar to ponderosa pine in having a more open structure (Muldavin and Tonne 2003; Swetnam and Baisan 1996) and a similar aggregated arrangement of trees in some stands (Binkley and others 2008; Sánchez Meador and others unpublished data, see Table 3 footnote). Lang and Stewart (1910; p. 19) noted that "evidence indicates light ground fires over practically the whole forest, some of the finest stands of yellow pine show only slight charring of the bark and very little damage to poles and undergrowth." Dutton (1882) observed that within both the ponderosa pine and mixed ponderosa pine/Douglas-fir forest types "the trees are large and noble in aspect and stand widely apart, except in the highest parts of the [Kaibab] plateau where the spruces predominate. Instead of dense thickets where we are shut in by impenetrable foliage, we can look far beyond and see the tree trunks vanishing away like an infinite colonnade." These observations are consistent with statements that "pure ponderosa pine forests and warm-dry mixed conifer forests were affected primarily by frequent, low-severity fires that maintained an open stand structure with a broad range of tree sizes and ages" (Romme and others 2009).

Empirical evidence also indicates that historical dry mixed-conifer forests had lower tree densities and a more open structure comprised of a higher proportion of old and large trees, were more spatially heterogeneous (having groups and patches of trees), and were more uneven-aged compared to current conditions (Fig.16) (Binkley and others 2008; Fulé and others 2002a, 2003, 2009; Heinlein and others 2005; Moore and others 2004). However, as mixed conifer forests transition toward cooler and wetter site conditions, less frequent and more severe fires result in mixtures of even- and uneven-aged forest structures. At the landscape scale, wet mixed-conifer forests were historically more spatially heterogeneous than ponderosa pine forests because of a mixed-severity fire regime affected by topography, soils, land use, and vegetation (Binkley and others 2008; Fulé and others 2002a, 2003, 2009; Muldavin and Tonne 2003; Smith 2006a; Romme and others 2009; Touchan and others 1996). Variable forest structures and spatial patterns across landscapes

Figure 16. Aerial photo of a dry mixed-conifer forest on a north-facing slope in the Cibola National Forest. In this stand, about 60-70 percent of the area is under mid- to old-age tree cover and 30-40 percent is in grass-forb-shrub interspaces.

resulted, in part, from variation among sites on the temperature/moisture continuum and their species compositions, successional status, and disturbance regimes. Warm, dry mixed-conifer sites likely experienced more frequent and less severe surface fire, resulting in more open forests with a mixture of small tree groups and areas with random tree spatial patterns. In contrast, cool, moist sites experienced mixed or high-severity fires at longer fire return intervals, resulting in relatively closed forests with tree cohorts distributed in larger patches (Fig. 14) (Fulé and others 2003; Romme and others 2009).

Studies of reference conditions for dry mixed-conifer forests reported mean tree densities and basal areas similar to those in ponderosa pine stands but with slight increases at the fine scale (Table 9; Fig. 17). For example, pre-Euro-American settlement dry mixed-conifer forests on limestone soils ranged between 36 and 100 trees per acre and 34 and 124 square ft of basal area per acre on sites in Arizona and New Mexico, respectively (Table 9; Fig. 10). For dry mixed-conifer forests on the Uncompahgre Plateau in Colorado, Binkley and others (2008) reported reference conditions for canopy cover ranging from 12.0-21.5 percent in areas that exhibit fine-scale aggregation; openness was therefore 78.5-88.0 percent in these areas. Fornwalt and others (2002) modeled reference canopy cover conditions of 13-22 percent (78-87 percent openness) for forests with fine-scale tree aggregation on the Colorado Front Range (Table 7). Based on reported studies, historical dry mixed-conifer forests were structurally similar to ponderosa pine with respect to tree groups with small meadows between them (Binkley and others 2008).

Abundance of snags, logs, and woody debris in dry mixed-conifer was likely similar to or slightly greater than that of ponderosa pine. Moore and others (2004) reported 4.9-34.9 snags per acre for dry mixed-conifer reference conditions as determined from extensive, historical stem-maps and relocation of historical evidences (e.g., logs, stumps, and snags). While the historical amount of these structural elements in dry mixed-conifer has received little attention, contemporary studies suggest that more productive dry mixed-conifer sites had higher fuel loads than ponderosa pine sites (Brown and others 2003; Graham and others 1994).

Despite the above similarities, dry mixed-conifer forests occur on a diverse range of sites and have more diversity in species composition, structure (Fig. 17), spatial pattern, processes (i.e., fire regimes and other disturbances), and functions than ponderosa pine forests. While studies demonstrate considerable similarity between dry mixed-conifer and ponderosa pine disturbance processes and forest structures, we point again to the limited numbers and geographical locations of studies of historic structural conditions in dry mixed-conifer and call for additional research to increase our understanding of historical ranges of conditions for these forests (see Monitoring, Adaptive Management, and Research Needs).

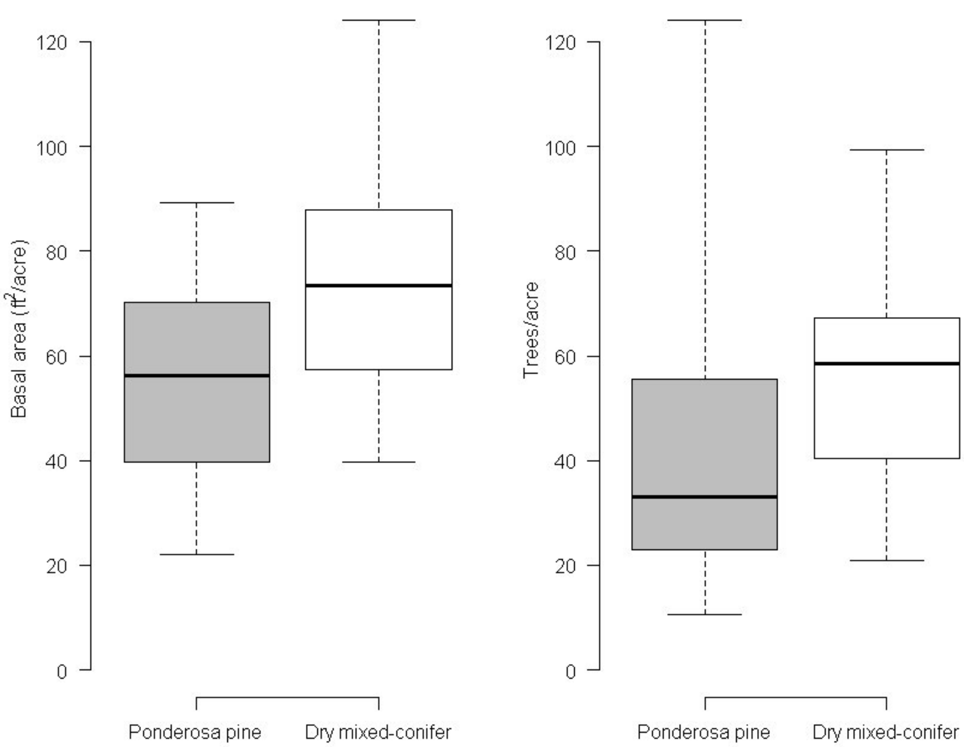

Figure 17. Distribution of reference conditions reported in Tables 6 and 9 for basal area and trees per acre in ponderosa pine and dry mixed-conifer forests. Lines bisecting boxes represent median values; lower and upper borders of boxes represent first and third quartile values; and whiskers (i.e., endpoints of dashed lines) represent maximum and minimum reported values.

The Restoration Framework

Here, we describe our framework for restoring resiliency to frequent-fire forests in the Southwest. We first provide an overview of our framework, including its ecological foundation, its key elements, and the sources of its science base. We then discuss the spatial and temporal scales at which forest structures are described, and follow this with a description of the desired key compositional and structural elements of a restored forest at those scales for ponderosa pine and then dry mixed-conifer forests. Finally, we provide recommendations for implementing the framework in these forests and finish with brief before and after descriptions of the composition and structure in a ponderosa pine area in New Mexico where we implemented our framework.

The framework is organized around key compositional and structural elements at three spatial scales and is based on a synthesis of reference conditions, literature on the ecology of frequent-fire forests (Table 4) (see Science Review: Forest Ecology), our understanding of the ecology of these forests, decades of collective experience of forest managers and researchers (e.g., Schubert 1974), and lessons learned during applications of our framework in Southwestern frequent-fire forests. Our framework is informed by the ranges of mean forest characteristics from reference conditions research plots, which were typically <10 acres and therefore best describe variability at the fine scale (Tables 3, 6, 7, and 9). Means across plots are more representative of mid-scale conditions than means reported for individual sample plots. Therefore, we point out that any point estimates with a range of mean values may not be appropriate for a given site and we recommend using local, site-specific biophysical conditions and historical evidences to inform specific treatments.

Forest ecology, historical (reference) conditions, and the natural range of variability are frequently used to define restoration goals, to estimate the restoration potential of sites, and to evaluate the success of restoration efforts. Natural range of variability is useful for understanding the natural variability in composition, structure, processes, and functions among sites and for understanding the dynamic nature of ecosystems. It is also a useful reference for establishing limits of acceptable change for ecosystem components and processes (Morgan and others 1994). Our framework is not intended to re-create specific reference conditions. Rather, the framework identifies key elements that characterized frequent-fire forests before industrial logging and the disruption of historical disturbance regimes. These key compositional and structural elements are:

(1) species composition (tree and understory vegetation);

(2) groups of trees;

(3) scattered individual trees;

(4) open grass-forb-shrub interspaces;

(5) snags, logs, and woody debris; and

(6) variation in arrangements of these elements in space and time.

The key elements provide inferences about species compositions, structural conditions, and the cumulative effects of disturbances on processes and functions that provide frequent-fire forests with resistance and resilience to disturbance.

Citations supporting our restoration framework appear mostly in the Science Review: Forest Ecology section but in other sections as needed. We recognize the limited number and geographic extent of scientific studies of reference conditions for ponderosa pine and especially for dry mixed-conifer, not only in the Southwest but throughout the western United States. Nonetheless, our framework is timely because of the growth in knowledge over the past decades regarding current and historical ecology of these forests. It is also timely because of increased frequencies, intensities, and extents of uncharacteristic disturbances, which may worsen under climate change (Littell and others 2009; Millar and others 2007; Miller and others 2009; Westerling and others 2006). We believe that moving current forest conditions toward their characteristic compositions, structures, and spatial patterns will increase their resistance and resilience to future disturbances and will result in outcomes as varied as fire fuels reduction, restoration of wildlife habitats, biodiversity, diverse food webs, and increased ability of these forests to provide ecosystem services.

Spatial and Temporal Scales

Ecosystems are structured hierarchically and their composition, structure, process, and function are temporally and spatially dynamic. Therefore, we characterize the key compositional and structural elements at three spatial scales: the fine-scale (<10 acres), mid-scale (10-1000 acres), and landscape-scale (1000-10,000+ acres) (Fig. 1). These scales generally correspond with structural features in frequent-fire forests. For example, the fine scale is an area in which the species composition, age, structure, and spatial distribution of trees (single and grouped), and open grass-forb-shrub interspaces are expressed. Aggregates of fine-scale units comprise mid-scale units, which are referred to as patches (i.e., stands) and are relatively homogeneous in vegetation composition and structure that differ from their surroundings. The landscape scale is composed of aggregates of mid-scale units and usually has variable elevations, slopes, aspects, soil types, plant associations, disturbance processes, and land uses. Understanding and incorporating temporal scales (seasonal, annual, decadal, and centuries) in a restoration framework is required to sustain vegetation dynamics of a forest that result from growth, succession, senescence, and the natural and anthropogenic disturbances that periodically reset the dynamics.

Key Elements by Forest Type: Ponderosa Pine

Southwest ponderosa pine forests occur at elevations ranging from approximately 5000-9000 ft and typically intergrade with woodland types on warm/dry sites (typically at lower elevations) and mixed-conifer types on cool/moist sites (typically at higher elevations). The characteristic fire regime for ponderosa pine is frequent, low-severity fires (Fire Regime 1; Table 2). Surface fuels (fine fuels, branches, and coarse woody debris) and small trees facilitate this fire regime. Fires burn primarily on the forest floor and rarely spread to tree crowns and canopies. Individual trees or tree groups may occasionally torch during fires. Based on plant associations, a system for classifying plant communities on their potential climax species compositions (Table 5) (USDA Forest Service 1997), we differentiated four Southwestern ponderosa pine forests subtypes: (1) ponderosa pine-bunchgrass, (2) ponderosa pine-Gambel oak, (3) ponderosa pine-evergreen oak, and (4) ponderosa pine-shrub (Appendix 2).

Ponderosa Pine: Fine-Scale Elements (<10 acres):

Species composition: Overstories are dominated by ponderosa pine but may occasionally contain other conifer or hardwood species. Herbaceous understories are typically grasses and forbs at the mid-point within the temperature/moisture gradient over which ponderosa pine occurs. At the warm/dry end of the gradient, ponderosa pine forest intergrades with pinyon-juniper or evergreen oak woodlands (e.g., juniper, pinyon, Emory oak, Arizona white oak, silverleaf oak, and grey oak) with a shrub component (e.g., manzanita, shrub live oak, sumac, or mountain mahogany). In the cool/moist portion of the gradient, Gambel oak is often a component of ponderosa pine forests, and grass and forb understories may include shrubs (e.g., ceanothus, and currants) (Table 5). At the cool/moist end of the gradient, ponderosa pine intergrades with dry mixed-conifer forests where there may be a minor presence of quaking aspen, Douglas-fir, Southwestern white pine, white fir, and blue spruce. Variation in overstory species composition influences forest structure, disturbance types and intensities, tree mortality rates, and the composition and structure of the grass-forb-shrub community.

- Trees typically occur in irregularly shaped, small groups with interlocking or nearly interlocking crowns when in the mid- to old-aged structures (Fig. 11), range in size from 2-72 trees, and occupy between 0.003 and 0.72 acres each (Table 3; Fig. 4). Groups can be even- or uneven-aged. Size, shape, number of trees per group, and number of groups per area are variable (see Science Review: Forest Ecology). If trees are aggregated (i.e., grouped), more productive sites will have more trees per group, and if not aggregated, will support more individual trees per acre. Where groups are even-aged, a high level of interspersion of groups of differing ages constitutes the desired uneven-aged structure at the fine- and mid-scale. Trees within groups are variably spaced with some tight clumps.
- Where reference conditions show the presence of scattered individual trees, their ages are variable (young to old) and they can comprise 15-70 percent of total stand basal area, with the remaining stand basal area being trees in groups (Table 3). Variability in number of individual trees is associated with various factors, such as soils, plant associations, climate, and disturbances.
- Grass-forb-shrub interspaces surround tree groups and individual trees (Fig. 8) and are variably shaped and sized.
- Snags, top-killed, lightning- and fire-scarred trees, and coarse woody debris (logs and other dead woody material greater than 3 inches in diameter) are generally large in diameter and height, scattered throughout the mid-scale, and concentrated in past disturbance sites in abundances of 1-10 snags and 3-10 tons per acre (Figs. 12 and 13). Overall, snags, logs, and coarse woody debris are spatially and temporally variable.

Figure 18. Uneven-aged forest comprised of an interspersion of tree groups of different ages.

Ponderosa Pine: Mid-Scale Elements (10-1000 acres):

The mid-scale is an aggregate of fine-scale units (i.e., tree groups, scattered individual trees, and grass-forb-shrub interspaces) and is collectively referred to as a patch or stand. Mid-scale patches are relatively homogeneous in vegetation composition and structure and differ from surrounding patches.

- Tree species composition is relatively homogenous within patches and is a function of disturbance, time since disturbance, tree density and size/age structure, topography, soils, local climate, site history, ecological legacy, and stochasticity (e.g., mass seeding and weather events).
- Average total tree densities and basal areas generally range from 11-124 trees per acre and 22-90 square ft of basal area per acre (Table 6).
- More productive sites may have more trees per area. Aggregates of many randomly distributed trees (areas >10 acres) function as patches.
- For sustainability and biodiversity purposes, it is desirable that patches comprise uneven-aged forests with an approximate balance of age classes ranging from young to old (Fig. 18). Infrequently, patches of even-aged forest structure may be present.
- All age classes of appropriate hardwood species (e.g., Gambel and evergreen oaks and other hardwoods) are present depending on a site's plant association (Table 5).
- "Openness" (estimated as the inverse of canopy cover) ranges from 52-90 percent. In areas exhibiting fine-scale aggregation of trees, mid-scale openness is typically high (78-90 percent; Table 7), and on more productive sites, especially where tree arrangement is random, openness may be less (see discussion of openness in Science Review: Forest Ecology).

Ponderosa Pine: Landscape-Scale Elements (1000-10,000+ acres):

- The landscape scale is an aggregate of mid-scale units and includes areas with variable topography (i.e., elevation, slope, and aspect), soils, plant associations, disturbance types, and land use legacies. The landscape is a functioning ecosystem that contains all components, processes, and functions that result from characteristic disturbances, including snags, downed logs, and old trees.
- Old-growth structural features occur throughout the landscape as tree groups or single trees within uneven-aged patches (stands) or occassionally as small even-aged patches. Old-growth structural features include old trees, snags, downed wood (coarse woody debris), and horizontal and vertical structural diversity in a grass-forb-shrub matrix (Table 10; Fig. 9). The location of old-growth structural features may shift on the landscape over time as a result of succession and disturbance.

Table 10. Essential structural features of old growth in frequent-fire forests. Note that whether or not a feature is essential may depend on scale—fine-, mid-, and landscape-scale. For example, age variability is possible at all scales, but snags and large dead and downed fuels may not exist in some groups and patches (adapted from Kaufmann and others 2007).

Structural feature	Essential structural feature?	Comment
Large trees	No	Tree size depends on species and site characteristics (moisture, soils, and competition). Young trees may be large, and old trees may be small.
Old trees	Yes	Trees develop unique structural characteristics when old (e.g., dead tops, flattened crowns, branching characteristics, bark color and texture).
Age variability	No	An important feature in some old-growth forest types. Some forests regenerate episodically (even-aged) with most trees establishing in a few years to a decade, probably in conjunction with wet years and large seed crops and in concurrence with relatively long intervals between fires. Others may regenerate over decades (uneven-aged).
Snags and large dead and downed fuels	Yes	Snags and large logs are essential for old growth, but forests with more frequent fires may have fewer logs. Densities and sizes of snags and logs vary depending on forest type, precipitation, and other factors. Snags, logs, and woody debris typically distributed unevenly in landscapes.
Between-patch structural variability	Yes	High variability is a critical feature. Within-patch variability may be low, but variation among patches may be high. Proportions of patches with different developmental stages vary depending on forest type, climate, etc.

- Plant associations vary across environmental gradients (e.g., changes in slope, aspect, climate, and soil type) and reflect their historical species composition, structure, and spatial aggregations.
- Denser tree conditions may exist as patches in locations such as north-facing slopes and canyon bottoms.
- Natural and anthropogenic disturbances such as fire or tree thinning treatments are sufficient to maintain desired overall species composition, tree density, age structures, snags, coarse woody debris, and nutrient cycling.

Key Elements by Forest Type: Dry Mixed-Conifer

Southwest dry mixed-conifer forests generally occur at elevations ranging from 5500-9500 ft. At lower elevations within this range, dry mixed-conifer forests commonly occur on north-facing slopes or canyon bottoms and ponderosa pine forests on south-facing slopes and ridgetops. At the upper elevation range, dry mixed-conifer forests typically occupy south and west slopes, with wetter forest types (e.g., wet mixed-conifer) on north aspects. Dry mixed-conifer forests are dominated by shade-intolerant trees such as ponderosa pine, Douglas-fir, Southwestern white pine, limber pine, quaking aspen, and other hardwoods, with a lesser presence of shade-tolerant species such as white fir and blue spruce depending on biophysical site conditions and the frequency of low-severity fire. Aspen may occur individually or in groups of variable size. While less is known about historical conditions in dry mixed-conifer than in ponderosa pine, available information shows a similarity in the structure and spatial pattern of these two forest types.

Characteristic fire regimes for Southwestern dry mixed-conifer are frequent low-severity fires (Fire Regime 1) with infrequent mixed-severity fires (Fire Regime 3; Table 2) operating at all spatial scales. Surface fuels and small trees facilitate this fire regime. While fires burn primarily on the forest floor, occasionally individual trees or tree groups may torch. Crown fires rarely spread from tree group to tree group.

Dry Mixed-Conifer: Fine-Scale Elements (<10 acres)

- Species composition: Overstories are dominated by fire-resistant, shade-intolerant trees such as ponderosa pine, Douglas-fir, Southwestern white pine, and limber pine, with occasional inclusion of aspen and other hardwoods. Shade-tolerant conifers, such as white fir and blue spruce, may be present but are subdominant in abundance. At the warm/dry end of the temperature/moisture gradient occupied by dry mixed-conifer types, this forest type intergrades with ponderosa pine-bunchgrass and ponderosa pine-Gambel oak subtypes. At the cool/moist end of the gradient, dry mixed-conifer intergrades with the wet mixed-conifer type typified by a mixed-severity fire regime. Differences in overstory species composition influences structure (tree density, tree group size, number of individuals, regeneration), disturbance events (species-specific insect and diseases, fuel type and quantity), distribution of snags and coarse woody debris, and species composition of the grass-forb-shrub community.

- Where dry mixed-conifer forests occur at the warmer/drier end of the environmental gradient (Fig. 2), trees typically occur in irregularly shaped groups, trees within groups are variably spaced, and group sizes generally range from a few trees up to an acre (Fig. 14), similar to ponderosa pine forest types. Reference conditions show tree group sizes ranging from 0.01-0.33 acres (Table 3) (see Science Review: Forest Ecology). Trees within groups are of similar or variable ages and groups are composed of one or more species. Crowns of trees within the mid-aged to old groups are interlocking or nearly interlocking (Fig. 11). Size, shape, number of trees per group, and numbers of groups per area are variable (see Science Review: Forest Ecology). If aggregated, more productive sites will have more trees per group, or if not aggregated will support more trees per acre.
- No data are available on the proportion of stand basal area in individual trees verses tree groups. More research is needed (see Monitoring, Adaptive Management, and Research Needs).
- Grass-forb-shrub interspaces surround tree groups and individual trees (Figs. 14 and 16) and are variably shaped and sized.
- Snags, top-killed, lightning- and fire-scarred trees, logs, and coarse woody debris (>3 inches diameter) are generally large in height and diameter, scattered throughout, and concentrated at past disturbance events in abundances of 5-35 snags and 8-16 tons per acre (see Science Review: Forest Ecology). Overall, snags, logs, and coarse woody debris are spatially and temporally variable.

Dry Mixed-Conifer: Mid-Scale Elements (10-1000 acres)

- The mid-scale is an aggregate of fine-scale units (i.e., tree groups, scattered individual trees, and grass-forb-shrub interspaces) and is collectively referred to as a patch or stand. At the mid-scale, patches can be relatively homogeneous in vegetation composition and structure and differ from surrounding patches. Vegetation is typically characterized by variation in the sizes and numbers of tree groups and the density and extent of patches of trees, each typically varying by elevation, soil type, aspect, and site productivity. Occasionally, patches may be composed of randomly arranged trees.
- In general, tree densities range from 20-100 trees per acre and 40-125 square ft basal area per acre (Table 9) (see Science Review: Forest Ecology). Stand density is likely to increase as site conditions transition toward the cooler/moister end of the environmental gradient for dry mixed-conifer forests and on more productive soil types.
- For sustainability and biodiversity purposes, it is desirable that patches have an uneven-aged forest structure with an approximate balance of age classes ranging from young to old. Infrequently, patches of even-aged forest structure may be present.
- Species composition may be variable within patches and is a function of disturbance, tree density, tree size and age structure, topography, soil, local climate, site history, ecological legacy, and stochasticity (e.g., weather events, mass seeding).
- It is desirable that all age classes of appropriate hardwood species (e.g., aspen, Gambel oak, and maple) are present depending on a site's plant association (Table 8).
- "Openness" is similar to ponderosa pine at the warmer/drier end of the environmental gradient occupied by dry mixed-conifer forests (Table 7) but is likely to decrease from the warmer/drier site conditions to the cooler/wetter end of the environmental gradient due to moister conditions, higher productivity, and less frequent low-severity fire.

Dry Mixed-Conifer: Landscape-Scale Elements (1000-10,000+ acres)

- The landscape scale is an aggregate of mid-scale units and includes areas with variable topography, soils, plant associations, disturbance types, and land use legacies. The landscape is a functioning ecosystem that contains all its components, processes, and functions that result from characteristic disturbances, including snags, downed logs, and old trees.
- Old-growth structural features occur throughout the landscape as tree groups or single trees within uneven-aged patches (stands) or occassionally as small even-aged patches. Old-growth structural features

include old trees, dead trees (snags), downed wood (coarse woody debris), and horizontal and vertical structural diversity in a grass-forb-shrub matrix (Table 10). The location of old-growth may shift on the landscape over time as a result of succession and disturbance (tree growth and mortality).

- Plant associations vary across environmental gradients (e.g., changes in slope, aspect, climate, and soil type) and reflect their historical species composition, structure, and spatial aggregations.
- Denser tree conditions may exist as patches in some locations such as north-facing slopes and canyon bottoms.
- Natural and anthropogenic disturbances such as fire or tree thinning treatments are sufficient to maintain desired overall species composition, tree density, age structures, snags, coarse woody debris, and nutrient cycling.

Implementation Recommendations

Here, we offer recommendations for implementing our framework. These were developed from our understanding of the body of forest ecology and management literature (see Science Review: Forest Ecology), our research and management experience, and lessons learned during implementations of our restoration framework. At the end of this section we present an overview of a case study on the implementation of our framework that illustrates its success in moving current forest conditions toward uneven-aged forest mosaics comprised mostly of fire-adapted species; tree groups; scattered individual trees; grass-forb-shrub interspaces; snags, logs, woody debris; and the spatial arrangement of these elements.

Classification of Site Variability

Ecological classification of a site indicates its biological capabilities regarding species composition, structure, processes, and functions. Ecological classification is useful for implementing our restoration framework because classification depends on variability of local climate, soil, vegetation, geology and geomorphology, and a site's characteristic disturbances and vegetation responses (USDA Forest Service 1997). The variability within and among sites across landscapes is the basis for describing the range of variation in forest conditions in our restoration framework. Recognition of within- and among-site variability is paramount for developing localized restoration objectives. Example classification systems include the U.S. Forest Service Terrestrial Ecosystem Unit Inventory (Winthers and others 2005), which classifies land units by soil, climate, slope, geology, geomorphology, and plant associations, and NatureServe's Ecological Systems (Comer and others 2003). The biotic and abiotic variables used in these classification systems describe a site's biophysical characteristics.

Recommendations by Key Elements

Species Composition

- Manage for percent species composition as indicated by local historical evidence (live trees and snags and logs from trees that originated prior to 1880), biophysical site conditions, and other management objectives (e.g., favoring scarce species; preserving genetic diversity; enhancing wildlife habitat; resilience to climate change; or achieving other resource objectives, social values, and regulatory requirements).

Tree Groups and Individual Trees

- Use a site's historical spatial patterns to inform restoration targets and treatments. Where information on reference conditions is not available, fine-scale spatial patterns may be informed by reference data in Table 3, 6, 7 and 9 and combined with local historical evidence (see Friederici 2004) such as grouped and individual old trees, large logs, and stumps, and a site's biophysical conditions.
- Evaluate current conditions in relation to desired conditions to develop management prescriptions. Avoid arbitrary constraints such as diameter limits for tree cutting (see Abella and others 2006; Triepke and others 2011).
- Where spatial heterogeneity is desired, consider combinations of burns, intermediate and free thinning, and individual tree or small group selection cutting methods to create a heterogeneous structure of groups, single trees, and grass-forb-shrub interspaces. Once heterogeneity is established, consider maintaining the desired structure and spatial pattern with fire and/or single tree and small group selection.
- Where trees are spatially aggregated, maintain interlocking or nearly interlocking crowns in mature and old groups and provide for variable tree spacing within groups; avoid thinning old tree groups.
- Manage young tree groups to create future variable tree spacing and interlocking crowns. Thin young tree-groups to facilitate development of desired within-group characteristics (e.g., variable tree spacing and interlocking or nearly interlocking crowns) in mid- to old-aged tree groups.
- Tree groups generally are small (2-72 trees per group, see Science Review: Forest Ecology) (Fig. 4). Use historical evidence and biophysical capabilities to determine a site's mean and range (minimum, maximum) of trees per group and numbers and spacing of tree groups per area.
- Mid-scale patches (stands) of less-aggregated or randomly arranged trees may be appropriate where

historical evidences do not exhibit spatial aggregation or for achieving other resource objectives.

- Where appropriate, retain or regenerate scattered individual trees between groups.
- Use historical evidence, biophysical site conditions, plant associations, and current conditions (e.g., competition from brush on certain plant association types, degree of disease or insect infestation) to inform regeneration treatments.
- Where management objectives are to maintain conifer dominance and where post-treatment dominance by shrub understories is undesired (e.g., in some ponderosa pine-evergreen oak, ponderosa pine-shrub, and dry mixed conifer-forb/shrub forest types), consider smaller interspaces to avoid excessive shrub response and increased ladder fuel accumulation.
- Consider temporary deviations from uneven-aged management to even-aged cutting methods to initiate recovery on sites damaged by epidemic (severe) insect or disease infestation or other disturbances.
- Manage fire (wildfire or prescribed) frequency and severity towards achieve desired forest structures, spatial arrangements, regeneration patterns, and fuel consumption objectives.
- Design and place regeneration treatments to favor recruitment of shade-intolerant, fire-resistant species.
- Vary treatment prescriptions (cutting and/or fire) to create a mosaic of groups of trees, scattered single trees, and grass-forb-shrub interspaces.

Grass-Forb-Shrub Interspaces

- The grass-forb-shrub community is the matrix in which tree groups and scattered individual trees are arranged (Fig. 8).
- The size and arrangement of grass-forb-shrub interspaces reflect local site conditions and historical evidence. Where trees are grouped, interspaces may be as wide as 1-2 mature tree heights from nearest drip lines of adjacent tree groups. Binkley and others (2008) reported approximately 150 ft between historic groups of trees in dry mixed-conifer in Southwest Colorado; Pearson (1923) reported 100-150 ft diameter openings (interspaces) between historic tree groups in ponderosa pine forests in northern Arizona.
- Sizes of grass-forb-shrub interspaces are a less useful metric for tree spacing in areas where trees are more randomly spaced (i.e., not aggregated). Use a site's historical vegetation spatial patterns as a guide for restoration.
- Grass-forb-shrub interspaces are generally larger on dry sites. Interspaces provide rooting space to support grouped trees.
- Meadows, grasslands, and other non-forested areas may be present as inclusions in forested landscapes; these areas are not considered interspaces.

Snags, Logs, and Woody Debris

- Manage for the continuous presence of snags, logs, and woody debris, especially large snags in various stages of decay throughout the landscape (Figs. 12 and 13). Frequent fires both recruit and consume these elements.

Arrangement of Key Elements in Space and Time

- Recognize the importance of spatial and temporal heterogeneity in forest composition and structure to ecological processes and functions.
- Where objectives include sustainability of wildlife habitat, biodiversity, and wood products, manage for a balance of age classes from cohort establishment (seedling/saplings) to old forest structure, and for grass-forb-shrub interspaces (Figs. 18 and 19).
- Where threatened, endangered, or other rare species are a concern, alternative composition and structures may be needed.

Management Feasibility

Our key elements focus on the compositional and structural features of frequent-fire forests with the goal of creating opportunities for the resumption of characteristic ecological processes and functions and to re-establish the pattern-process link. In some cases, fire can be used to develop the desired composition and structure, while in other cases, it may be more effective when it follows the restoration of forest composition and structure through mechanical treatments. Some of the recent wildfire events in the Southwest may present opportunities to initiate the post-fire "reset" of composition and structure toward desired conditions through broad-scale application of managed fires. In many Southwestern areas, restoration of frequent-fire forests will be labor intensive and costly. In other areas, implementation, or certain implementation tools, may be constrained by logistic, economic, social considerations, and special land designations (e.g., wilderness and protected areas). For example, degraded conditions in current forests may limit the use of fire. In such areas, mechanical treatments may be necessary before introducing fire. In areas where silvicultural treatments

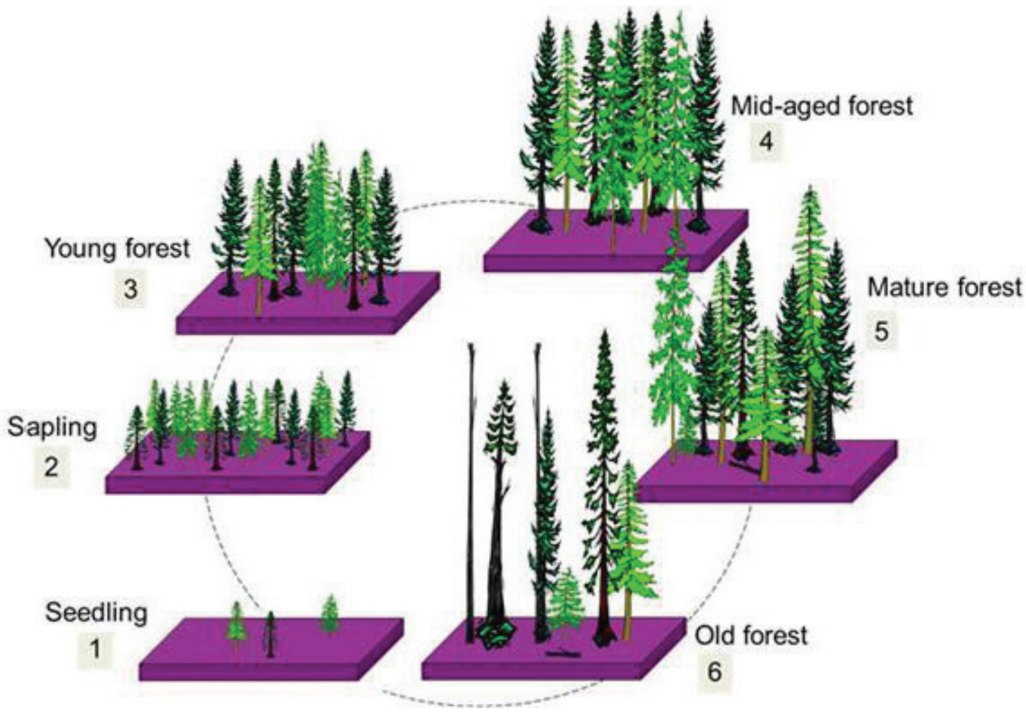

Figure 19. Illustration of the development of tree groups from seedlings to old forest at the fine scale.

are constrained by operational feasibility (e.g., access, slope, or economics) or in wilderness areas, fire may be the only management tool.

- It may not be feasible for management to approximate historical composition and structure patterns and/or fully restore characteristic ecological processes and functions everywhere.
  - o Socio-economic considerations (e.g., smoke, operational capacity, and public safety) may limit the use of fire and prescribed cutting. Some areas may require combinations of treatments to create and maintain desired compositions, structures, processes, and functions.
- Existing conditions influence treatment prescription and choice of tools.
  - o Fire alone can be used where there may be less need for precise outcomes. Fire may result in more variable forest density, numbers, and sizes of groups, and greater distribution of age classes.
  - o Where sustained production of ecosystem services is desired, managing at the extremes of the natural range of variability may be desired. For example:
    - ▪ Higher forest density and a balance of forest structural stages may be desirable to ensure economic sustainability (i.e., to maintain some level of sustained wood products) and for maintaining denser tree habitat conditions for some wildlife species.
    - ▪ Lower forest density and open forest structure may be desirable to facilitate additional reductions in fire hazard and for maintenance of more open habitat for some wildlife species.
  - o Depending on existing conditions, achieving the key elements may require multiple treatments (e.g., prescribed cutting and fire) over long time periods.
- Past disturbances, such as those resulting from fire and insects, may provide early management opportunities (i.e., reforestation and fire management) to put recovering forests on trajectories toward development of key compositional and structural elements.
- Consider strategic placement of restoration treatments to capitalize on the use of wildfire, under appropriate conditions, across broad landscapes.

Implementation of the Framework: Bluewater Demonstration Site

One of several implementations of our restoration framework was on the Cibola National Forest (Bluewater demonstration project) in New Mexico in 2010. Objectives of this project were to:

(1) create resilient forest composition and structure;

(2) move a predominately mid-aged forest toward uneven-aged conditions with an approximate balance of tree age classes;

(3) restore grass-forb-shrub interspaces;

(4) reduce fuels and fire hazard; and

(5) promote wildlife habitat, biodiversity, and wood products.

Our attempt to achieve the key compositional and structural elements in one treatment on the Bluewater site was limited by existing conditions; a portion of the mature and old trees had been harvested in prior treatments, there was little existing regeneration, and the site had a preponderance of mid-aged ponderosa pine trees. A comparison of pre- and post-treatment conditions (Figs. 20 and 21; unit 5A) attests to on-the-ground feasibility and utility of our framework recommendations for restoring the key elements in Southwestern ponderosa pine forests. Details for this project are available from the Forestry Staff with the USDA Forest Service Southwestern Region in Albuquerque, New Mexico.

Pre-Treatment Conditions

The Bluewater demonstration site is a 73-acre ponderosa pine stand (Fig. 22) that contained three different plant associations: ponderosa pine/mountain muhly, ponderosa pine/Arizona fescue, and ponderosa pine/blue grama, all of which are characterized as bunchgrass plant associations. The ponderosa pine site index is 72 for a base age of 100 years (Minor 1964). Soils are moderately productive and variable throughout the unit, comprised of alluvium and residuum from granite, and residuum derived from sandstone and claystone. The climate is temperate, with an average 180-day frost-free growing season from mid-May through mid-September and annual precipitation ranging from 17-25 inches, with greater than half occurring during the growing season.

Sanitation and improvement harvests occurred in the stand in the mid-1980s to remove diseased, dying, and poorly formed trees and, with the exception of piled slash burning in that treatment, the site had not experienced fire since the early 1900s. Prior to treatment, stand density averaged 216 trees and 125 square ft of basal area per acre. The stand was uneven-aged but had a predominance of mid-aged trees (Table 11). Fire behavior modeling demonstrated that 11 percent of the area had potential to support torching and active crown fire under dry conditions (i.e., completely dried fuel) and 15-mile/hr unobstructed wind speed.

Prescription Description

Tree marking occurred in spring 2010, tree cutting occurred in summer 2010, and prescribed burning is scheduled for fall and winter 2013. Treatment prescriptions were developed to produce the composition, structure, and spatial pattern identified in our framework for ponderosa pine: a predominant composition of ponderosa pine; re-establishment of a grass-forb-shrub community in interspaces between trees; groups of trees with interlocking or nearly interlocking crowns in the older age-classes; scattered individual trees; and retention of snags, logs, and woody debris.

The objective was to adjust stocking and spatial arrangement of residual trees (i.e., leave trees) to create or move the forest toward an uneven-aged and aggregated stand structure with a balance of age classes. Treatment prescriptions allowed within-site flexibility in numbers of trees per group and numbers and dispersions of groups per area as informed by historical evidence (i.e., old trees, logs, stumps with establishment date <1880) and existing forest structure. Treatment prescriptions used group selection to create grass-forb-shrub interspaces and regeneration sites and free thinning in immature leave tree groups to develop/retain interspersion of tree groups of different age classes and group sizes. Tree marking crews were instructed not to thin mature and old groups of trees except to remove young trees within these groups to reduce ladder fuel. Our intent was to have about 40 percent of the forested area occupied by mature-to-old tree groups, both of which meet old-growth objectives.

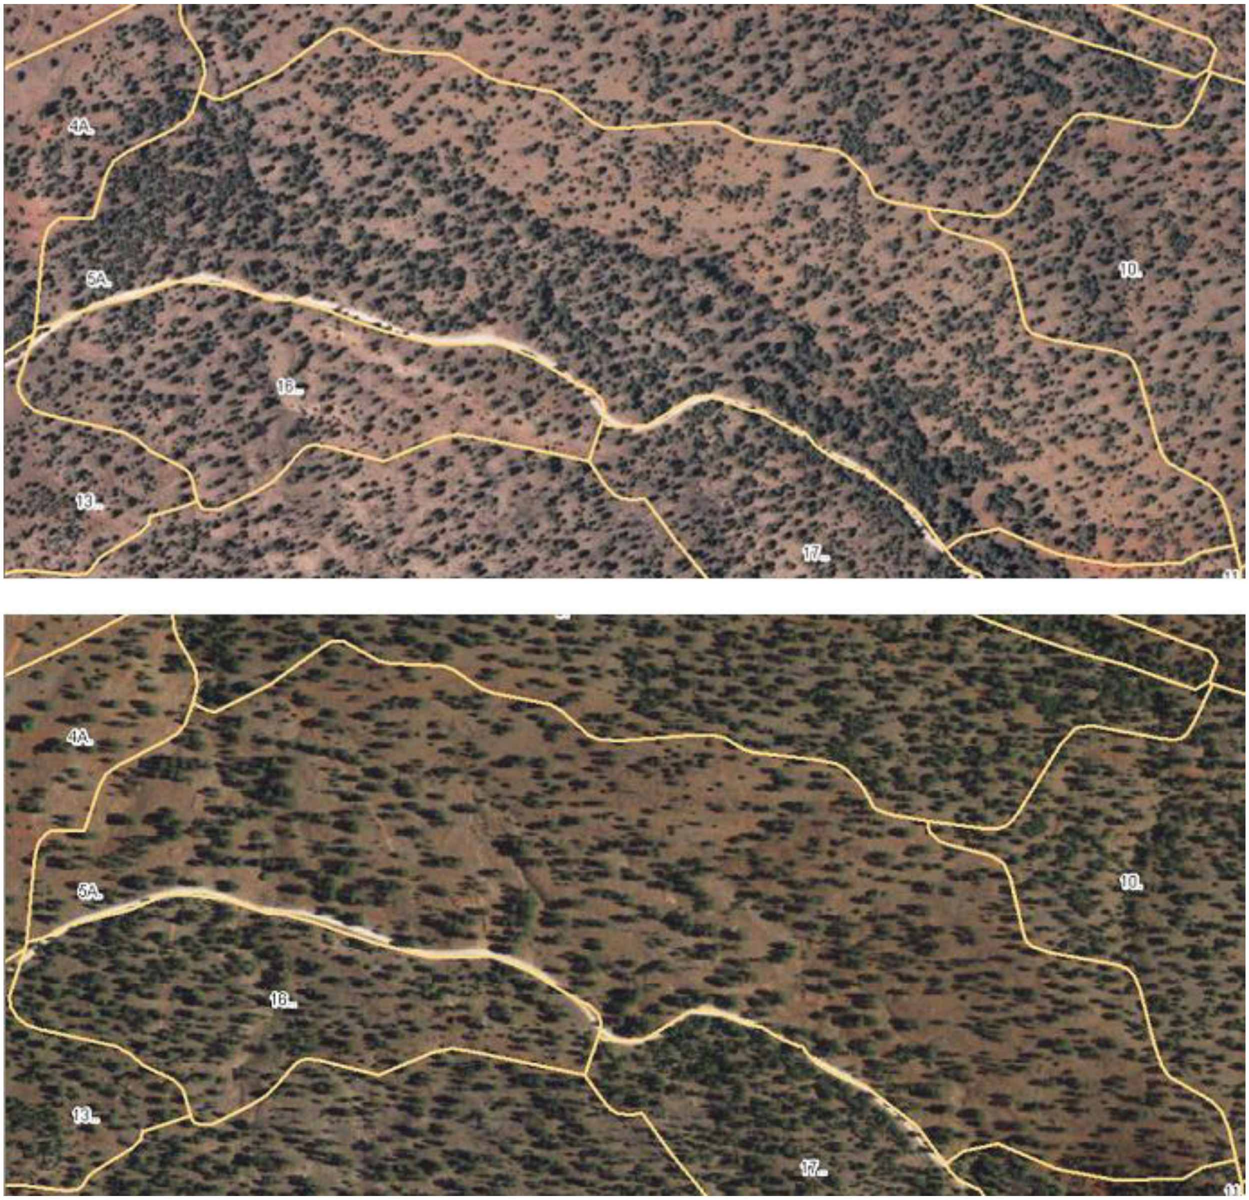

Figure 20. Aerial views of unit 5a on the Bluewater demonstration site in the Cibola National Forest, New Mexico. Prior to treatment (top image), forest density was substantially greater and more spatially homogenous than after the 2010 restoration treatment (bottom image) that applied the principles of our restoration framework.

Objectives were to favor retention of Southwestern white pine, ponderosa pine, and Douglas-fir; maintain minor components of pinyon pine and some juniper species; and favor Gambel oak and Rocky Mountain juniper trees for wildlife habitat. Leave-tree marking identified tree groups and single trees for retention. Leave trees were selected based on tree vigor and ages, with the objective of retaining an approximate balance of age classes. Special emphasis was also placed on within-group structure, including the retention of subdominant, dead-topped, and lightning-struck trees for wildlife habitat. Because no snags were present on the site, trees with declining vigor were retained for snag recruitment. Leave tree groups were either a single size or a blend of variably-sized trees. Trees within young groups were selected to encourage the development of future interlocking crowns. Overly dense young tree groups were thinned to facilitate vigor and future crown growth. Leave tree groups were generally 0.25-0.75 acres, but groups as small as a few trees and as large as 2 acres were also desired. After an initial training period, the marking crew successfully created the desired pattern of groups, scattered single trees, and grass-forb-shrub interspaces. However, they tended to mark numerous small-sized groups instead of a range of group sizes. To establish group size variability, we revisited the treatment area and added trees to some groups.

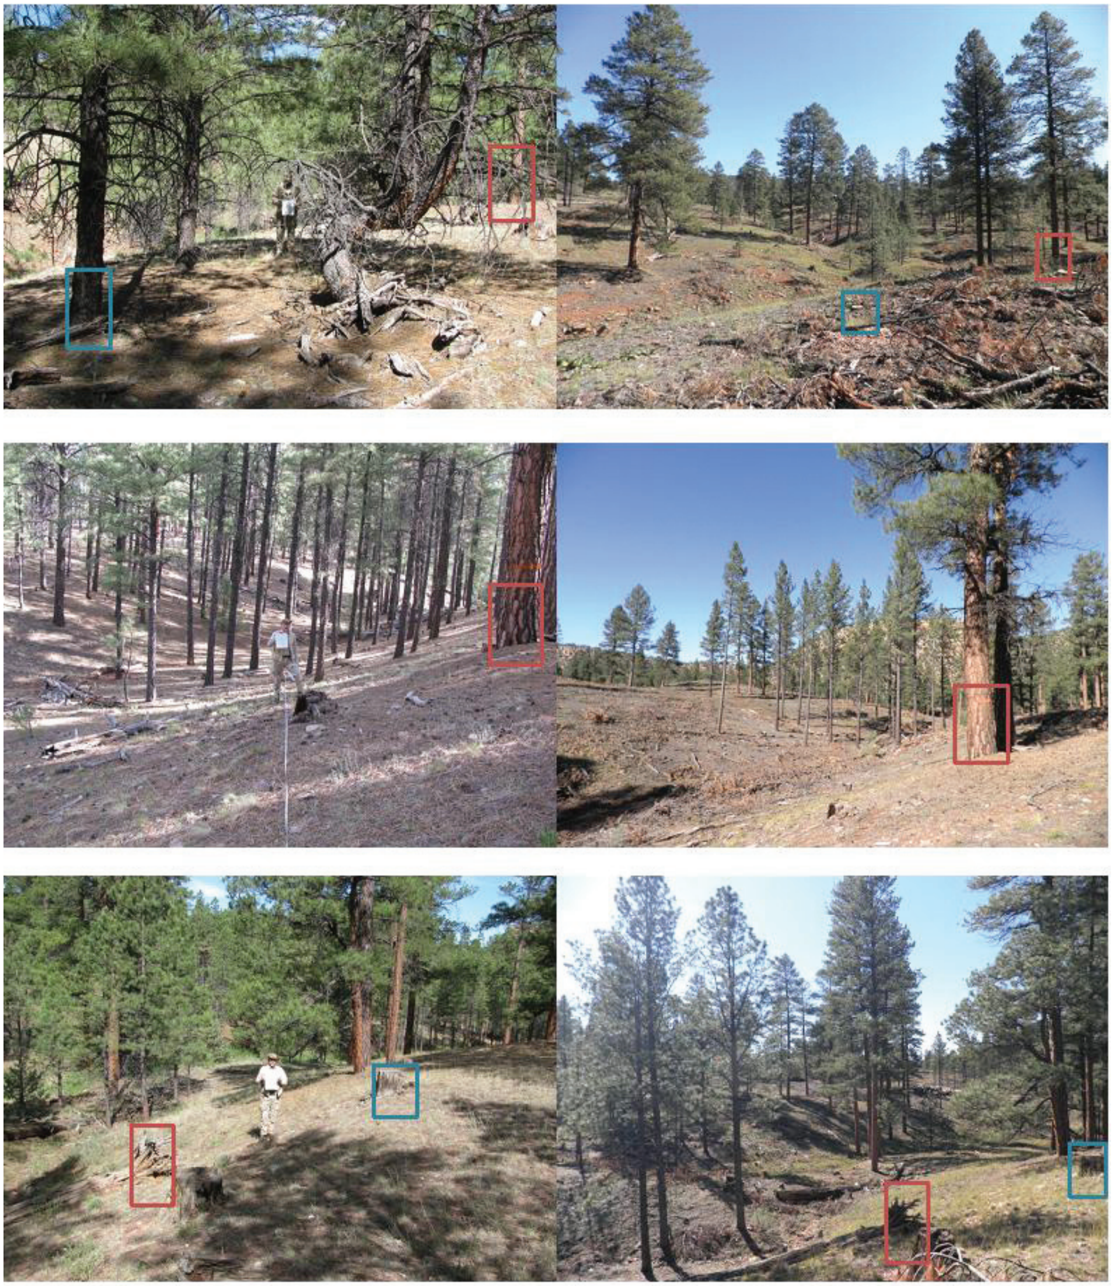

Figure 21. Paired photos from the same point before (left) and after (right) treatment in the Bluewater demonstration site, Cibola National Forest, New Mexico, USA. Colored boxes identify the same trees, cut stumps, or logs in before and after photos.

Interspaces between tree groups were created to provide for grass-forb-shrub vegetation and areas for root development. Desired interspace distances between leave groups ranged from 20-100 ft (drip line to drip line), with most distances ranging from 50-70 ft. To remedy a deficit of seedlings and saplings, regeneration sites ranging from 0.33-1.0 acre were created.

Treatment prescriptions specified the desired abundance of snags, logs, and woody debris: averages of 2 snags per acre with diameter at breast height (dbh) >12 inches and 3 downed logs per acre with dbh >12 inches. Where existing snag density was less than 2-3 per acre, live trees with broken tops or defects or fading green trees were retained for future snag and log recruitment.

The northern goshawk, tassel-eared squirrel, and Merriam's turkey were given special consideration. The treatment prescription was consistent with the restoration of habitats of plants and animals in the northern goshawk's food web (Reynolds and others

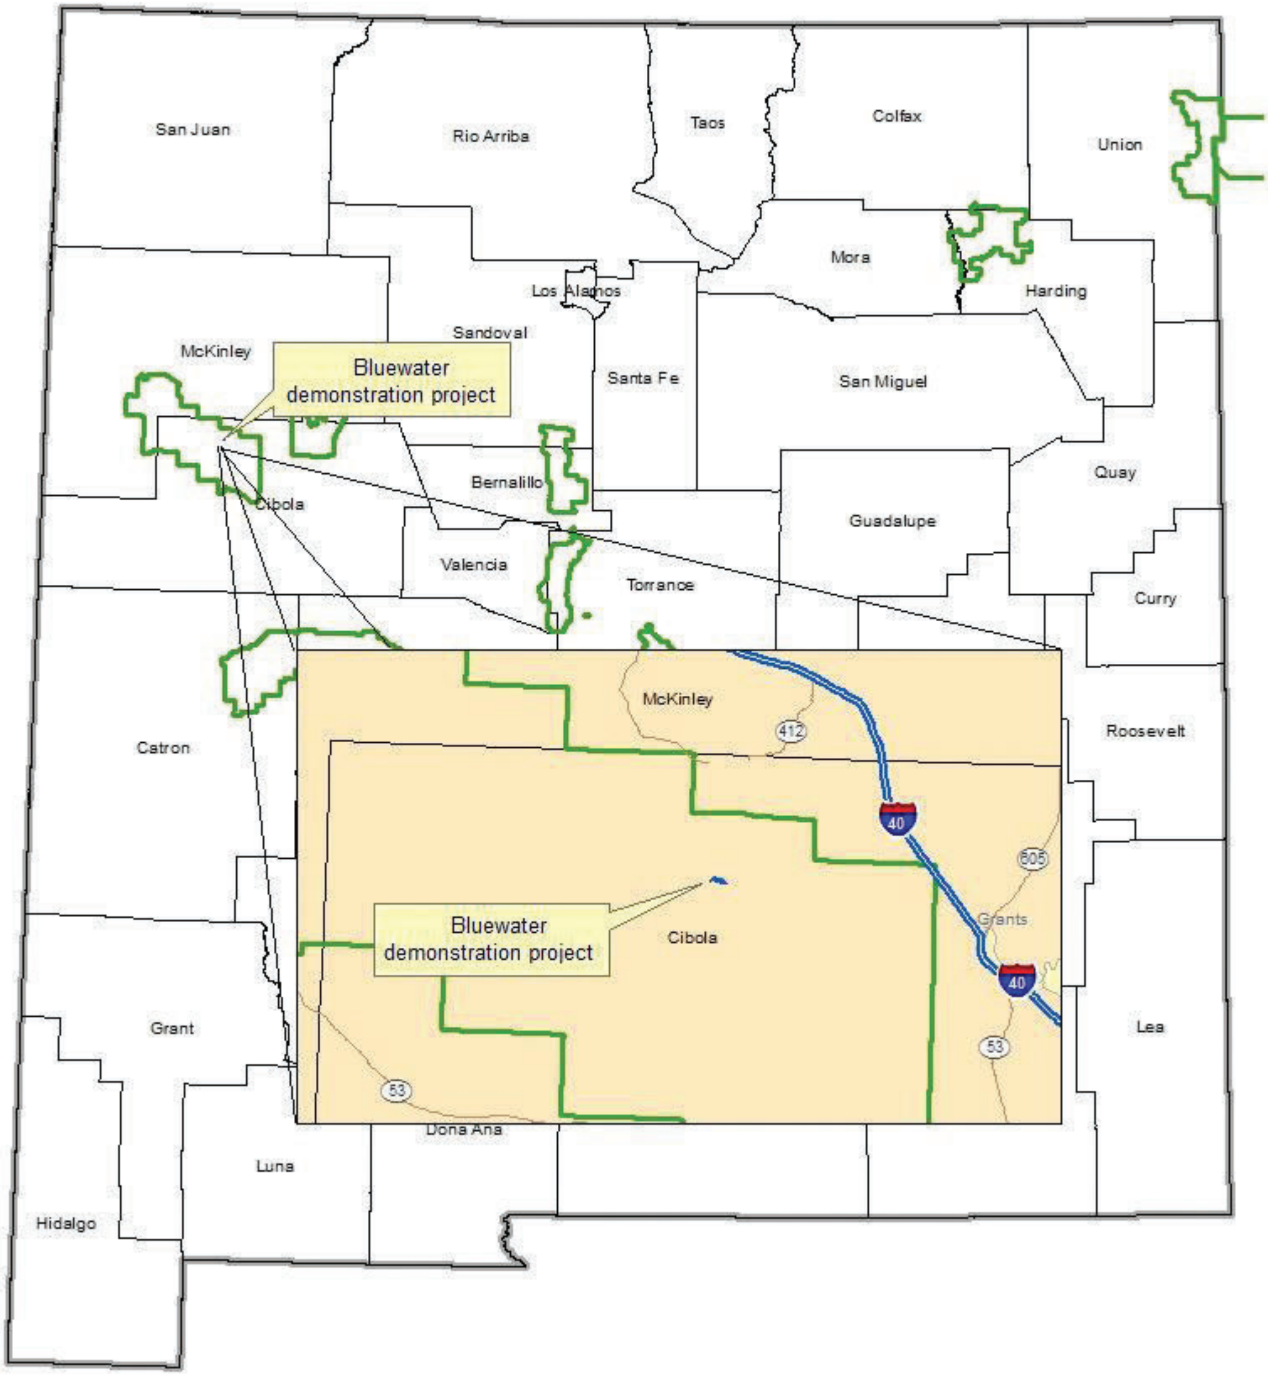

Figure 22. Location of the Bluewater demonstration project (108.45555° W, 38.45461° N) on the Cibola National Forest (green outline) in New Mexico, USA.

Table 11. Estimated proportion of stand area represented by different tree ages and sizes pre- and post-treatment on the Bluewater demonstration site.

Tree structural classes		Proportion of stand area under tree canopy	
Tree age[a]	dbh[b] range (inches)	Pre-treatment conditions	Post-treatment conditions
Seedling/sapling	0-4.9	5%	22%
Young	5-11.9	35%	26%
Mid-aged	12-17.9	40%	32%
Mature	18-23.9	10%	10%
Old	>24	10%	10%

[a]Tree ages are assumed to be related to sizes of dominant /co-dominant trees
[b]dbh = diameter at breast height

1992, 2006a, 2006b), including older tree groups with interlocking crowns for tassel-eared squirrels (Dodd and others 2003, 2006; Reynolds and others 1992) and high interspersion of grass-forb-shrub interspaces (foraging and brood habitat), closed-canopied tree groups (nesting and hiding cover), and large, old trees (roosting habitat) for Merriam's turkey (Hoffman and others 1993; Porter 1992).

Post-Treatment Conditions

This restoration treatment succeeded in creating the key compositional and structural elements identified in our framework (Figs. 21 and 23). The treatment retained the uneven-aged structure in the stand, increased the degree of interspersion of age classes, and is on a trajectory toward an approximate balance of age classes. The stand still had fewer seedling-saplings and mature and old trees than desired due to deficits in pre-treatment conditions (Tables 11 and 12). Approximately 28 percent of the area in the post-treatment stand was under the crowns of mid- to old-aged trees and 72 percent was open with no tree cover (Fig. 20). Approximately 20 percent of the post-treatment open area is designated for future tree recruitment, which will result in a desired 52 percent openness and 48 percent under tree cover. Open interspaces between tree groups were created for grass-forb-shrub communities and fire-safe sites were created for tree regeneration (Fig. 23). Post-treatment stand densities averaged 57 trees and about 40-80 square ft of basal area per acre. Most leave trees were arranged in groups with interlocking crowns, but scattered individual trees were retained across the site. Tree group sizes ranged from a few trees to 0.47 acres based on the area covered by tree crowns estimated from aerial photographs.

The post-treatment composition, structure, and spatial pattern of the stand reduced the risk of crown fire from pre-treatment conditions. Post-treatment FlamMap simulations predicted surface fires across 99 percent of the area and passive crown fire on 1 percent. Post-treatment abundance of small diameter woody debris was higher than intended, but prescribed burning will consume much of this material. Post-treatment abundance of logs and snags was lower than desired; however, these key structural features are expected to accumulate over time and with maintenance treatments. Mechanical treatments moved this forest stand toward restored conditions, but many years and multiple follow-up treatments (fire, mechanical, or combinations of these) will be needed to produce and maintain the desired key elements.

Future Management

Future plans are to broadcast burn the Bluewater site in the fall and winter of 2013 in order to initiate nutrient cycling and maintain fuels at desired levels. Subsequent entries will involve either tree felling, fire, or combinations of these to maintain or enhance the restoration treatment and manage for the desired mix and balance of tree age structures. Post-treatment conditions are being monitored at fixed photo-plots (Fig. 21) to determine whether compositional and structural objectives are being met and to inform future management.

Figure 23. Implementation of our framework in a ponderosa pine forest on the Bluewater demonstration site created groups of trees of a variety of vegetation structural stages (Table 11). The mechanical treatment also created open areas that will support grass-forb-shrub communities and tree regeneration.

Table 12. Post-treatment stocking level for the Bluewater demonstration site. All tree species are included in these estimates.

dbh[a] range (inches)	**Trees/acre**	**Basal area (ft^2/acre)**
1-4.9	3	0.4
5-8.9	17	4.6
9-12.9	23	16.2
13-16.9	5	6.1
17-20.9	5	10.2
21-24.9	2	4.3
>25	2	6.1

Expected Outcomes of Framework Implementation

Our restoration framework is intended to promote ecosystem resilience by using fire and prescribed cutting treatments to restore the species compositions, structures, and spatial patterns of Southwestern frequent-fire forests. Restoring these features should allow re-establishment of characteristic processes such as disturbance regimes, nutrient cycling, food webs, hydrologic function, and ecosystem services such as biodiversity, old-growth, wood products, aesthetics, and recreation. Restoring characteristic compositions, structures, processes, and functions should also re-establish the evolutionary environment to which plants and animals native to these forests were adapted. Having intact, self-regulating, productive, and adaptive ecosystems is a compelling strategy for allowing species in the ecosystem to adapt to changing environments and facilitate their migration in the face of uncertain climate changes and disturbances. The following description of expected outcomes from restoring forest composition, structure, and spatial pattern in Southwestern frequent-fire forests is intended as an overview of some important outcomes from the restoration of these forests; this overview is not a comprehensive review of the literature. Improved understandings of these and other outcomes will require additional research (see Monitoring, Adaptive Management, and Research Needs).

Ecosystem Resilience to Climate Change

Restoring ecosystem resilience based on historical conditions has been a central concept in ecosystem management (Covington 2003; Folke and others 2004; Scheffer and others 2001). However, the relevance of historical conditions as reference points and targets for restoration has been questioned on the basis of uncertainty of future ecological conditions due to global climate change (Harris and others 2006; Millar and others 2007; Wagner and others 2000). Specific challenges for restoring and sustaining frequent-fire forests in the face of climate change are uncharacteristically rapid alterations of environments and combinations of disturbances and non-native biotic factors producing conditions never before documented in evolutionary time—conditions that may overwhelm characteristic ecological processes (Fulé 2008). In light of these challenges, we review the evolutionary history of these forests.

Over the past several million years, forests and woodlands in the Southwest, including their associated microbial, plant, and animal communities, have tracked favorable habitats and climates whose migrations across geographical and elevational ranges were driven by major climate fluctuations (Bonnicksen 2000; Covington 2003; Delcourt and Delcourt 1988). Since the end of the last major glacial period (14,000 years ago), ponderosa pine returned to the high elevation plateaus and mountains of Arizona about 10,000 years ago and to the central Rocky Mountains only about 5000 years ago (Baker 1986; Covington 2003; Latta and Milton 1999; Millar 1998). In the last 50 million years, frequent-fire forests survived wide swings in environmental conditions (Moore and others 1999). Component species of frequent-fire forests adapted over evolutionary time to arid environments that have been characterized by variable wet and dry periods, including prolonged droughts, and disturbances such as fire, insects, and diseases. These disturbances varied in frequency, intensity, and extent (Covington and Moore 1994b); served as checks on the demographic rates of component species; and resulted in self-regulating processes of nutrient cycling, productivity, and regeneration (Allen and others 2002; Cooper 1960; Covington and others 1997; Covington and Moore 1994b; Falk 2006).

The highest confidence in future climates is associated with projections that are consistent among climate change models and observed climate changes. Surface temperatures in the Southwest are predicted to increase substantially, with more warming in the summer and fall than in winter and spring; summer heat waves will become longer and hotter, with reductions of late winter/spring mountain snowpack due mostly to warmer temperatures (Overpeck and others 2012). Observed Southwest droughts have been exacerbated by warmer summer temperatures and are projected to become hotter, more severe, and more frequent, suggesting an increased drying in the Southwestern United States and that historical drought levels may become the norm (Overpeck and others 2012; Seager and others 2007). Such droughts will directly increase tree mortality and vulnerability to pathogen attacks (Breshears and others 2005) and enhance the size and severity of wildfires (Fulé 2008). Thus, current conditions in frequent-fire forests (i.e., high stand densities, accumulations of fuels on the forest floor, and encroachment of fire-susceptible species; Cocke and others 2005; Cooper 1960) will increase the susceptibility to stand-killing fire (Fulé 2008). It is also likely that on some sites, fire-caused changes in vegetation (e.g., forest to grasslands or shrublands) may not at all resemble those of historical forests (Barton 2002; Savage and Mast 2005; Strom and Fulé 2007). Predicted changes to warmer climates in the American Southwest are expected to affect forests via geographical shifts in suitable environments for the dominate forest species. Shifts are expected to be to higher elevations and northward (Fulé 2008; Shafer and others 2001).

Uncertainties associated with future climate changes make the development of restoration strategies increasingly complex and challenging. The scenario of future hotter, more severe, and more frequent droughts in the Southwest (see Karl and others 2009) includes increased competition for water and increased frequency and extent of high-severity fire, insect, and disease disturbances. Restoring the characteristic composition, structure, and spatial pattern in frequent-fire forests would thereby:

- reduce tree densities and canopy continuity;
- recreate grass-forb-shrub plant communities;
- reduce competition for space, water, and nutrients (Covington and others 1997); and
- provide for the re-establishment of characteristic disturbance regimes (Covington and others 1997; Fulé and others 2002b; Kolb and others 1998).

Nonetheless, restoration strategies should account for an ecosystem's current condition as they may influence an ecosystem's development under future climate. Alternative successional pathways under future climactic variability may invalidate reference conditions as baselines for restoration (Clewell and others 2005; Pilliod and others 2006).

While climate forecasting remains imperfect, fire predictions for Western North America suggest substantial increases in occurrences, spread, and intensity (Brown and others 2004; Honig and Fulé 2012; McKenzie and others 2004; Spracklen and others 2009). Thus, managing frequent-fire forests toward the historical composition, structure, and spatial pattern is consistent with a reduced vulnerability to catastrophic loss (Allen and others 2002; Falk 2006; Honig and Fulé 2012). While we recognize that uncertainties in how species and communities can and will respond to rapid climate change, we agree with Fulé (2008) that it makes sense to restore fire and fire-related composition, structures, and spatial patterns to enhance resistance to catastrophic loss. Restoring the composition, structure, and spatial pattern of these forests should increase their resistance and resilience to climate changes, thereby providing opportunities for species to migrate or develop local adaptations. In fact, Fulé (2008) suggested a restoration strategy that focuses on mesic areas at higher latitudes and elevations (i.e., upper portions of the ponderosa zone and the transitional dry mixed-conifer zone) where forests are more likely to survive climate change. Fulé (2008) recommended using reference conditions from low and southerly areas to guide management in higher-elevation ecosystems to provide for the migration of species as climate warms.

In summary, both reference conditions and natural range of variability are useful guides for management because Southwest frequent-fire forests were historically resilient to drought, insect pathogens, and severe wildfire. Our restoration framework should therefore increase the resistance (by forestalling impacts), resilience (through improved recovery after disturbance), and response (allowing transitions or migrations to new conditions) of frequent-fire forests to climate change (Millar and others 2007; Parker and others 2000; Price and Neville 2003; Spittlehouse and Stewart 2003).

Disturbance Regimes

Restoring the composition, structure, and spatial patterns of frequent-fire forests will provide for the re-establishment of feedback relationships between pattern and disturbance processes in these forests (Larson and Churchill 2012). Disturbances are temporary changes in environmental conditions that cause changes in ecosystem composition and structure. Restoring the composition and structure of frequent-fire forests will result in a more open forest structure and decrease the potential for epidemic outbreaks of insects and diseases and stand-replacing fire (Fitzgerald 2005; Fulé and others 2002, 2004; Graham and others 2004; Roccaforte and others 2008; Strom and Fulé 2007). The restoration of grass-forb-shrub interspaces and resultant separation of tree canopies will increase herbaceous plant development and provide fuels to carry frequent surface fires. In turn, restoration of characteristic fire regimes should sustain forest composition, structure, processes, and functions. Reduced tree densities result in reduced competition for resources, increased tree vigor, and reduced insect and disease infestations (Hessburg and others 1994; Kolb and others 1998).

The intent of our framework is not to eliminate insects and diseases but to return populations and their effects to an endemic, low background level of tree mortality (Miller and Keen 1960). In areas with higher tree densities that may have escaped repeated surface fire, bark beetles can be a significant agent for shaping forest structure and fine-scale spatial heterogeneity. Increasing the spacing between groups of trees can reduce the continuity of mistletoe occurrence across the landscape and reduce mistletoe spread between groups, creating the opportunity for groups of trees that are free of mistletoe (Hawksworth 1961). Frequent surface fires can elevate tree crown bases and increase tree spatial heterogeneity, both of which can slow mistletoe spread (Conklin and Geils 2008). Frequent surface fire can also reduce the severity of mistletoe infection by killing heavily infected trees (Conklin and Geils 2008; Koonce and Roth 1980).

Nutrient Cycling

A restored fire regime can also improve soil nutrient conditions. Intense heat from fire volatilizes nitrogen from the soil and surface fuels, often causing the total nitrogen concentration of forest soils to decline (Boerner and others 2009; DeLuca and Sala 2006). However, nitrogen concentrations tend to recover and even increase two to four years following fire as soil microbes decompose ash and plant litter (Boerner and others 2009). Fire can also cause an immediate pulse of inorganic nitrogen due to the combustion of organic matter and mortality of soil microbes (DeLuca and Sala 2006). Soil ammonium concentrations in ponderosa pine forests may increase as much as 20-fold following fire followed by dramatic increases in nitrate levels after the first year (Covington and Sackett 1992). Frequent burning can maintain elevated levels of inorganic nitrogen in forest soils by depositing charcoal, which binds to inorganic nitrogen and slows its leaching, and by promoting the establishment of grasses and herbaceous vegetation (DeLuca and Sala 2006; Hart and others 2005). Grasses and herbaceous vegetation produce litter with higher nitrogen-to-carbon ratios than conifer vegetation; thus, the presence of herbaceous vegetation may stimulate decomposition and enhance the availability of inorganic nitrogen in forest soils (Hart and others 2005). Fires also kill large trees, creating snags that ultimately become coarse woody debris that plays an important role in nutrient cycling (Brown and others 2003; Cram and others 2007; Graham and others 1994; Harvey and others 1988; Lowe 2006).

Biodiversity and Food Webs

Many ecosystem processes influence plant productivity, soil fertility, water availability, and other local and global environmental conditions. These processes are often controlled by the diversity and composition of plant, animal, and microbial species native to an ecosystem, and recent studies suggest that losses in biodiversity can alter the magnitude and stability of ecosystem processes (Naeem and others 1999). As a dominant species in frequent-fire forests, ponderosa pine influences the understory vegetation, soils, and plant and animal habitats and communities (Moore and others 1999). A community is a group of organisms that interact and share an environment. Organisms in a community may compete for resources, profit from presence of other organisms, or use other organisms as a food source. In the Southwest, ponderosa pine forests are occupied by over 250 species of vertebrates, invertebrates, soil organisms, and plant species (Allen and others 2002; Patton and Severson 1989), many of which adapted to high levels of the spatial heterogeneity and biodiversity that characterized historical frequent-fire forests. A compositionally and structurally diverse understory provides food and cover for many species of vertebrates and invertebrates, each contributing to ecological functioning and food webs. For example, the dispersion of mycorrhizal fungi, a root symbiont critical to the growth and health of trees, is likely reliant on small mammal transfer via feces (Johnson 1996).

Current frequent-fire forests are uncharacteristically homogeneous in composition and structure with reduced plant and animal habitats and lowered biodiversity (Allen and others 2002; Kalies and others 2012; Laughlin and others 2006; Patton and Severson 1989; Villa-Castillo and Wagner 2002; Waltz and Covington 2003). Achieving our restoration framework's key elements restores habitats at multiple spatial scales, especially through the re-establishment of species-rich grass-forb-shrub communities and the productivity, biodiversity, and trophic interactions they support (Abella 2009; Clary 1975; Kalies and others 2012; Oliver and others 1998; Reynolds and others 1992, 2006a; Rieman and Clayton 1997). Dense tree conditions in current frequent-fire forests favor plants and animals that do better in more close-canopied forests. Restoration to more open forest conditions may result in the decline of these species but should increase abundance of more open forest species (Kalies and others 2012). Nonetheless, because our framework creates a variety of forest age and structural stages, including groups and patches with dense forest structures, declines of denser-forest obligates may be minimized (e.g., tassel-eared squirrel; Dodd and others 2003, 2006; Kalies and others 2012), resulting in higher overall species diversity (Noss and others 2006).

Another concern is that the fine-scale structural heterogeneity of forests resulting from restoration of frequent-fire forests may lower the abundance and viability of large-area-dependent species (e.g., spotted owl; Holthausen and others 1999; Prather and others 2008). These concerns might be ameliorated by developing specific desired conditions for breeding sites (e.g., on denser north slopes) and feeding sites with prey habitats (Prather and others 2008; Reynolds and others 1992). It is worth noting that breeding sites or entire refugia for imperiled species may receive protection from loss by encircling them with restored forests, lowering risk of catastrophic loss through fire or insects (Prather and others 2008). This indicates that restoration of these forests and the habitats they contain may provide for the historical distribution and abundance of plants and animals in Southwestern frequent-fire forests.

Restoration of frequent-fire forests should lead to more robust food webs by re-creating diverse habitats across landscapes. Species diverse and productive grass-forb-shrub communities in interspaces between tree groups support broad-based food webs that many invertebrates, birds, mammals, and their predators depend upon (Abella 2009; Dodd and others 2003; Ganey and others 1992; Kalies and others 2012; Linkhart and others 1998; Reynolds and others 1992, 2006a; Rosenstock 1998). The importance of diverse tree and grass-forb-shrub habitats and robust food webs at multiple spatial scales was demonstrated by temporal variations in the vital rates of northern goshawk (Reynolds and others 1992, 2005, 2006a, 2006b), a sensitive species that has been the subject of extensive research in the Southwest (Beier and Drennan 1997; Beier and others 2008; Boal and Mannan 1994; Ingraldi 2005). In the Southwest, goshawk reproduction typically varied extensively year-to-year and was strongly associated with the abundance and availability of food; in years when prey numbers were low, goshawk population reproduction was a fraction of reproduction in years when prey was abundant (Beier and others 2008; Reynolds and others 2005; Salafsky and others 2005, 2007). Goshawks typically feed on a broad suite of prey—from robins, jays, woodpeckers, doves, and grouse to tree squirrels, ground squirrels, rabbits, and hares, each occupying different habitats (Reynolds and others 1992, 2006a). Annual population highs and lows of each prey species are not always in phase; a year's population low of one or more prey is often compensated by higher abundances of other species (Salafsky and others 2005). Due to compensation, forest management strategies that provide a fine- to mid-scale interspersion of habitats are more likely to successfully maintain an entire suite of prey at higher total abundance through both good and poor prey years in individual goshawk home ranges (Reynolds and others 1992, 2006a). For the goshawk and the many other avian and mammalian predators (e.g., raptors, weasels, bobcats, and coyotes) in Southwestern frequent-fire forests, the grass-forb-shrub prey community is particularly important because it is occupied by a large proportion of the birds and mammals native to these forests as well as many important prey species, including rabbits, grouse, ground squirrels, mice, and voles. Prey species in this vegetation layer had larger body masses than most other species occurring in frequent-fire forests (Reynolds and others 1994; Salafsky and others 2005). Furthermore, several of these species are known to attain high population abundance in response to grass-forb-shrub productivity and biodiversity (Ernest and others 2000; Gross and others 1974; Hernández and others 2011; Hostetler and others 2012; McKay 1974). Others of our framework's key elements also create important habitats in Southwestern frequent-fire forests, including:

- dense groups and patches of older-aged trees with interlocking crowns for tree squirrels and species requiring denser forest conditions;
- snags for woodpecker foraging and nesting;
- snags for secondary-cavity nesters, bark gleaning birds, and hunting and sallying perches;
- logs for many invertebrate species (spiders, ants), woodpeckers, mice, rabbits, ground squirrels, grouse, and wild turkey; and
- woody debris for many small mammals.

Old-Growth

The key elements described in the restoration framework provide and sustain old-growth tree components at all spatial scales. Old-growth components provide a number of ecosystem services—plant and animal habitat, biodiversity, carbon sequestration, hydrologic function, high-quality wood products, aesthetics, and spiritual values. Old-growth structure includes old trees, dead trees (snags), downed wood (coarse woody debris), and structural diversity (Figs. 9, 12, and 13) (Franklin and Spies 1991; Helms 1998; Kaufmann and others 2007). The concept of old-growth includes multiple spatial and temporal scales, ranging from individual trees to tree groups and patches to landscapes and their development overtime. Definitive characteristics of old growth in the Southwest vary by forest type as a consequence of differences in species composition, tree longevities and sizes, and the characteristic types, frequencies, and severities of disturbances (Harmon and others 1986). Old-growth forests in the Southwest have been partitioned into three groups based on different fire regimes and resultant compositional and structural features (Table 10): frequent, low-severity fire; mixed-severity fire; and infrequent, high-severity fire (Table 2).

Old-growth in frequent-fire forests occurs as old trees in groups and as scattered individuals within uneven-aged forests. These forests are less dense and have fewer logs and woody debris than high-severity infrequent-fire forests. Old-growth structural features typically occur at the fine scale (Meyer 1934; Weaver 1951) and are composed of small, old tree groups interspersed with similarly sized groups of younger trees, seedlings to mid-aged (Table 10) (Cooper 1961; Harrod and others 1999; Morgan and others 2002; Pearson 1950; Woolsey 1911). The fine-scale age diversity through growth and development sustained the old-growth tree components. Our framework's key restoration elements in frequent-fire forests include all the essential structural features of old growth distributed throughout the uneven-aged forest (Kaufmann and others 2007).

In contrast to frequent-fire forests, old-growth in forests with a mixed-severity fire regime (Table 2) is characterized by adjacent forest patches burned by either low- or high-severity fire (Fulé and others 2003; Grissino-Mayer and others 1995). This results in landscapes with patches of old-growth intermixed with patches of different forest ages. Under an infrequent, high-severity regime (Table 2), old-growth forests are driven by mid- to landscape-scale, high-severity fire followed by vegetation recovery and succession occurring over long periods between fires. Infrequent, high-severity fire regimes typically have large (>100 acres) patches of forests dominated by large, old trees with multiple canopy layers with similar times since disturbance and vegetation origin dates.

Hydrologic Function

We found no published studies that evaluated the long-term effects of restoration on hydrologic function and water yield in Southwestern frequent-fire forests (see Monitoring, Adaptive Management, and Research Needs). However, studies on the effects of different tree harvest prescriptions on hydrologic function and water yield offer insights into the probable effects of reducing current high tree densities through restoration of frequent-fire forests in the Southwest. Hydrologic function and water yield in forests are greatly influenced by the amount and distribution of vegetation, precipitation, snow melt, basin physiography, and soil type. In dense (92-140 ft^2/acre) ponderosa pine forests, reduction of residual basal area to less than 100 ft^2 per acre resulted in increased water yield, although large variations in yield are typical. In addition, initial mean increases in water yield of 15-45 percent can be realized in ponderosa pine forests on basalt-derived soils when high basal area in current forests is reduced. However, increases can be expected to decline with time as vegetation establishes and develops (Baker 1986; Douglas 1983; Harr 1983; MacDonald and Stednick 2003; Troendle 1983). Removal or reduction of forest cover can increase soil water storage, which then becomes available for groundwater recharge (Baker and others 2003). Soil water content was reported to be higher in thinned and thinned-and-burned areas than in untreated-control areas on basalt soils in northern Arizona. However, observed annual variation in water yield showed that the amount and timing of precipitation had a greater overall effect on water yield than did the removal of trees (Feeney and others 1998).

From the above it seems reasonable that restoring our framework's key elements will benefit hydrologic function by reducing stand density and creating open grass-forb-shrub interspaces, decreasing canopy transpiration and interception losses, concentrating snow in interspaces, and increasing soil infiltration, water storage, and stream and spring flow (Baker 1986; Ffolliott and others 1989). While an objective of increasing water yield may not be a sufficient justification for forest restoration, increases in water yield are a significant incidental benefit (Baker 2003).

Wood Products

The re-establishment of frequent, low-severity fire is critical to the success of our restoration framework. However, because of limitations such as proximity to human developments, air quality restrictions, and workforce capacity, the use of fire will probably continue to be limited. Therefore, mechanical-only treatments, or perhaps combinations of fire and mechanical treatments, are likely to be the restoration tools of choice in much of the Southwestern landscape. Another limitation to restoration is the economic viability of treatments; can treatments generate revenue to fund restoration or must they be subsidized? In the initial stages of forest restoration, an abundant supply of lower-valued wood products could help create local products, industries, and enterprises and generate some revenue. Establishment of small-diameter tree markets, followed by shifts to markets targeting the use of restoration by-products (e.g. traditional and emerging products utilizing a wider range of tree sizes), will be essential to long-term restoration and stable local industries. Yields between 400 and 700 cubic ft per acre seem reasonable from a cutting cycle of 25 to 30 years once restoration achieves an approximate balance of structural stages in frequent-fire forests (Youtz and Vandendrieshe 2012). Such yields would help offset costs of achieving multiple objectives.

Aesthetics and Recreation

The public often judges the ecological health of a forest by appearance. Hill and Daniel (2008) found that acceptance of restoration activities may be contingent on public perceptions of aesthetics and knowledge of ecological benefits. People prefer landscapes with large trees, openings, and varied spatial distribution of vegetation that provide views through the site and into the landscape (Brush 1979). Recreational campers preferred camp-sites that were about 60 percent shaded (James and Cordell 1970), while others preferred uneven-aged forest landscapes over even-aged, dense stands (Brown and Daniel 1984, 1986, 1987; Ryan 2005). Restored forests meet these scenery preferences, suggesting greater public acceptance and support.

Monitoring, Adaptive Management, and Research Needs

Frequent-fire forests in the Southwest are complex and dynamic, and our understanding of how they function and respond to disturbances is limited by available data. Knowledge gaps and unexpected events inevitably make forest management and restoration inherently challenging. Key to meeting restoration challenges are the conduct of ecological monitoring, adaptive management, and additional research. This framework and its application are intended to be dynamic and adaptive and will evolve with accumulations of new monitoring and research information.

Ecological monitoring is the means by which managers evaluate whether the current conditions of an ecological system match, or are on a trajectory to match, some desired condition (Noon 2003). Monitoring provides feedback on the impacts of management treatments (Lindenmayer and Likens 2010; Palmer and Mulder 1999) and is typically divided into three categories: implementation, effectiveness, and validation (Busch and Trexler 2003). Implementation monitoring occurs during implementation and determines whether treatments were carried out as intended. Effectiveness monitoring determines the extent to which treatments achieved their ultimate objectives. Validation monitoring assesses the degree to which underlying assumptions about ecosystem relationships are supported (Block and others 2001; Busch and Trexler 2003) and functions to identify knowledge gaps or research needs.

Adaptive management requires feedback obtained from monitoring regarding the success or failure of treatments (Walters 1986). Adaptive management is the "rigorous approach for learning through deliberately designing and applying management actions as experiments" (Murray and Marmorek 2003). In contrast to simply measuring treatment effects and making slight adjustments to future treatments, adaptive management depends on structured, adaptive decision making (Williams and others 2009). It is most useful when managers and scientists identify threshold values for triggering management actions (Noon 2003). A clear description in a plan of how monitoring will be used in decision-making is essential (Noon 2003; Williams and others 2009). This could be achieved administratively (Mulder and others 1999; Sitko and Hurteau 2010), legally via the National Environmental Policy Act process (Buckley and others 2001), or through collaborative agreements (Gori and Schussman 2005). Monitoring data should be compiled, analyzed, and reported in a timely manner so that managers are provided information to improve decision-making (Mulder and others 1999) and to identify knowledge gaps.

Although much is known about historical forest composition, structure, and disturbance in frequent-fire forests, our knowledge of the mechanisms of spatial pattern formation and maintenance is limited, indicating a research need (Larson and Churchill 2012). A limited understanding of reference conditions on different parent material, especially in dry mixed-conifer, is an important data limitation for designing and implementing appropriate resource management. While the number of reference data sets is increasing, existing data have focused largely on tree density. There is a clear need for studies on spatial patterns and the sizes and shapes of grass-forb-shrub interspaces, as well as the mechanisms for the formation and maintenance of spatial patterns. Additional research needs are:

- Increased understanding of reference conditions and the natural range of variation across ecological gradients such as latitude and longitude, soils, topography, and climate in Southwest frequent-fire forests, especially in dry mixed-conifer.
- Increased understanding of differences between ponderosa pine and dry mixed-conifer forests in reference conditions and the historical types, frequencies, severities of disturbances, and responses of vegetation. Of particular need are:
  (1) A greater understanding of variation of reference conditions (composition, structure, and spatial pattern) in forest subtypes and different plant associations.
  (2) How reference conditions influenced the effects of fire on tree regeneration and mortality in forest subtypes and in the transition zones between subtypes.
  (3) The effectiveness of restoration treatments at achieving desired objectives, especially on avoiding the conversion of these subtypes to alternative plant associations.
- Increased understanding of ecosystem processes and functions as they respond to restoration of the composition and structure of frequent-fire forests.

- Increased understanding of the mechanisms of spatial pattern formation (e.g., aggregated and random tree distributions) within- and among-groups, including the presence, abundance, and dispersion of individual trees.
- An understanding of historical roles of insect and disease in shaping forest composition, structure, and spatial pattern, and the effects of restoration on the frequency and severity of insect and disease disturbances at all scales.
- An understanding of the effects of exotic insect, disease, plant, and animal species, and how these may alter forest composition, structure, processes, and functions.
- Increased understanding of the efficacy of fire versus tree cutting only and cutting combined with fire at achieving the desired composition, structure, processes, and functions in frequent-fire forests at all scales.
- Identification of management strategies for restoring composition and structure in transitional zones between forest types and future directions given climate change.
- Development and refinement of new and existing tools and metrics for measuring spatial heterogeneity at ecologically meaningful scales.
- Improved understanding of wildlife habitat and wildlife uses of restored composition and structure of frequent-fire forests.
- Improved understanding of long-term effects of restoration and maintenance treatments (mechanical, fire, and a combination of the two) on water yield and quality.
- Assessment of ecological, economic, and social benefits and costs (e.g., invasive species) of different restoration methodologies and implementation practices, such as methods for treating slash, tree marking approaches, spatial scales of treatment, and frequency of maintenance treatments.
- Exploration of management applications to implement our framework on broad landscapes in an economically efficient manner.

Summary

Our forest restoration framework provides managers and researchers a review of existing knowledge regarding the historical compositions and structures in Southwest frequent-fire forests and how these operated through feedback mechanisms that sustained their characteristic compositions, structures, and functions. Current forest conditions, the cumulative consequences of various human activities that altered historical conditions, are reviewed in light of historical conditions with a focus on how human-caused changes lowered the resistance and resilience of these forests to historical disturbance agents that themselves have become more intense and frequent. Guided by our understanding of how the composition, structure, and spatial pattern of historical frequent-fire forests affected their resistance, resilience, and responses to disturbances, our restoration framework identifies desired key compositional and structural elements of these forests and provides management recommendations for restoring those key elements. We believe implementation of our framework provides opportunities for re-establishing characteristic processes such as frequent, low-severity fire and ecological functions such as habitat, biodiversity, and food webs.

The key compositional and structural elements of historical frequent-fire ponderosa pine and dry mixed-conifer forests in the Southwest can be envisioned over time as a shifting mosaic of groups of trees with interlocking crowns; single trees; open grass-forb-shrub interspaces; and dispersed snags, logs, woody debris (Larson and Churchill 2012; Long and Smith 2000; Reynolds and others 1992). Research shows that the degrees of tree aggregation; sizes and numbers of tree groups; numbers and dispersion of single trees; sizes and shapes of grass-forb-shrub interspaces; and numbers, sizes, and dispersions of snags, logs, and woody debris in reference conditions varied among sites by soil, topography, climate, disturbance regime, and past stochastic events. Our restoration framework recognizes this site-to-site variability and articulates the importance of restoring that variability by using existing evidence (e.g., old trees, snags, stumps, and logs) and biophysical site indicators as guides for restoring local variability. In our view, restoration of spatial and non-spatial elements of forest structure on a per-site basis is the most practical, science-based strategy to return frequent-fire forest ecosystems in the Southwest to resistant, resilient, and responsive conditions that will best position them to adapt to future disturbance regimes and climates (Larson and Churchill 2012; Millar and others 2007). We intend this framework and its application to be flexible and adaptive (i.e., learn-as-you-go) and to evolve with accumulation of knowledge, and for its conceptual approach to provide a blueprint against which management plans and practices can be evaluated.

Acknowledgments

We acknowledge the many valuable comments from the following reviewers: S. Baggett (USDA Rocky Mountain Research Station), M. Battaglia (USDA Rocky Mountain Research Station), C. Fiedler (University of Montana), D. Huffman (Ecological Restoration Institute, Northern Arizona University), M. Kaib (USDI Fish and Wildlife Service), and three anonymous reviewers. We thank Forest Service colleagues C. Dawe, B. Higgins, E. Irwin, R. Maes, M. Manthei, and J. Stringer for participating in discussions during development of early desired condition drafts of this framework. We thank R. Davis, R. Periman, W. Robbie, J. Triepke, and M. Turner of the Southwestern Regional Office for helpful comments on an early draft, and comments and discussions of the many scientists, managers, and interested publics who attended our multiple restoration workshops. All of the above helped improve our understanding of the ecology and management challenges in frequent-fire forests and all contributed to the improvement of the manuscript. We thank Rocky Mountain Research Station, the Forest Service Southwestern Region, and the Ecological Restoration Institute and Northern Arizona University for allowing the authors' time and travel during the development of the framework.

Glossary

Age class is defined as trees that originated within a relatively distinct range of years. Typically, the range of years is considered to fall within 20 percent of the average maturity (e.g., if 100 years is required to reach maturity, then there would be five 20-year age classes) (Helms 1998).

Basal area is the cross-sectional area of all stems of a species or all stems in a stand measured at breast height (4.5 ft above the ground) and expressed per unit of land area.

Biodiversity is the variety and abundance of life forms, processes, functions, and structures of plants, animals, and other living organisms, including the relative complexity of species in communities, gene pools, and ecosystems at spatial scales from local to regional to global (Helms 1998).

Canopy cover (*see* forest canopy cover)

Canopy fuels are all burnable materials, including live and dead foliage, lichen, stems, and branch wood located in the forest canopy.

Characteristic (natural) conditions (e.g., vegetation composition and structure), processes (e.g., disturbance regimes), and functions (e.g., habitat, biodiversity, and food webs) of a forest type that are present under the natural range of variability.

Clump refers to (1) the aggregate of stems issuing from the same root, rhizome system, or stool; or (2) an isolated generally dense group of trees (Helms 1998). A clump is relatively isolated from other clumps or trees within a group of trees, but a standalone clump of trees can function as a tree group or a single structure (Fig. 4).

Coarse woody debris is dead woody material on the ground greater than 3 inches in diameter, including logs (Figs. 12 and 13).

Composition is the array of species present in an ecosystem. In forestry, this term often refers to the proportion of each tree species in a stand expressed as a percentage of the total number, basal area, or volume of all tree species in the stand (Helms 1998).

Diameter at breast height (DBH) is the diameter of a tree typically measured at 4.5 ft above ground level.

Disturbance (characteristic and uncharacteristic): Any relatively discrete event in time that disrupts ecosystems, communities, or population structure and changes resources, substrate availability, or the physical environment (Helms 1998). Characteristic disturbances are those whose extent, frequency, and severity fall within the natural range of variability. Uncharacteristic disturbances are outside the natural range of variability and interrupt characteristic processes and functions.

Dry mixed-conifer forests occupy the warmer and drier sites between elevations of 5000 and 10,000 ft and are characterized by a relatively frequent historic fire regime (<35 years fire return interval), resulting in surface fire and infrequently, mixed-severity fire effects. This forest type is typically dominated by shade-intolerant species such as ponderosa pine, with minor association of aspen, Douglas-fir, and Southwestern white pine during early seral stages. More shade-tolerant conifers such as Douglas-fir, white fir, and blue spruce are dominant at climax stages. In the Southwestern United States, this type is primarily described by the Society of American Foresters cover types interior Douglas-fir and white fir.

Ecological (ecosystem) health (*see* forest health)

Ecological restoration is the process of assisting the recovery of an ecosystem that has been degraded, damaged, or destroyed. Restoration initiates or accelerates ecosystem recovery with respect to its health (productivity), processes, and functions (biodiversity, food webs, and sustainability) (adapted from SER 2004).

Ecosystem integrity is the state or condition of an ecosystem that displays the biodiversity characteristic of the reference, such as species composition and community structure, and is fully capable of sustaining normal ecosystem functioning (SER 2004).

Ecosystem resiliency is the ability of an ecosystem to absorb and recover from disturbances without altering its inherent functions (SER 2004).

Ecosystem services are the benefits people obtain from ecosystems, including provisioning services such as food and water; regulating services such as flood and disease control; cultural services such as spiritual, recreational, and cultural benefits; and supporting services such as nutrient cycling, that maintain the conditions for life on Earth (Millennium Ecosystem Assessment 2005).

Ecosystem stability is the ability of an ecosystem to maintain its given trajectory (SER 2004).

Ecosystem sustainability is the capacity of ecosystems to maintain ecosystem services in perpetuity without degradation of its productivity and function at all scales. For example, in the context of our restoration framework, sustainability results in maintaining the key elements in space and time.

Even-aged forests are forests that are comprised of one or two distinct age classes of trees.

Evolutionary environment refers to the range of abiotic and biotic conditions that have exerted selection pressure on and are critical to the survival of species or groups of species (Kalies and others 2012; Moore and others 1999).

Fine fuels are fast-drying dead or live fuels, generally characterized by a comparatively high surface area-to-volume ratio, that are less than 0.25 inch in diameter and have a time-lag of one hour or less. These fuels (grass, leaves, needles, etc.) ignite readily and are consumed rapidly by fire when dry (NWCG 2012).

Fire regime refers to the patterns of fire occurrences, frequency, size, severity, and sometimes vegetation and fire effects in a given area or ecosystem. A fire regime is a generalization based on fire histories at individual sites (McPherson and others 1990).

Fire return interval is the number of years between two successive fires in a specified area (McPherson and others 1990).

Forest canopy cover is the proportion of ground or water covered by a vertical projection of the outermost perimeter of tree canopies, regardless of tree spatial arrangement.

Forest health is the state or condition of forest ecosystems in which its attributes (i.e., productivity) are expressed within "normal" ranges of activity relative to its ecological stage of development. A restored ecosystem expresses health if it functions normally relative to its reference ecosystem (adapted from SER 2004).

Frameworks provide a set of assumptions, concepts, values, and practices that constitute a way of viewing reality (American Heritage Dictionary 2011).

Free thinning is the removal of trees to control stand spacing and favor desired trees using a combination of thinning criteria without regard to crown position (Helms 1998).

Frequent-fire forests are forests with fire regime 1, those forests with fire frequency <35 years (Schmidt and others 2002).

Functions (ecological functions) are the outcomes of ecosystem components and processes (e.g., interactions within and among species). Examples include primary and secondary production and mutualistic relationships. Ecosystem functions are broadly categorized as regulation functions, habitat functions, production functions (e.g., genetic and medicinal resources), and information functions (e.g., spiritual and historic information) (De Groot and others 2002).

Group refers to a cluster of two or more trees with interlocking or nearly interlocking crowns (Fig. 4 and 12) at maturity surrounded by grass-forb-shrub interspaces (Fig. 8). Size of tree groups is typically variable depending on forest type and site conditions and can range from fractions of an acre (i.e., a two-tree group), such as in ponderosa pine or dry mixed-conifer forests, to many acres, as is common in wet mixed-conifer and spruce fir forests. Trees within groups are typically non-uniformly spaced, some of which may be tightly clumped.

Group cutting (selection) is the removed of small groups of trees to establish of new age classes (Helms 1998).

Improvement harvests involve the removal of poorly formed or low-vigor trees to improve stand productivity and/or quality (Helms 1998).

Interspaces are areas not currently under the vertical projection of the outermost perimeter of tree canopies (Fig. 8). They are generally composed of grass-forb-shrub communities but could also be areas with scattered rock or exposed mineral soil. Interspaces do not include meadows, grasslands, rock outcroppings, and wetlands (i.e., exclusions adjacent to and sometimes within forested landscapes).

Leave trees or snags (*see* residual (leave) trees or snags)

Matrix refers to the background cover type of an area. In frequent-fire forests, grass-forb-shrub communities form the background matrix upon which tree groups and individual trees are spatially arranged. It is the most extensive and connected landscape element that plays the dominant role in landscape functioning. The expression of this matrix between tree groups and individual trees is referred to as interspace. The location of tree groups and individual trees on the matrix and the proportion of patches represented by the matrix will change over time due to disturbance.

Mixed-severity fire regimes are characterized by closely juxtaposed forest patches affected by low- and high-severity burning (Fulé and others 2003).

Natural (historical, characteristic) range of variation describes the variability of ecological conditions (e.g., reference compositional and structural conditions) and the spatial and temporal variation in these conditions during a period of time specified to represent characteristic conditions (i.e., conditions relatively unaffected by people) for an ecosystem in a specific geographical area (Kaufmann and others 1994; Landres and others 1999).

Old growth in Southwestern forested ecosystems is defined differently than the traditional definition based on Northwestern infrequent-fire forests. Due to large differences among Southwest forest types and their characteristic disturbances, old growth forests vary extensively in tree size, age classes, presence and abundance of structural elements, stability, and presence of understory. Important structural features of old growth in frequent-fire forests are large trees, old trees, age variability, snags, large dead and downed fuels, and between-patch structural variability (Fig. 9 and Table 10) (Kaufmann and others 2007).

Openness is estimated as the inverse of forest canopy cover for a given area. For example, a forest with 70 percent canopy cover would have openness of 30 percent.

Patches are areas larger than tree groups in which the vegetation composition and structure are relatively homogeneous (sensu Forman 1995). Patches can be composed of randomly arranged trees or multiple tree groups, and they can be even-aged or uneven-aged. Patches comprise the mid-scale, ranging in size from 10-1000 acres. Patches and stands are roughly synonymous.

Pattern (*see* spatial pattern)

Plant associations are plant community types based on land management potential, successional patterns, and species composition (Helms 1998).

Ponderosa pine forests are widespread in the Southwest occurring at elevations ranging from 6000-7500 ft and occupying warmer and drier sites within the montane forest life zone. These forests are characterized by a relatively frequent historic fire regime resulting in surface fire effects. Ponderosa pine is the dominant tree species in this forest type, but other tree species may be present, including Gambel oak, pinyon pine, and juniper species. This forest type often has a shrubby understory mixed with grasses and forbs but sometimes occurs as savannah with extensive grasslands interspersed between widely spaced clumps or individual trees. The ponderosa pine type is distinguished from dry mixed-conifer types by the plant community successional stages. The ponderosa pine forest type is dominated at all successional stages from seral to climax by ponderosa pine. Ponderosa pine often dominates early seral stages of dry mixed-conifer forests also, but these types are not considered to be ponderosa pine forest types because the climax species composition is dominated by other conifer species or ponderosa pine in mixtures with other conifer species.

Processes (ecological processes) are the dynamic attributes of ecosystems in terms of matter and energy, including interactions among organisms and interactions between organisms and their environment (De Groot and others 2002; SER 2004). Examples of processes are: evolution, fire and insect disturbances, photosynthesis, seed dispersal, decomposition, and soil formation.

Reference conditions are conditions existing prior to the suppression or exclusion of the primary processes and mechanisms influencing a system along a natural trajectory (sensu Kaufmann and others 1994). The reference can consist of one or several specified locations that contain model ecosystems, a written description, or a combination of both. Information collected on the reference includes both biotic and abiotic components (SER 2004)

Regeneration sites are tree-free areas created by group cutting for the purpose of establishing tree regeneration.

Residual (leave) trees or snags are those remaining after an intermediate or partial cutting of a stand (Helms 1998).

Resilience (*see* ecological resiliency)

Resiliency (*see* ecological resiliency)

Restoration (*see* ecological restoration)

Sanitation harvests involve the removal of trees to improve stand health by stopping or reducing the actual or anticipated spread of insects and disease (Helms 1998).

Safe zones (fire-free zones) are microsites where seedlings can establish and grow above the lethal flaming zone. Safe zones can be created by fire, such as the ash bed of a consumed log.

Single tree selection cutting is removal of individual trees of all size classes more or less uniformly throughout the stand to promote growth of remaining trees and to provide space for regeneration (Helms 1998).

Site index is an indicator of site quality expressed in terms of the average height of trees (defined as a certain number of dominants, codominants, or the largest and tallest trees per unit area) of a given species at a specified index or base age (Helms 1998).

Snags are standing dead or partially dead trees (snag-topped), often missing many or all limbs. They provide essential wildlife habitat for many species and are important for forest ecosystem function (Fig. 12).

Spatial pattern is the spatial arrangement of elements at the fine-, mid-, and landscape-scales that determine the function of a landscape as an ecological system (adapted from Helms 1998).

Stand density index is a widely used measure that expresses relative stand density based on some standard condition such as the relationship of number of trees to the stand quadratic mean diameter (Helms 1998) or the biological maximum density for a specific species (Long 1985).

Stands are areas in which the biophysical site conditions and the vegetation composition and structure are relatively homogeneous. Stands comprise the mid-scale, thus ranging in size from 100-1000 acres. Stands and patches are roughly synonymous

Structure is the physiognomy or architecture of an ecosystem with respect to the density, horizontal stratification, spatial pattern, and frequency distribution of vegetation (i.e., overstory, understory, etc.) size, age, and/or life form (adapted from SER 2004).

Surface fuel includes all fuels lying on or near the surface of the ground, consisting of leaf and needle litter, dead branch material, downed logs, bark, tree cones, and low stature living and dead plants (adapted from NWCG 2012).

Sustainability (*see* ecosystem sustainability)

Uneven-aged forests are forests that are comprised of three or more distinct age classes of trees, either intimately mixed or in small groups (Fig. 18) (Helms 1998).

Appendix 1. Common and Scientific Names for Species Referenced in This Document.

Common name	Scientific name
Tree species	
Arizona walnut	*Juglans major*
Arizona white oak	*Quercus arizonica*
Bigtooth maple	*Acer grandidentatum*
Blue spruce	*Picea pungens*
Bristlecone pine	*Pinus aristata*
Chihuahua pine	*Pinus leiophylla*
Corkbark fir	*Abies lasiocarpa* var. *arizonica*
Douglas-fir	*Pseudotsuga menziesii* var. *glauca*
Emory oak	*Quercus emoryi*
Evergreen oaks	*Quercus* spp.
Gamble oak	*Quercus gambelii*
Grey oak	*Quercus grisea*
Junipers	*Juniperus* spp.
Limber pine	*Pinus flexilis*
Pinyon pines	*Pinus* spp.
Ponderosa pine	*Pinus ponderosa*
Quaking aspen	*Populus tremuloides*
Silverleaf oak	*Quercus hypoleucoides*
Southwest white pine	*Pinus strobiformis*
Subalpine fir	*Abies lasiocarpa*
Two-needle pinyon	*Pinus edulis*
White fir	*Abies concolor*
Shrub species	
Big sagebrush	*Artemisia tridentata*
Black sagebrush	*Artemisia nova*
Ceanothus	*Ceanothus* spp.
Common juniper	*Juniperus communis*
Creeping barberry	*Mahonia repens*
Currant	*Ribes* spp.
Kinnikinnik	*Arctostaphylos uva-ursi*
Manzanita	*Arctostaphylos* spp.
Mountain mahogany	*Cercocarpus montanus*
Mountain ninebark	*Physocarpus monogynus*
Mountain snowberry	*Symphoricarpos oreophilus*
Netleaf oak	*Quercus rugosa*
New Mexico locust	*Robinia neomexicana*
Pointleaf manzanita	*Arctostaphylos pungens*
Rockspirea	*Holodiscus dumosus*
Shrub live oak	*Quercus turbinella*

Stansbury cliffrose	*Purshia stansburiana*
Sumac	*Rhus* spp.
Wavyleaf oak	*Quercus undulata*
Grass and sedge species	
Arizona fescue	*Festuca arizonica*
Blue grama	*Bouteloua gracilis*
Dryspike sedge	*Carex siccata*
Fringed brome	*Bromus ciliatus*
Indian ricegrass	*Achnatherum hymenoides*
Longtongue muhly	*Muhlenbergia longiligula*
Mountain muhly	*Muhlenbergia montana*
Muttongrass	*Poa fendleriana*
Parry's oatgrass	*Danthonia parryi*
Screwleaf muhly	*Muhlenbergia virescens*
Forb species	
Forest fleabane	*Erigeron eximius*
Nevada pea	*Lathyrus lanszwertii*
Parasitic plant species	
Douglas-fir dwarf mistletoe	*Arceuthobium douglasii*
Southwestern (Ponderosa pine) dwarf mistletoe	*Arceuthobium vaginatum* subsp. *cryptopodum*
Fungus species	
Armillaria root disease	*Armillaria* spp.
Black stain root disease	*Leptographium* spp.
Insect species	
Bark beetles	*Dendroctonus* spp. and *Ips* spp.
Douglas-fir tussock moth	*Orgyia pseudotsugata*
Roundheaded pine beetle	*Dendroctonus adjunctus*
Spruce budworm	*Choristoneura occidentalis*
Mammal species	
Ground squirrels	*Callospermophilus* spp.
Coyote	*Canis latrans*
Tassel-eared squirrel	*Sciurus aberti*
Hares	*Lepus* spp.
Bobcat	*Lynx rufus*
Rabbits	*Sylvilagus* spp.
Bird species	
Northern goshawk	*Accipiter gentilis*
Merriam's turkey	*Meleagris gallopavo* var. *merriami*

Appendix 2. Major Ponderosa Pine Forest Subtypes: (a) Ponderosa Pine/Bunchgrass, (b) Ponderosa Pine/Gambel Oak, (c) Ponderosa Pine/Evergreen Oak, and (d) Ponderosa Pine/Evergreen Shrub.

Rocky Mountain Research Station

The Rocky Mountain Research Station develops scientific information and technology to improve management, protection, and use of the forests and rangelands. Research is designed to meet the needs of the National Forest managers, Federal and State agencies, public and private organizations, academic institutions, industry, and individuals. Studies accelerate solutions to problems involving ecosystems, range, forests, water, recreation, fire, resource inventory, land reclamation, community sustainability, forest engineering technology, multiple use economics, wildlife and fish habitat, and forest insects and diseases. Studies are conducted cooperatively, and applications may be found worldwide. For more information, please visit the RMRS web site at: www.fs.fed.us/rmrs.

Planning for Connectivity

A guide to connecting and conserving wildlife within and beyond America's national forests

Defenders of Wildlife

The Center for Large Landscape Conservation

Wildlands Network
Reconnecting Nature in North America

Yellowstone to Yukon Conservation Initiative

ACKNOWLEDGEMENTS

Planning for Connectivity is a product of The Center for Large Landscape Conservation, Defenders of Wildlife, Wildlands Network and Yellowstone to Yukon Conservation Initiative. This guide focuses on requirements established under the National Forest System land management planning rule to manage for ecological connectivity on national forest lands and facilitate connectivity on planning acrosss land ownerships. The purpose of the guide and its parent publication, *Planning for Diversity*, is to help people inside and outside of the Forest Service who are working on forest plan revisions navigate these complex diversity and connectivity requirements.

TABLE OF CONTENTS

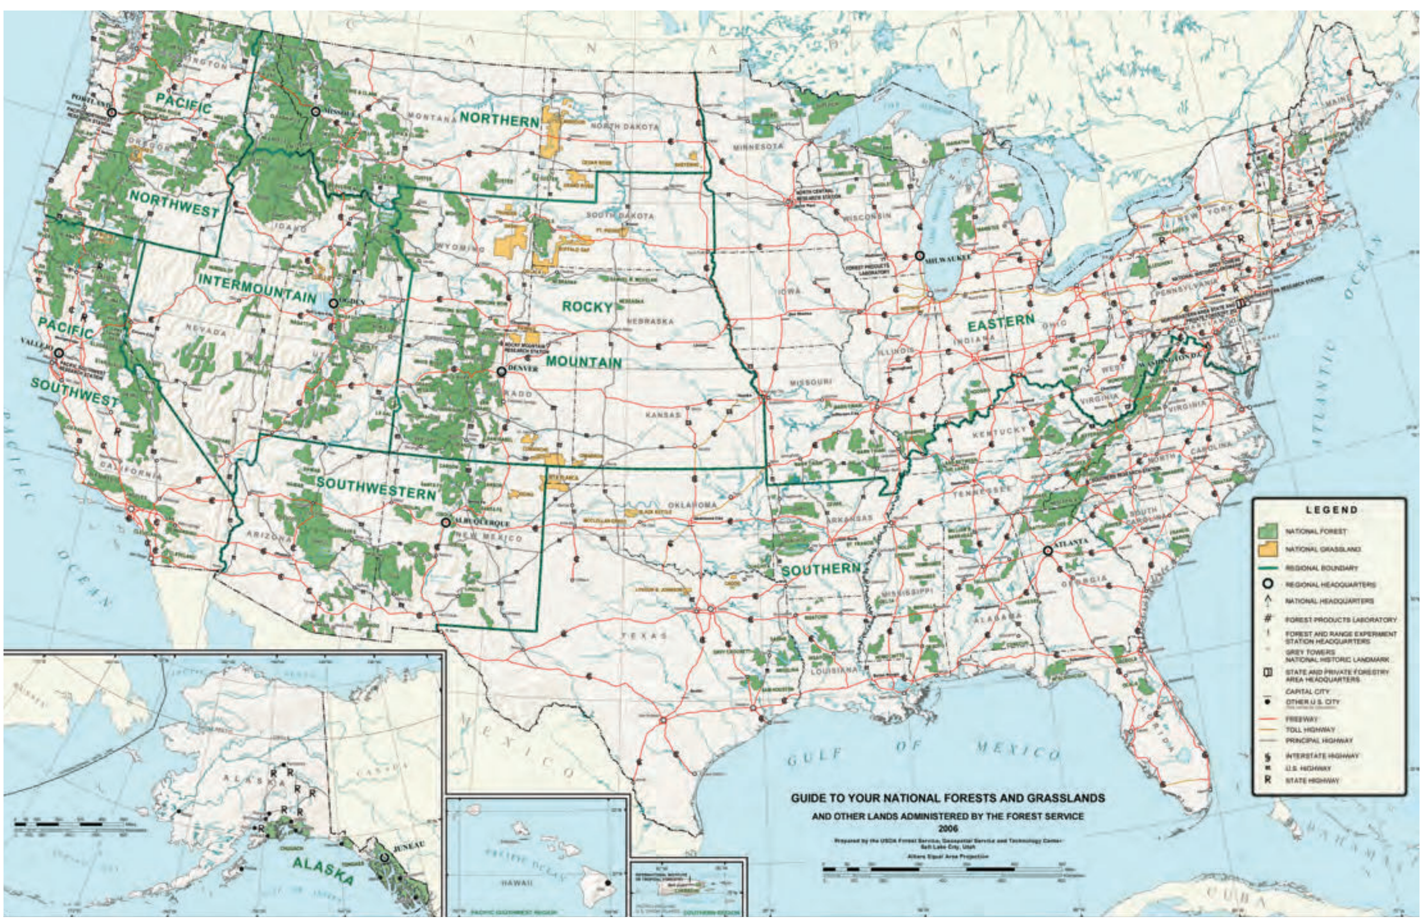
INTRODUCTION

The United States Forest Service manages more than 193 million acres—over 8 percent of all U.S. lands—an area about the size of Texas and twice the size of the National Park System. The National Forest System comprises 154 national forests and 20 national grasslands and one national prairie (collectively referred to as "national forests" in this guide). Located in 42 states, Puerto Rico and the U.S. Virgin Islands, these public lands are essential to the conservation of wildlife habitat and diversity. National forests encompass three-quarters of the major U.S. terrestrial and wetland habitat types—including alpine tundra, tropical rainforest, deciduous and evergreen forests, native grasslands, wetlands, streams, lakes and marshes. This variety of ecosystems supports more than 420 animals and plants listed under the Endangered Species Act (ESA) and an additional 3,250 other at-risk species.

To guide the management of each national forest, the Forest Service is required by law to prepare a land management plan (forest plan). Forest plans detail strategies to protect habitat and balance multiple uses to ensure the persistence of wildlife, including at-risk and federally protected species.

In April 2012, the Forest Service finalized regulations implementing the National Forest Management Act (NFMA). These regulations, commonly referred to as the "2012 Planning Rule" established a process for developing and updating forest plans and set conservation requirements that forest plans must meet to sustain and restore

The National Forest System



the diversity of ecosystems, plant and animal communities and at-risk species found on these public lands (36 C.F.R. §§ 219.1-219.19, abbreviated throughout this report by omitting “36 C.F.R. §”).

The forest planning rule includes explicit requirements for managing for ecological connectivity on national forest lands and facilitating connectivity planning across land ownerships—the first such requirements in the history of U. S. public land management. The pending revisions of most forest plans provide a significant opportunity to protect and enhance the diversity of habitat and wildlife on national forest lands by developing forest plans that promote the conservation and restoration of ecological connectivity.

This guide is designed to help people, working within and outside of the Forest Service, develop effective connectivity conservation strategies in forest plans developed under the 2012 Planning Rule. It summarizes the role of connectivity within the conservation framework of the rule and offers guidance and examples of how to conduct connectivity planning in the land management planning process.

The guide is a collaboration of Defenders of Wildlife, The Center for Large Landscape Conservation, Wildlands Network and Yellowstone to Yukon Conservation Initiative and is our collective interpretation of the connectivity requirements of the 2012 Planning Rule. The guide is intended to add value to official agency policies developed to support implementation of the rule. In January 2015, the Forest Service published Final Agency Directives for Implementation of the 2012 Planning Rule (FSM 1900 Planning, FSH 1909.12). While this guide and those directives may in some cases describe different approaches to implementing the connectivity requirements of the planning rule, we believe our interpretations are consistent with the planning rule and NFMA and hope the guide is viewed as a useful companion set of recommendations from the perspective of conservation organizations experienced in national forest planning, connectivity science and policy.

The guide covers the unique connectivity aspects of the planning rule, a rule that addresses complex ecosystem and species conservation processes and has many specific requirements.

How to Use This Guide

Planning for Connectivity presents guidance and best practices for connectivity planning, including examples from case studies in forest planning. Resources associated with the case studies are listed in the references section. We suggest using this guide in tandem with *Planning for Diversity,* a companion publication that addresses the overarching conservation framework of the 2012 Planning Rule. *Planning for Diversity,* additional resources on diversity and connectivity science and planning and a collection of forest planning case studies are available online at www.defenders.org/forestplanning.

THE IMPORTANCE OF CONNECTIVITY

It is useful to think of connectivity contributing to both the structure and function of ecosystems and landscapes. Structural connectivity is the physical relationship between patches of habitat or other ecological units; functional connectivity is the degree to which landscapes actually facilitate or impede the movement of organisms and processes of ecosystems (Ament et al. 2014).

The structure or pattern of an ecosystem or landscape can be defined as the arrangement, connectivity, composition, size and relative abundance of patches that occur within an area of land at a given time. Patches are surface areas that differ from their surroundings in nature or appearance (Turner et al. 2001). They can be characterized by vegetation type, seral stage, habitat type or other features relevant to a species and also by the condition of surrounding lands, which can significantly affect the biological character of a habitat patch.

Fragmentation, the breaking up of habitat or cover type into smaller disconnected patches (Turner et al. 2001), may result from natural or anthropogenic disturbances that introduce barriers to connectivity. In natural landscapes, patches that differ from the surrounding area would likely be areas disturbed by fire, flood, blowdown or other natural processes. In managed landscapes, habitat or cover can be fragmented by human caused disturbances such as road-building or removal of vegetation. In natural and managed fragmented landscapes, patches can be thought of as the remaining undisturbed areas. The greatest conservation needs are usually associated with maintaining or restoring connectivity among patches.

©HOWIE GARBER

The arrangement of patches of vegetation defines the pattern of a landscape like this one in Medicine Bow National Forest.

Other terms related to connectivity and wildlife movements include (Ament et al 2014):

- **Corridor.** A distinct component of the landscape that provides connectivity (think of it as a linear patch).
- **Linkage area or zone**. Broader regions of connectivity important to maintain ecological processes and facilitate the movement of multiple species.
- **Permeability.** The degree to which landscapes are conducive to wildlife movement and sustain ecological processes.

The 2012 Planning Rule defines connectivity as:

> *Ecological conditions that exist at several spatial and temporal scales that provide landscape linkages that permit the exchange of flow, sediments, and nutrients; the daily and seasonal movements of animals within home ranges; the dispersal and genetic interchange between populations; and the long distance range shifts of species, such as in response to climate change* (219.19).

The planning rule definition reflects both structural and functional aspects of connectivity. The rule's reference to spatial scales and "landscape linkages" suggests a structure of connected patches and ecosystems. Functional connectivity is also part of the definition: water flows, sediment exchange, nutrient cycling, animal movement/dispersal, species climate adaptation and genetic interchange are all ecological processes that are sustained by connectivity.

Any comprehensive strategy for conserving biological diversity requires maintaining habitat across a variety of spatial scales and includes the maintenance of connectivity, landscape heterogeneity and structural complexity (Lindenmayer and Franklin 2002). Connectivity is especially important for enabling adaptation to changing stressors, including climate change. The challenge of climate change was a driving factor in the development of the 2012 Planning Rule (77 Fed. Reg. 21163). A review of 22 years of recommendations for managing biodiversity in the face of climate change found improving landscape connectivity is the most frequently recommended strategy for allowing biodiversity to adapt to new conditions (Heller and Zaveleta 2009).

Wildlife species are becoming increasingly isolated in patches of habitat surrounded by a human-dominated landscape. Exacerbating this fragmentation is the effect of exurban development that continues to encroach on Forest Service lands (Hansen et al. 2005; Stein et al. 2007). The distribution of many wildlife populations continues to shrink as a result. Aquatic and terrestrial landscape patterns have been substantially altered, reducing or eliminating ecological connectivity for many wildlife populations. Physical barriers with human development further reduce connectivity. Changes in habitat, such as the simplification of complex forest vegetation, can also make critical areas for movement less permeable to some species. Scientists recognize that preserving or enhancing connectivity can be a practical tool for conserving biodiversity in such circumstances (Worboys et al. 2010).

THE 2012 FOREST PLANNING RULE

The 2012 Planning Rule is a federal regulation implementing NFMA (1600 U.S.C. § 1600 et seq.). NFMA was enacted in 1976 in large part to elevate the value of ecosystems, habitat and wildlife on our national forests to the same level as timber harvest and other uses. NFMA codified an important national priority: forest plans must provide for the diversity of habitat and animals found on national forests.

NFMA established a process for integrating the needs of wildlife with other multiple uses in forest plans. Most importantly, the law set a substantive threshold Forest Service actions must comply with for sustaining the diversity of ecosystems, habitats, plants and animals on national forests. However, the law gave discretion to the Forest Service, through the development of forest planning regulations and forest plans, to define that threshold.

THE PLANNING PROCESS

According to NFMA, forest plans are to be revised on a 15-year cycle. The planning rule provides a process for developing, revising or amending plans that is adaptive and science-based, engages the public and is designed to be efficient, effective and within the agency's ability to implement (77 Fed. Reg. 21162).

The planning rule establishes a three-phase process:

1. **Assessment**. The assessment identifies and evaluates information relevant to the development of a forest plan. The assessment is used during plan revision to evaluate what needs to change in the current plan, including what is needed to meet the requirements of the planning rule.
2. **Development.** During the plan development stage, the Forest Service develops and finalizes the forest plan and plan monitoring program. A draft proposal is developed and management alternatives are evaluated through the process established by the National Environmental Policy Act (42 U.S.C. § 4321 et seq.).
3. **Implementation/monitoring.** After finalizing the forest plan, the agency begins to implement the plan, including the development and implementation of management projects. Projects must be consistent with the forest plan and implementation of the plan must be evaluated through a monitoring program. Monitoring information is then evaluated to determine if aspects of the forest plan should be changed.

In addition, the Forest Service must use the best available scientific information to inform the planning process (219.3) throughout all three phases.

The planning rule describes these phases as iterative, complementary and sometimes overlapping. The intent is to provide a planning framework that is responsive to new information and changing conditions.

FOREST PLAN COMPONENTS

Forest plans guide subsequent project and activity decisions, which must be consistent with the forest plan. Forest plans do this through the use of plan components, the basic building blocks of forest plans. Plan components (Table 1) shape implementation of the forest plan and are the means of meeting the requirements of the 2012 Planning Rule.

Two fundamental types of plan components are associated with the diversity requirements of the rule: landscape components and project components.

Landscape components relate to the vision and priorities for the plan area, a landscape larger than individual project areas. These components are outcome-oriented, describe how the Forest Service would like the plan area to look and function and include desired conditions and objectives. Projects to be initiated under the forest plan are designed to contribute to achieving one or more of these outcomes. It is important that desired conditions and objectives be specific enough to establish a purpose and need for the projects designed to help achieve them.

Project components pertain to how individual projects are designed and implemented under the forest plan. They include standards, guidelines and suitability determinations that prohibit specific uses. They can preclude or regulate particular management options, dictate the outcome specifications for project areas or establish procedures

Table 1. Plan components under the 2012 Planning Rule

Plan Component	Description (219.7(e))
Desired Conditions (Landscale-level)	A description of specific social, economic and/or ecological characteristics of the plan area (or a portion of the plan area) toward which management of the land and resources should be directed. Desired conditions must be described in terms specific enough to allow progress toward their achievement to be determined, but do not include completion dates.
Objectives (Landscape-level)	A concise, measurable and time-specific statement of a desired rate of progress toward a desired condition or conditions. Objectives should be based on reasonably foreseeable budgets.
Standards (Project-level)	A mandatory constraint on project and activity decision-making established to help achieve or maintain the desired condition or conditions, to avoid or mitigate undesirable effects or to meet applicable legal requirements.
Guidelines (Project-level)	A constraint on project and activity decision-making that allows for departure from its terms as long as the purpose of the guideline is met. Guidelines are established to help achieve or maintain a desired condition or conditions, to avoid or mitigate undesirable effects or to meet applicable legal requirements.
Suitability of Lands (Project-level)	Specific lands within a plan area are identified as suitable for various multiple uses or activities based on the desired conditions applicable to those lands. The plan also identifies lands within the plan area as not suitable for uses that are not compatible with desired conditions for those lands.

that must be followed in preparing projects. It is very important to note that project plan components—especially standards—are most useful when greater certainty is important, such as in meeting diversity requirements necessary to protect at-risk species. Under the planning rule, every action proposed on Forest Service lands must comply with standards and guidelines and may not occur on lands unsuitable for that action.

DIVERSITY

NFMA requires that the Forest Service's planning regulations "provide for diversity of plant and animal communities based on the suitability and capability of the specific land area in order to meet overall multiple-use objectives" (16 U.S.C. § 1604(g)(3)(B)). This diversity requirement has been interpreted by the agency in the NFMA planning regulations and by the courts.

The Forest Service has interpreted the diversity requirement in NFMA through the development of the 2012 Planning Rule, which offers an approach to meeting the diversity requirement described in more detail in the following section on the ecosystem-species approach. A pivotal piece of the diversity interpretation is the persistence of individual species on national forest lands. Maintaining viable populations of native species is the scientifically accepted method of achieving the conceptual goal of maintaining species diversity. According to a 1999 Committee of Scientists report commissioned for the purposes of forest planning, "[d]iversity is sustained only when individual species persist; the goals of ensuring species viability and providing for diversity are inseparable" (Committee of Scientists 1999: 38).

The federal judiciary's interpretation of the diversity requirement in the rule include a ruling that the NFMA diversity mandate not only imposes a substantive standard on the Forest Service, it "confirms the Forest Service's duty to protect [all] wildlife" (*Seattle Audubon Society v. Moseley*, 1489). Courts have also recognized that the Forest Service's "statutory duty clearly requires protection of the entire biological community" (*Sierra Club v. Espy*, 364).

THE ECOSYSTEM-SPECIES APPROACH

Three overarching substantive requirements (Table 2) in the planning rule pertain to NFMA's diversity requirement:

1. Maintain or restore the ecological integrity of terrestrial and aquatic ecosystems (219.9(a)).
2. Maintain or restore the diversity of ecosystems and habitat types (219.9(a)).
3. Provide the ecological conditions necessary for at-risk species (219.9(b)).

The fundamental premise of the planning rule for meeting the NFMA diversity requirement is that plan components for ecosystem integrity and diversity will provide the ecological conditions to both maintain the diversity of plant and animal communities and support the persistence of most (but not all) native species in a

Table 2. Ecological concepts and requirements of the 2012 Planning Rule[1]

Ecological Concept	Definition and Requirement from the Planning Rule (219.9, if applicable)
Ecosystem	*Definition:* A spatially explicit, relatively homogeneous unit of the Earth that includes all interacting organisms and elements of the abiotic environment within its boundaries. An ecosystem is commonly described in terms of its composition, structure, function and **connectivity**. *Requirement:* The plan must include plan components, including standards or guidelines, to maintain or restore the diversity of ecosystems and habitat types throughout the plan area. In doing so, the plan must include plan components to maintain or restore key characteristics associated with terrestrial and aquatic ecosystem types, rare aquatic and terrestrial plant and animal communities, and the diversity of native tree species similar to that existing in the plan area.
Ecological Integrity	*Definition:* The quality or condition of an ecosystem when its dominant ecological characteristics (e.g., composition, structure, function, **connectivity**, species composition and diversity) occur within the natural range of variation and can withstand and recover from most perturbations imposed by natural environmental dynamics or human influence. *Requirement:* The plan must include plan components, including standards or guidelines, to maintain or restore the ecological integrity of terrestrial and aquatic ecosystems and watersheds in the plan area, including plan components to maintain or restore their structure, function, composition and **connectivity**.
At-risk Species ▪ Threatened and Endangered ▪ Candidate and Proposed ▪ Species of Conservation Concern	*Definition:* Threatened and endangered species are federally listed under the ESA; proposed and candidate species have been either formally proposed or are being formally considered for listing under the ESA. Species of conservation concern are species for which the regional forester has determined that the best available science indicates substantial concern over the species' capability to persist over the long-term in the plan area. *Requirement:* The responsible official shall determine whether or not the (ecosystem) plan components provide the ecological conditions necessary to contribute to the recovery of federally listed threatened and endangered species, conserve proposed and candidate species, and maintain a viable population of each species of conservation concern within the plan area. If the responsible official determines that the (ecosystem) plan components are insufficient to provide such ecological conditions, then additional, species-specific plan components, including standards or guidelines, must be included in the plan to provide such ecological conditions in the plan area.
Ecological Conditions	*Definition:* The biological and physical environment that can affect the diversity of plant and animal communities, the persistence of native species and the productive capacity of ecological systems. Ecological conditions include habitat and other influences on species and the environment, e.g., the abundance and distribution of aquatic and terrestrial habitats, **connectivity**, roads and other structural developments, human uses and invasive species.
Viable Population	*Definition:* A population of a species that continues to persist over the long term with sufficient distribution to be resilient and adaptable to stressors and likely future environments.
Focal Species	*Definition:* A small subset of species whose status permits inference to the integrity of the larger ecological system to which it belongs and provides meaningful information regarding the effectiveness of the plan in maintaining or restoring the ecological conditions to maintain the diversity of plant and animal communities in the plan area. Focal species would be commonly selected on the basis of their functional role in ecosystems.

plan area (219.9). To meet the rule's requirements for at-risk species (which include federally listed threatened and endangered species, proposed and candidate species, and species of concern (SCC)), additional "species-specific" plan components may be necessary. The rule's two-tiered conservation approach (alternatively called the "ecosystem-species" or "coarse-fine filter" planning method) relies on the use of surrogate measures, or key characteristics,

1. Ecological "conditions" are defined broadly to include human structures and uses, while "ecological integrity" stresses dominant "characteristics" that suggest natural conditions and should not include human structures and uses. The term "key ecosystem characteristics" is commonly used in discussions of ecological integrity, but should not be understood to apply to human structures and uses in that context. Human structures and uses are nevertheless relevant to species viability and persistence, and therefore to diversity.

©SANDY SISTI

Connectivity is an ecological condition that pronghorn and other species need to persist within and beyond the boundaries of national forests and grasslands.

to represent the condition of ecosystems, as well as the identification of at-risk species and evaluation of whether those species will be sustained through ecosystem-level plan components, or whether they require specific management attention in the form of species-level plan components.

At the ecosystem scale, the rule requires forest plans to have plan components to maintain or restore the integrity of terrestrial and aquatic ecosystems in the plan area (219.9(a)(1)) and the diversity of ecosystems and habitat types (219.9(a)(2)). Essentially this requires forest plans to maintain or restore the variety of ecosystems and habitat types found on the forests (e.g., conifer forests, wetlands, grasslands), as well as the condition of the ecosystems themselves. If the ecosystem-scale plan components are not sufficient to provide ecological conditions (i.e., meet the conservation needs) for at-risk species, additional plan components to do so are required (219.9(b)(1)). In some cases, the Forest Service may determine that it is beyond its authority or "not within the inherent capability of the plan area" to provide those conservation conditions and thus other requirements apply (219.9(b)(2)).

Connectivity plays a key role in the rule's conservation approach (see Table 2). As a key characteristic of ecosystems, connectivity should be addressed through ecosystem-scale plan components in order to maintain or restore "ecological integrity." Connectivity may also be an "ecological condition" needed by individual species, and so forest plans may need to address connectivity at the species level. For example, a recent amendment to forest plans in Wyoming protects migration corridors between seasonal habitats for pronghorn (Ament et al. 2014).

The rule's approach to conservation planning relies on the use of key characteristics in assessments, planning and monitoring to represent the condition of ecosystems, as well as the identification of at-risk species, some of which may require connectivity conditions to persist. It will be necessary for forest plans to identify key characteristics of ecosystem connectivity, as well as structure, function and composition (Table 3).

The concept of ecological integrity is used to represent the status of an ecosystem. An ecosystem is considered to have integrity when its key ecosystem characteristics occur within the natural range of variation (NRV) (219.19). NRV can be thought of as a reference condition reflecting "natural" conditions. Those conditions can be estimated using information from historical reference ecosystems or by other science-based methods. For example, many current forest ecosystems exhibit landscape connectivity patterns that differ from historical or reference conditions. For the purpose of sustaining ecosystems and wildlife, the 2012 Planning Rule directs the Forest Service to manage key characteristics of ecosystems, including their connectivity characteristics, in light of these reference conditions.

It is therefore important that forest plans have plan components, including desired conditions, to move landscapes toward a more natural range of connectedness.

ISSUES OF SCALE

The definition of connectivity in the planning rule intends for it to be provided at appropriate ecological scales. Strategies for managing connectivity in forest plans will vary based on the relevant species and their particular requirements for connectivity. The planning process must consider the habitat needs of target species and the nature of their movements. Forest plans should provide for habitat connectivity to address localized movements, as well as landscape-scale linkages between larger blocks of habitat.

Land managers must look at the broader landscape context when addressing connectivity in forest plans (219.8(a)(1)). They should consider what they are connecting and be alert to connecting specific watersheds or other geographic areas identified as being relatively more important for a particular species. Aquatic species provide a good example of large-scale connectivity needs because the existence of a connected network of aquatic ecosystems is known to be critically important to migratory aquatic species, especially when disturbances occur.

Chinook salmon and other migratory fishes need a connected network of aquatic ecosystems to survive. Forest plans must consider the large-scale connectivity needs of these species.

For many species, persistence within a national forest depends on connectivity that extends beyond forest boundaries. While the Forest Service has no authority to regulate land uses outside national forests, it can influence conservation on adjacent lands by how it chooses to manage its own lands. A forest plan should consider

Table 3. The use of key characteristics in forest planning

Ecosystem Character	Definition (219.19)	Examples of Key Characteristics
Connectivity	Ecological conditions that exist at several spatial and temporal scales that provide landscape linkages that permit the exchange of flow, sediments and nutrients; the daily and seasonal movements of animals within home ranges; the dispersal and genetic interchange between populations; and the long-distance range shifts of species, such as in response to climate change.	Structural: size, number and spatial relationship between habitat patches, mapped landscape linkages and corridors. Functional: measure of ability of native species to move throughout the planning area and cross into adjacent areas.
Composition	The biological elements within the different levels of biological organization, from genes and species to communities and ecosystems.	A description of major vegetation types, patches, habitat types, soil types, landforms and wildlife populations.
Structure	The organization and physical arrangement of biological elements such as snags and down woody debris, vertical and horizontal distribution of vegetation, stream habitat complexity, landscape pattern and connectivity.	Arrangement of patches within a landscape, habitat types within a forest, trees within a forest stand, wildlife within a planning area.
Function	Ecological processes that sustain composition and structure such as energy flow, nutrient cycling and retention; soil development and retention; predation and herbivory; and natural disturbances such as wind, fire and floods.	Types, frequencies, severities, patch sizes, extent and spatial pattern of disturbances such as fires, landslides, floods and insect and disease outbreaks.

connectivity when prioritizing lands for acquisition or conservation easements on adjacent ownerships. At a finer scale, a forest plan's requirements for size and arrangement of patch characteristics may be sufficient to produce an appropriately structured landscape for connectivity.

CONNECTIVITY INFORMATION

The scientific literature includes many connectivity and corridor studies and analyses. Peer-reviewed connectivity information pertaining to all regions of the country is readily available to inform national forest planning. In recent years, the Forest Service Research and Development Branch itself has produced numerous materials on various aspects of connectivity that can be used to support analyses of conditions, trends and sustainability. The available literature includes general publications about the science of connectivity and research on specific locations and/or species.[2] Examples include Cushman and others' analysis of corridors (2012) and McKelvey and others' (2011) identification of wolverine corridors.

Independent analyses of connectivity are also now available for many areas. The nationwide system of Landscape Conservation Cooperatives (LCC) has prioritized managing for connectivity across the country. For example, the South Atlantic LCC is completing a project titled "Identifying and Prioritizing Key Habitat Connectivity Areas for the South Atlantic Region." The Western Governors Association spearheaded the development of databases and mapping systems in the western states to identify important habitat and corridors region-wide.

The planning rule also cites other governmental management plans as sources of information to consider in assessing and planning for connectivity (219.6(a)(1)). It is critical that forest plans take into account land uses on adjacent lands and the importance of such lands to connectivity. The Forest Service should engage with highway departments, state wildlife agencies, tribal governments and county planning organizations that might affect connectivity on adjacent or intervening landscapes. These entities may have identified potential corridors that should be recognized in the forest planning process.

CONNECTIVITY COORDINATION

There is an additional requirement in NFMA that is particularly important to developing plan components for connectivity. It is a procedural requirement that the planning process be "coordinated with the land and resource management planning processes of State and local governments and other Federal agencies" (16 USC § 1604(a)). One of the purposes of the planning rule was to "[e]nsure planning takes place in the context of the larger landscape by taking an 'all-lands approach'" (77 Fed. Reg. 21164).[3] To accomplish this, forest plans should consider how habitat is connected across ownership boundaries.

The planning rule accounts for this type of "all lands" connectivity by:

- Requiring assessments to evaluate conditions, trends and sustainability "in the context of the broader landscape" (219.5(a)(1)).
- Recognizing that sustainability depends in part on how the plan area influences, and is influenced by, "the broader landscape" (219.8(a)(1)(ii), (iii)).
- Requiring coordination with other land managers with authority over lands relevant to populations of species of conservation concern (219.9(b)(2)(ii)).
- Requiring coordination with plans and land-use policies of other jurisdictions (219.4(b)).
- Requiring consideration of opportunities to coordinate with neighboring landowners to link open spaces and take joint management objectives into account (219.10(a)(4)).

Achieving the broader scale "all-lands" goals of the planning rule requires partnerships and compatible management across landscapes among multiple landowners and jurisdictions. In particular, there is a need for a landscape-scale strategic approach to conserving connectivity. NFMA has established that the way to communicate a long-term and reliable management commitment for National Forest System lands is through forest plan decisions for specific areas.

There is a significant commitment to connectivity conservation within Forest Service policy and from many agency partners. Examples of coordinated multi-agency planning efforts that specifically address connectivity and can guide the Forest Service as it seeks to implement the new rule are summarized in Appendix A.

2. Forest Service research publications on the topic may be found by entering the search term "connectivity" at www.treesearch.fs.fed.us/.

3. The planning rule defines landscape as "[a] defined area irrespective of ownership or other artificial boundaries, such as a spatial mosaic of terrestrial and aquatic ecosystems, landforms, and plant communities, repeated in similar form throughout such a defined area" (219.19).

BEST PRACTICES FOR CONNECTIVITY PLANNING

The following sections present guidance and best practices for connectivity planning, including examples from case studies in forest planning. Resources associated with the case studies are listed in the references at the end of the guide. Additional forest planning case studies are available online at www.defenders.org/forestplanning.

ASSESSING CONNECTIVITY

The planning rule requires that assessments be conducted prior to plan revisions to determine what needs to be changed in the existing forest plan, to serve as the basis for developing plan components and to inform a monitoring program. The Forest Service must review all relevant existing information and then determine the best available scientific information about conditions, trends and sustainability for connectivity in relationship to the forest plan within the context of the broader landscape (219.5(a)(1)). The Forest Service must document in the assessment report "how the best available scientific information was used to inform the assessment" (219.6(b)).

For connectivity, the assessment should address both ecosystem and species-level connectivity issues. At the ecosystem-scale, the assessment needs to identify the ecosystems and habitat types within the planning area, and then evaluate the diversity and integrity of those based on information related to their structure, function, composition and connectivity.

We recommend including the following in an assessment of connectivity at the ecosystem level:

- The selection of key characteristics for connectivity (see Table 3, page 10).
- A discussion of the NRV or "reference conditions" for the characteristics (e.g., historical pattern and connectivity).
- An evaluation of system drivers (e.g., climate change) and stressors (e.g., barriers to connectivity) on the characteristics.
- A discussion of the future status of the characteristic under current management and the current plan.

The end result should be a connectivity assessment that can be used to determine:

- How the current plan needs to change to maintain or restore connectivity.
- What plan components may be necessary to achieve the ecosystem-based connectivity requirements in the rule.

Connectivity must also be assessed as a potential condition necessary to sustain individual species. In the assessment, the Forest Service will present information on the ecological needs of species so that plan components can be developed to meet the rule's requirements for species. Particular attention should be paid to the connectivity needs of all at-risk species. To demonstrate that plan components will be effective in maintaining a "viable population" in the plan area, the assessment must provide a means of determining a "sufficient distribution" (see Table 2, page 8). The assessment should describe the relationship between connectivity and the distribution of species necessary for persistence, especially with regard to stressors like climate change. It is important that the assessment evaluate how species move, what barriers to those movements may exist and how the Forest Service can reduce the impact of those barriers within the context of recovery, conservation and viability.

The Flathead National Forest plan revision (assessment, 2014), which is being conducted under the 2012 Planning Rule, offers an example of assessing connectivity needs. The Flathead assessment includes a significant discussion of connectivity for terrestrial habitat, views connectivity from both an ecosystem and species perspective and considers both shorter term vegetation barriers on the forest and longer term human barriers between national forest lands. The example below shows how the Flathead National Forest presented a key ecosystem characteristic, description and data source for connectivity (adapted from Flathead 2014: 103, Table 26):

Key Ecosystem Characteristic: Horizontal Patterns and Landscape Connectivity

Description: The horizontal pattern of forest size/structure classes across the landscape and the spatial linkages between them, which is influenced both by human activities, such as harvesting and development, and natural processes, such as wildland fire.

Data Source for Current Condition: Montana Natural Heritage Program databases; Flathead National Forest VMap; Flathead National Forest NRV analysis.

The assessment provides a description of current and reference (NRV) conditions and expected trends for this key characteristic, as well as an evaluation of the impact of stressors (e.g., from timber harvest and developments) on habitat. The following is a key finding from the assessment:

> *Significant departures from historical conditions in patch sizes and density was noted in the NRV analysis for nearly all forest structural classes forest-wide. This trend mirrored that occurring at the larger Northern Rocky Mountain ecoregion, where drastically increased forest fragmentation was noted. The analysis found a decrease in patch size and corresponding increase in patch density, resulting in a trend of increasing forest fragmentation. The changes were most dramatic for the early successional forest patches and found to be outside the range of historical variability, which is of particular concern to ecological integrity* (Flathead 2014: 137, internal citations omitted).

JOHN JACOBSON/WASHINGTON DEPARTMENT OF FISH AND WILDLIFE

The Flathead National Forest connectivity assessment for the fisher specifies that this at-risk species requires mature forests arranged in connected, complex shapes with few isolated patches.

The Flathead assessment also presented connectivity information for an at-risk species, the fisher. This information can be used to determine the effectiveness of the current plan in providing for habitat connectivity for the species or to develop new plan components:

> *At the scale of 50–100 km2 (12,355–24,710 acre) landscapes, fishers in northern Idaho and west-central Montana selected for home ranges with greater than 50 percent mature forest arranged in connected, complex shapes with few isolated patches, and open areas comprising <5 percent of the landscape. Jones and Garton (1994) stated that preferred habitat patches should be linked by travel corridors of closed canopy forest and that riparian areas make excellent corridors provided they are large enough to enable fishers to avoid predation* (Flathead 2014: 197).

CONNECTIVITY MANAGEMENT AREAS

For connectivity, it is especially important to determine where plan components will apply. While it may be relatively easy to state desired forest-wide conditions related to connectivity, this approach by itself fails to focus efforts on areas with known connectivity values (e.g., roadless areas) and may not effectively promote integration with other uses that can lead to recognition of conflicts.

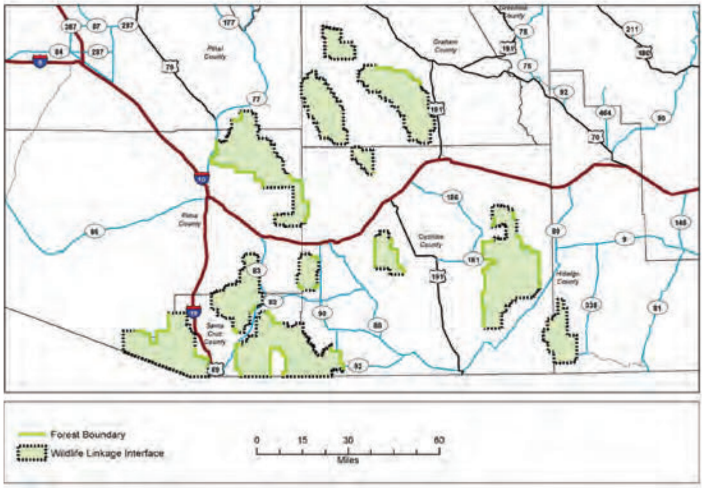
The planning rule states that the plan must indicate to which part of the plan area each plan component applies (219.7(e)). It defines "management areas" as parts of the plan area that have "the same set of applicable plan components" (219.19). Desired conditions and other plan components should be specified for particular linkage areas or corridors where they can be identified and the assessment finds them to be important to the persistence of target species in the plan area. Where connectivity is constrained, it may be necessary to identify specific areas to be managed as patches and their connecting corridors. Identifying specific management area(s) for connectivity provides clear forest plan direction on the importance of these areas and clarity for future projects.

The following case studies are examples of spatially recognizing connectivity in forest planning. An additional example is provided in the section on "Barriers to Connectivity" on page 18.

CASE STUDY: Wildlife Linkages in the Sky Islands

The mountainous "sky islands" of the Coronado National Forest in Arizona are made up of forested ranges separated by valleys of desert and grassland plains. They are among the most diverse ecosystems in the world because of their topographic complexity and location at the convergence

Figure 1. Wildlife linkages on the Coronado National Forest



Source: Coronado 2013: 64, Figure 3

U.S. FISH AND WILDLIFE SERVICE

A remote camera captured this image of an ocelot in the Huachuca Mountains of Arizona, an area where the proliferation of highways has affected connectivity among ocelot populations. To address the problem, the Coronado National Forest plan designated linkage areas on the boundary of the forest to coordinate connectivity management with other jurisdictions.

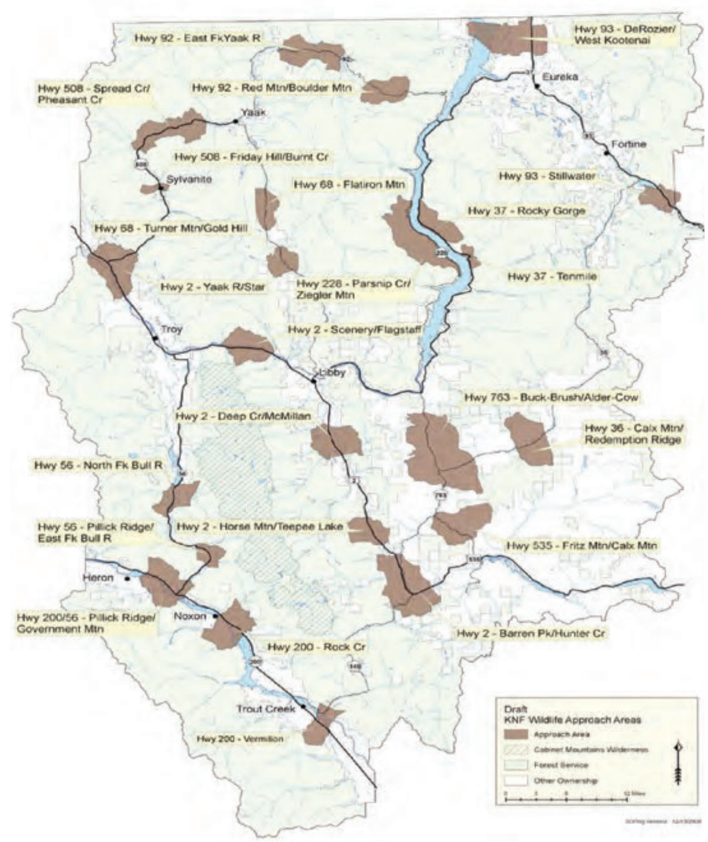
of several major desert and forest biological provinces. The valleys act as barriers to the movement of certain woodland and forest species. Species such as mountain lions and black bears depend on movement corridors between mountain islands to maintain genetic diversity and population size. Ocelots and jaguars at the northern end of their range here depend on connectivity to source populations in Mexico. The proliferation of highways and resulting increase in the number of road deaths among dispersing ocelots has affected connectivity among ocelot populations and colonization of new habitats. Movement corridors for jaguars in the American Southwest and northern Mexico are not well known but probably include a variety of upland habitats that connect some of the isolated, rugged mountains, foothills and ridges in this region.

The revised plan for the Coronado (draft, 2013) designates "wildlife linkages interface" areas, based on a statewide interagency effort that produced *Arizona's Wildlife Linkages Assessment* (Arizona Wildlife Linkages Workgroup 2006). The forest plan recognized that land management outside of the national forest boundaries affects biological resources on the national forest. Using data from the interagency group, the plan designates linkage areas on the boundary of the national forest (see Figure 1). These designated areas have management direction to maintain and reduce connectivity barriers and to coordinate connectivity management with other jurisdictions.

CASE STUDY: Grizzly Bear Approach Areas

The Kootenai National Forest in Idaho and Montana provided an excellent example of how to plan strategically for connectivity that has been confined to identifiable corridors and linkage areas. In 2008, the Kootenai identified and mapped locations of 24 approach areas important for grizzly bear connectivity using the best available scientific information from existing government and nongovernmental organizations, criteria for barriers (land ownership, topography, forest cover, land development) and wildlife use (Figure 2). Approach areas were defined as places where corridors or linkage zones cross what are termed "fracture zones" (e.g., valley bottoms

Figure 2. Grizzly bear approach areas on the Kootenai National Forest[4]



Source: Brundin and Johnson 2008: 3, Figure 1

4. The approach areas were not carried forward into the final, revised forest plan.

NATIONAL PARK SERVICE

The Kootenai National Forest plan identified "approach areas"—places where roads and other barriers to connectivity may hinder grizzly bear movement.

with highways and railways) where animal movements may be hindered and mortality risk elevated. The Kootenai also identified conservation measures that could be included in the forest plan as plan components for the approach areas and identified private lands where land exchanges, conservation easements or direct acquisition may be appropriate to improve management for one or more wildlife species (IGBC Public Lands Wildlife Linkage Taskforce 2004).

CASE STUDY: Blue Mountains Wildlife Corridor Management Area

The draft Blue Mountains National Forests plan (proposed plan, 2014), which covers the Malheur, Umatilla and Wallowa-Whitman national forests (the three forests span the states of Oregon, Washington and Idaho), establishes a management area identified as a "wildlife corridor" to connect wilderness areas and provide for landscape connectivity and defined as follows:

> *Wildlife corridors are areas designed to maintain habitat linkages between wilderness areas. Although disagreement exists regarding the utility of corridors, this management area emphasizes management for landscape connectivity, which is "the degree to which the landscape facilitates or impedes movement among resource patches," [sic] (Taylor et al. 1993) or "the functional relationship among habitat patches, owing to the spatial contagion of habitat and the movement responses of organisms to landscape structure," [sic] (With et al. 1997). A wide variety of vegetation structure and composition is present, with some showing evidence of past human disturbance and others showing affects primarily from natural disturbances, such as wildfires. Both summer and winter motor vehicle travel is restricted to designated routes. Recreation users can expect to find evidence of human activity in the form of vegetation management, mining, and road building. However, many of the roads that are closed to motor vehicle travel occur in these areas* (Blue Mountains 2014: 90).

The plan also provides a "strategy" for each management area. While the draft forest plan has drawn some criticism over unrelated issues, establishing a management area for corridors based on landscape function and structure allows for the design of habitat linkages in a variety of forms other than just simple linear connection between habitat patches.

LANDSCAPE PLAN COMPONENTS FOR CONNECTIVITY

Forest plan connectivity assessments should indicate if plan components are necessary to maintain or restore connectivity, either as an important contribution to ecological integrity or to provide conditions necessary for an at-risk species. An early consideration in forest plan connectivity planning should be the desired structure and pattern of the planning area landscape and the development of landscape plan components—desired conditions and objectives, where the desired condition describes how the connected landscape should look, and the objectives describe the timeframe and steps for achieving the desired condition.

Forest plans should include desired conditions and objectives for the sizes and distribution of habitat patches and other key characteristics of connectivity. It is also important to show the general areas where connectivity will be emphasized on a map and that the identification and management of these areas take into account the role and contribution of national forest lands to connectivity across other land ownerships.

©ALANNA SCHMIDT

The Canada lynx, a species listed as threatened under the Endangered Species Act, requires connected habitat across wide areas. Forest plan standards are in place to ensure that the connectivity and other habitat needs of lynx are met on national forests.

Table 4. Examples of landscape connectivity plan components in forest plans

Landscape Plan Components	Case Study and Comments
▪ Forest boundaries are permeable to animals of all sizes and offer consistent, safe access for ingress and egress of wildlife. In particular, segments of the national forest boundary identified in [the wildlife linkages interface] remain critical interfaces that link wildlife habitat on both sides of the boundary. Fences, roads, recreational sites and other man-made features do not impede animal movement or contribute to habitat fragmentation.	The Coronado National Forest consists of isolated mountain ranges, leading the draft plan to explicitly recognize the importance of connectivity and the value of coordinated planning with adjacent jurisdictions. This is especially important to ocelots and jaguars, which occur here at the northern end of their range and depend on connectivity to source populations in Mexico (Coronado 2013). This is direction for a specific management area.
▪ Retain natural areas as a core for a regional network while limiting the built environment to the minimum land area needed to support growing public needs. ▪ Reduce habitat loss and fragmentation by conserving and managing habitat linkages within and, where possible, between the national forests and other public and privately conserved lands. ▪ Preserve wildlife and threatened, endangered, proposed, candidate and sensitive species habitat and connecting links between the San Diego River Watershed and San Dieguito/Black Mountain.	The forest plan for the Cleveland National Forest was revised in conjunction with three other California national forests. The forests face a common management challenge of collaborating in nontraditional formats with local communities and governments to maintain and restore habitat linkages between the national forests and other open space reserves. This is forest-wide direction, but also refers to specific locations.
Landscape patterns are spatially and temporally diverse and have a positive influence on overall ecological function and scenic integrity. Landscape patterns provide connectivity, allowing animals to move across landscapes. Landscape patterns are resilient and sustainable, considering the range of possible climate change scenarios. The plans include a forest-wide desired condition that mentions “the ability of species and individuals to interact, disperse, and find security within habitats in the planning area” (Blue Mountains 2014: 30).	The Blue Mountains National Forests provide an important wildlife corridor connecting habitats and wildlife migration routes between the Rocky Mountains and central Oregon (Blue Mountains 2014). This is forest-wide direction about landscape patterns, in addition to the specific management area direction described above.
Federal ownership is consolidated when opportunities arise to improve habitat connectivity and facilitate wildlife movement.	This is forest-wide direction in the proposed action for the Nez Perce-Clearwater plan revision for use in subsequent land adjustment planning. Identifying priority locations in the plan would be more helpful (Nez Perce-Clearwater 2014).

Table 4 presents examples of landscape connectivity plan components in forest planning. (The language of the plan components is either verbatim or summarized. See the “References” section for source materials.) It should be noted that these examples (drawn from older forest plans) would need to be worded more explicitly under the 2012 Planning Rule, which requires desired conditions to be “specific enough to allow progress toward their achievement to be determined” (219.7(e)(1)(i)).

PROJECT PLAN COMPONENTS FOR CONNECTIVITY

Project components pertain to how projects are designed and implemented under the forest plan. Standards and guidelines, and suitability determinations for connectivity should be designed to promote achievement of the desired conditions and objectives for connectivity. Connectivity standards should be developed when greater certainty is important, such as in meeting diversity requirements necessary to protect at-risk species.

Table 5 provides examples of standards and guidelines for connectivity in forest planning. (The language of the plan components may be verbatim or summarized. See the “References” section for source materials.)

AQUATIC ECOSYSTEM CONNECTIVITY

Forest Service lands are most often found in the higher elevations of watersheds where streams provide clear, high-quality water. Management of aquatic ecosystems often centers on providing habitat that will support important fisheries.

Plan components for ecosystem integrity (including connectivity) must take into account the interdependence of terrestrial and aquatic ecosystems (219.8(a)(1)). There

Table 5. Examples of connectivity standards and guidelines in forest plans

Project Connectivity Plan Component	Case Study and Comments
▪ Retain connections of at least 400 feet in width to at least two other [late-successional/old growth] stands. ▪ Connections should occur where medium diameter or larger trees are common, and canopy closures are within the top one-third of site potential. ▪ The length of connecting corridors should be as short as possible. ▪ Understory should be left in patches or scattered to assist in supporting stand density and cover.	The Eastside Screens are rules for logging adopted as amendments to forest plans east of the Cascade crest in Washington and Oregon in 1996. They are intended to protect remaining late-successional and old-growth forests and to retain "connectivity corridors" between them (USFS 1995).
▪ When highway or forest highway construction or reconstruction is proposed in linkage areas, identify potential highway crossings. ▪ [National forest] lands in lynx linkage areas shall be retained in public ownership. ▪ New permanent roads should not be built on ridge-tops or saddles, or in lynx linkage areas.	The Canada lynx was listed as a threatened species in March 2000, largely due to a lack of adequate regulatory mechanisms in existing land management plans for federal lands. Lynx are known to disperse over wide areas, therefore it was important to add conservation measures to forest plans for lynx connectivity, which the Forest Service did in 2007 (USFS 2007) .

is an additional requirement in the planning rule to maintain or restore the ecological integrity of riparian areas, "including plan components to maintain or restore structure, function, composition, and connectivity …" (219.8(a)). This must be done by establishing "riparian management zones" and applying plan components to them that address riparian management issues. In particular, plan components for riparian management areas must specifically address ecological connectivity, blockages of watercourses, and aquatic and terrestrial habitats (219.8(a)(3)).

Many connectivity issues become intertwined in riparian areas, and plans can address them in conjunction with either terrestrial or aquatic connectivity or both. At a broad scale, management of riparian zones contributes to overall ecological integrity by providing connectivity between watersheds for both terrestrial and aquatic species. Riparian zones also provide connectivity that contributes to the terrestrial and aquatic integrity of individual watersheds. At a fine scale, the integrity of riparian areas themselves depends on the quality of aquatic and terrestrial habitat and often requires connectivity within and from riparian areas to other systems, including the hydrologic connectivity of a water body to floodplains or groundwater (floodplain connectivity can be a limiting factor for fish).

Sophisticated conservation strategies for salmonid species have been included in forest plans in the inland Pacific Northwest for two decades. The "PACFISH" and "INFISH" conservation strategies (1995) developed by the Forest Service and the Bureau of Land Management address connectivity in two primary ways. At the broader scale, they designate watersheds where management will emphasize water quality and fish habitat. This includes existing stronghold populations of fish and, importantly, additional watersheds that can be connected to those strongholds and restored. This will create a network of connected high-quality habitat that allows recolonization after a disturbance event such as a wildfire, flood or drought has rendered an area temporarily unsuitable.

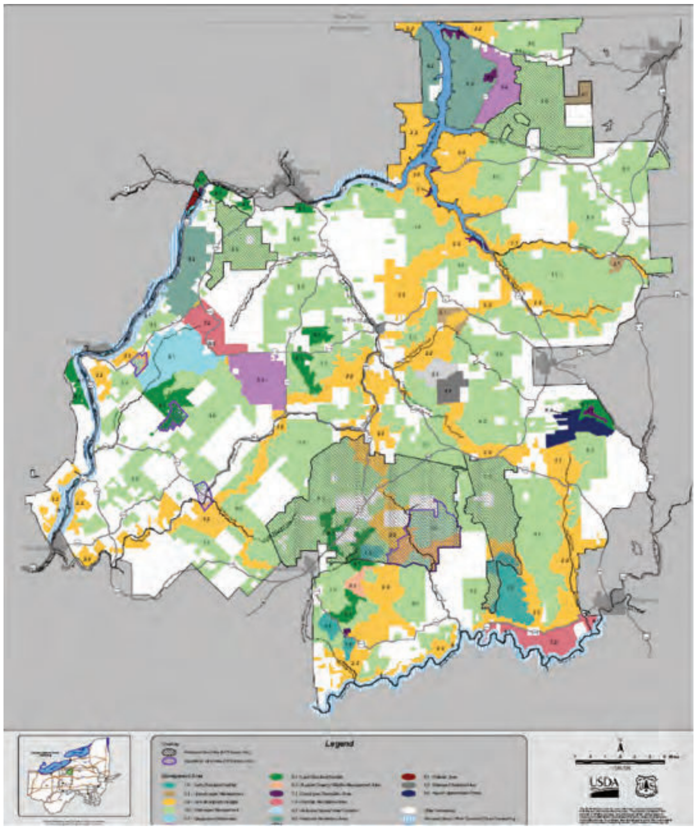
The Eastern Brook Trout Joint Venture, a partnership of state and federal agencies, nongovernmental organizations, and academic institutions, used a similar approach with the eastern brook trout in its native habitat (Maine to Georgia).According to its publication, *Conserving the Eastern Brook Trout: Action Strategies*, restoration should focus on habitat supporting populations that are doing relatively well, and then extend to adjacent habitats. An important part of this strategy is to "[i]dentify barriers to fish passage and re-establish habitat connectivity where possible" (Eastern Brook Trout Joint Venture 2008: 26).

The combination of designating watersheds and identifying connectivity barriers should lead to objectives that prioritize locations for restoration, such as the following connectivity objectives:

- Increase aquatic habitat connectivity through replacement of 90 culverts.
- Restore stronghold watersheds connectivity for aquatic species in four to six subwatersheds or on 80 to 120 stream miles.
- Establish self-sustaining brook trout populations in 10 percent of known extirpated key watersheds by 2025.

Existing forest plans also define riparian management areas, where standards and guidelines to protect aquatic resources apply to various management activities. While

Figure 3. Old forest connectivity management



Source: Allegheny National Forest Management Area Map (2007)

these plan components are primarily for the purpose of protecting resident fish, they also facilitate migration. The following type of standard would specifically address this connectivity issue: Construction or reconstruction of roads shall provide for passage of fish at all stream crossings.

BARRIERS TO CONNECTIVITY

National forest lands encompass a variety of permanent developments such as roads, railways, energy and mineral development infrastructure, recreation infrastructure and fencing. Evaluation and management of connectivity require determining the nature and effect of barriers on permeability and providing direction to reduce the effects of existing barriers and to avoid the creation of new ones. The more confined and unique the corridors or linkage zones are, the more attention should be paid to how barriers are managed. Forest plans must address barriers to connectivity that are relevant to ecological diversity and the persistence of species in a plan area.[5]

One key aspect of barriers that must be considered in relation to national forest management is their cause and degree of permanence. If barriers to wildlife movement and connectivity are due to natural disturbance (e.g., a forest opening caused by a fire or landslide), they can be viewed as transitory barriers that can be expected to "move" from place to place as new openings are created and then closed by natural succession. However, if the movement barrier for a particular species of wildlife is a lack of habitat that is difficult to restore, such as old-growth forest, the connectivity problem may be longer term and the need to protect existing patches using project plan components may be greater.

The Allegheny National Forest in Pennsylvania provides an example of old forest connectivity management, where habitat diversity was one of the key issues identified at the beginning of the plan revision process. The forest plan paid specific attention to "providing late structural and old growth forests and habitat connectivity across the landscape" (ROD, 2007: B-3). The revised plan established a management area for "late structural linkages" based on

©ELIZABETH ALDORA

Forest plans should recognize the value of rare habitats, such as old-growth forest like this in the Siuslaw National Forest, in providing for connectivity.

5. While the effectiveness of habitat corridors providing connectivity is no longer disputed (Gilbert-Norton et al. 2010), potential negative consequences may result from movement of invasive, exotic, and otherwise harmful species or diseases, especially in aquatic habitats. This has been noted especially for inland trout species, where enhancing connectivity could do more harm than good by promoting competition or hybridization with non-native species, or introducing diseases. These kinds of risks should be identified and mitigated to the extent possible when designing landscape connections. Moreover, efforts to connect landscapes that have not historically been connected should be avoided.

existing core blocks of wilderness areas, research natural areas, national recreation areas and other protected areas. It was also designed to specifically include areas of known goshawk nest sites and rattlesnake dens, thus affording additional protection for these species (see Figure 3).

ROADS AND CONNECTIVITY

Roads and their associated human uses are one of the most common, persistent and obstructive barriers to terrestrial and aquatic wildlife connectivity. The National Forest System has approximately 375,000 miles of roads.[6] Decisions to build, decommission, open or close roads can affect connectivity in significant ways. Recognition of the role of unroaded (i.e., roadless) areas for the purposes of connectivity planning is equally important. Forest plans provide the overall guidance for how many roads there will be on a forest and how they are to be used.

Use of roads by the public is also governed by the Forest Service "Travel Management Rule," regulations published in 2005 to establish a nationally consistent approach to local determinations of where excluding motorized use is necessary to protect other resources or, conversely, where such use is desirable and ecologically acceptable. The regulations require each national forest to identify and designate roads, trails, and areas that are open to motor vehicle use. Motorized use is prohibited anywhere that is not so designated. These decisions are part of travel management plans, and these plans must be consistent with forest plans.

Clearly, decisions to have a road or to allow motorized use should take into account the effect of that particular road on connectivity. To fully understand the effects, it is necessary to know what role an area or corridor is expected to play in providing connectivity and what else is likely to happen there that will affect its connectivity value. The forest plan is the place to provide answers to those questions.

Where motorized use is inconsistent with the desired condition for an area, including desired connectivity conditions, a forest plan can identify the area as one that is not suitable for motorized use. This precludes the establishment of motorized routes in the area. It should also lead to eliminating any existing motorized use through road or area closures.

Site-specific desired conditions for connectivity are helpful in deciding where to manage for motorized use. The Gallatin National Forest Travel Plan Final

Roads and their associated human uses are one of the most common, persistent and obstructive barriers to connectivity on national forest lands. The National Forest System has about 375,000 miles of roads.

6. See www.fs.fed.us/eng/transp/.

Environmental Impact Statement (2006) includes a site-specific goal for identified "wildlife corridors," which provides a good example of a desired condition that should be included in a forest plan:

> *Provide for wildlife movement and genetic interaction (particularly grizzly bear and lynx) between mountain ranges at Bozeman Pass (linking the Gallatin Range to the Bridger/Bangtails); across highway 191 from Big Sky to its junction with highway 287 (linking the Gallatin and Madison Mountain Ranges); the Lionhead area (linking the Henry's Lake Mountains to the Gravelly Mountains and areas west); Yankee Jim Canyon (linking the Absoroka Mountains to the Gallatin Range); and at Cooke Pass (linking the Absoroka/Beartooth Range to areas south)* (Gallatin 2006: 3-88 – 3-89).

A connectivity characteristic commonly used in forest plans to protect wildlife and fish habitat is road density. Road density limits are especially useful for protecting big game hunting opportunities. The presence and use of roads have also been found to create risks to movement of large carnivores such as grizzly bears, a federally listed threatened species. To comply with the ESA, forest plans in grizzly bear range include restrictions on road density.

The Flathead National Forest provides some of the most important grizzly bear habitat in the National Forest System. As a result of ESA consultation on the forest plan, the Forest Service adopted Amendment #19 in 1995 that applied objectives and standards for each of 70 grizzly bear management subunits across the Flathead (where national forest ownership is greater than 75 percent) (Flathead 1995). For example, an objective was developed stating that within five years total road density of greater than two miles per square mile would occur on less than 24 percent of the grizzly bear management unit and in 10 years that would be further reduced to less than 19 percent. Similarly, standards were used to ensure there would be no net increases in road densities above a certain threshold and to maintain the security of core grizzly bear habitat areas. These types of connectivity and security plan components have been successful in reducing the number of roads forest-wide by approximately 700 miles and increasing secure core area from 63 percent to 70 percent (Flathead 2012: unpaginated, Tables 16b-9 and 16b-10).

For terrestrial species, it is often the use of the road that is more of a barrier to connectivity than the physical presence of the road. Many current plans address the need to limit motorized access during big game hunting season or to protect sensitive big game habitat such as winter range.

CONCLUSION

The connectivity planning direction found in the 2012 Planning Rule provides a significant opportunity to develop and implement landscape- and project-scale connectivity strategies on Forest Service lands and to coordinate connectivity planning across land ownerships. To be successful, forest planning stakeholders—including Forest Service planners, conservation advocates, scientists and other agencies and governments—must collaborate to devise innovative approaches.

Connectivity planning also requires forward thinking to execute the vision of a connected landscape. There is no one way to develop and implement connectivity strategies within forest plans. We hope this guide stimulates innovative ideas and is a starting point for developing effective approaches to connectivity planning within forest plans.

APPENDIX:

EXAMPLES OF COORDINATED CONNECTIVITY PLANNING

Multi-Organization Initiatives, including the Forest Service

America's Great Outdoors Initiative

www.doi.gov/americasgreatoutdoors/index.cfm

One of the goals of the President's America's Great Outdoors Initiative is "the conservation of land, water, wildlife, historic, and cultural resources, creating corridors and connectivity across these outdoor spaces, and for enhancing neighborhood parks." The "Large Landscapes Initiative" seeks to "improve collaboration across federal agencies and with state and local partners, especially given the inherent cross-jurisdictional nature of restoring large landscapes." It currently includes a study of specific wildlife linkage locations across major highways in the "Crown of the Continent" ecosystem in Montana.

Department of the Interior, Landscape Conservation Cooperatives

www.fws.gov/landscape-conservation/lcc.html

LCCs provide a forum for federal agencies (including the Forest Service), states, Tribes, non-governmental organizations, universities and others to work together to coordinate management response to climate change at the landscape level. "New wildlife corridors" was one of the specific needs identified nationally. The Great Northern LCC partners, for example, agreed to conservation goals that prominently feature connectivity as an important element of ecosystem integrity, and they also identified "target species" that depend on connectivity. Land management plans would be the vehicle for the Forest Service to incorporate broader landscape conservation goals.

Western Governors' Association Wildlife Corridors and Crucial Habitat Initiative

www.westgov.org/wildlife-corridors-and-crucial-habitat

The Western Governors' Association's initial policy stated that federal land management agencies should identify key wildlife migration corridors in their land management plans. The Forest Service is participating in implementing this connectivity guidance. In November 2012, the Forest Service encouraged forest supervisors conducting forest planning to consider information compiled by states for this initiative as part of implementing the 2012 Planning Rule.

Grizzly Bear Recovery Planning

www.igbconline.org/index.php/population-recovery/grizzly-bear-linkage-zones

The Recovery Plan for Grizzly Bear identifies the need to evaluate potential linkage areas within and between recovery areas. The Interagency Grizzly Bear Committee (IGBC, which includes the Forest Service) determined that "… linkage zone identification and the maintenance of existing linkage opportunities for wildlife between large blocks of public lands in the range of the grizzly bear are fundamental to healthy wildlife." Maps of linkage areas have been developed by the U.S. Fish and Wildlife Service and sanctioned by the IGBC.

Forest Service Initiatives

Properly addressing connectivity in land management plans will also promote coordination and integration within the Forest Service and advance other agency prerogatives.

The Forest Service Strategic Framework for Responding to Climate Change includes "development of wildlife corridors to facilitate migration" as a strategy to address climate change effects (www.fs.fed.us/climatechange/pdf/Roadmapfinal.pdf). One of the "immediate initiatives" in the roadmap is connecting habitats to improve adaptive capacity by:

- Collaborating with partners to develop strategies that identify priority locations for maintaining and restoring habitat connectivity. Seeking partnerships with private landowners to provide migration corridors across private lands.
- Removing or modifying physical impediments to species movement most likely to be affected by climate change.
- Managing forest and grassland ecosystems to reduce habitat fragmentation.
- Continuing to develop and restore important habitat corridors for fish and wildlife.

The Forest Service Open Space Conservation Strategy states that "[o]ur vision for the 21st century is an interconnected network of open space across the landscape that supports healthy ecosystems and a high quality of life for Americans" (www.fs.fed.us/openspace/national_strategy.html).

LANDFIRE

To cite this guide, please use the following reference:

Helmbrecht, Donald J. and Kori Blankenship. 2016. Modifying LANDFIRE Geospatial Data for Local Applications. Available: http://www.conservationgateway.org/ConservationPractices/FireLandscapes/LANDFIRE/Pages/landfire.aspx.

Introduction

The LANDFIRE Program provides "wall-to-wall" geospatial data of vegetation, wildland fuel, fire regime, disturbance, and topographic characteristics for the United States (Rollins 2009). LANDFIRE data are often an excellent choice for wildland fire and land management planning applications due to their consistent mapping methodologies across land ownership boundaries and relevancy to common conservation and land management questions. LANDFIRE data are distributed free of charge through the Program's website at www.landfire.gov.

This guide will focus on LANDFIRE data for the conterminous United States, Alaska, and Hawaii. A subset of LANDFIRE data products is available for the Pacific and Caribbean U.S. insular areas; however, the mapping methodologies for these areas vary substantially enough from those for the conterminous U.S., Alaska, and Hawaii that we do not include discussion of these data in this version of the guide. We also focus primarily on LANDFIRE versions 1.0.5 (LANDFIRE 2001) through 1.3.0 (LANDFIRE 2012) as some major changes to mapping methodology occurred between version 1.0.0 (LANDFIRE National) and LANDFIRE 2001.

Although developed for sub-regional to national-scale planning applications, the utility of LANDFIRE data at finer scales has been demonstrated. The data are commonly applied on active wildland fire incidents (Noonan-Wright et al. 2011) and in landscape-level land management planning (Helmbrecht et al. 2012, Price et al. 2012, Scott et al. 2012, Tuhy et al. 2010). However, the applicability of LANDFIRE data at finer scales varies by the data product in question, its intended use, and location of interest. The LANDFIRE Program states that:

> *"Managers and planners must evaluate LANDFIRE data according to the scale and requirements specific to their needs (for example, habitat requirements for the species being considered or requirements by community leaders and interagency partners)…. It is the responsibility of the user to be familiar with the value, assumptions, and limitations of LANDFIRE products"* (USFS 2015).

It is within this context that we present this guide, with the purpose of providing direction on the critique and modification of LANDFIRE geospatial data products for local applications. This guide builds upon previous work on this topic by others (Stratton 2006, 2009; The Nature Conservancy 2011a; The Nature Conservancy 2011b; The Nature Conservancy 2013). It is not so much a "cookbook" or "how-to" guide, as the specifics vary greatly by data product, intended use, scale, and location. Rather, we present primary considerations for using and modifying the data for use in local applications and provide examples and demonstrations of available tools and methods for completing common critique and modification tasks.

This guide is presented in seven chapters:

Chapter 1 provides a brief overview of LANDFIRE data products; discusses general considerations of scale, accuracy, and resolution in the critique of LANDFIRE geospatial data; and provides examples of common reasons for modifying LANDFIRE geospatial data.

Chapter 2 presents a conceptual framework for critiquing and modifying geospatial data, emphasizing the importance of framing analysis objectives and an iterative approach.

Chapter 3 describes the LANDFIRE disturbance data mapping process and discusses considerations specific to data currency, disturbance causality, and modifying data to reflect changes due to new disturbances.

Chapter 4 defines LANDIFRE potential and existing vegetation data products; describes the LANDFIRE vegetation mapping process; and discusses considerations specific to application of the NatureServe Ecological Systems classification, map zone boundaries, and succession class mapping rules.

Chapter 5 defines LANDFIRE fuel data products; describes the LANDFIRE fuel mapping process; and discusses considerations specific to map zone boundaries, application scale, disturbance updates, and modeling.

Chapter 6 describes the LANDFIRE vegetation dynamics models and their role in developing fire regime and vegetation departure products and discusses considerations specific to the integrated nature of LANDFIRE vegetation products, knowledge uncertainty, map zone boundaries, differences between data versions, and conducting local vegetation departure analysis.

Chapter 7 presents two interpreted examples of critiquing and modifying LANDFIRE data for local applications. The first example focuses on using LANDFIRE data for wildfire hazard analysis in the Rogue Basin of southwest Oregon. The second example focuses on using LANDFIRE data for vegetation departure analysis in the southern Sierra Nevada Mountains.

Chapter 1: Background

LANDFIRE Product Overview

LANDFIRE produces more than 20 geospatial data layers, a suite of vegetation dynamics models representing pre-Euro-American settlement vegetation conditions, and databases with vegetation plot and management activities information. The geospatial data, which are the focus of this guide, cover all lands in the United States and are developed using methods that utilize Landsat imagery, plot data, and biophysical gradient modeling (Rollins 2009). The mapping methodology is generally consistent by version across all regions of the country. LANDFIRE periodically updates its data products to incorporate changes over time (Nelson et al. 2013, Table 1).

Table 1: Comparison of LANDFIRE versions 1.0.0 (LANDFIRE National) through 1.3.0 (LANDFIRE 2012).

LANDFIRE Version	Currency	Distribution Date	Version Information
National (1.0.0)	Circa 2001	2008	The first full iteration of LANDFIRE data based on Landsat imagery from 1999-2001.
2001 “Refresh” (1.0.5)	Circa 2001	2011	Enhanced National by improving biophysical setting and existing vegetation type, cover and height mapping.
2008 “Refresh” (1.1.0)	Circa 2008	2011	Updated 2001 products for disturbance and succession. Landsat 1984-2008 imagery analyzed for change.
2010 (1.2.0)	Circa 2010	2013-14	Products updated for disturbance and succession. Landsat 2007-2011 imagery analyzed for change. Refined urban, agriculture, and wetlands mapping.
2012 (1.3.0)	Circa 2012	2014-15	Products updated for disturbance and succession. Landsat 2010-2013 imagery analyzed for change.

LANDFIRE geospatial data can be divided into five primary categories: vegetation, wildland fuels, fire regime, disturbance, and topography (Table 2). The vegetation data layers characterize both existing and potential vegetation type, vegetation structure, and vegetation development stage, and are primary inputs for developing other data layers. The wildland fuel data layers depict surface and canopy fuel characteristics that are inputs to various geospatial fire modeling systems. The fire regime data layers estimate the fire frequency and severity prior to European-American settlement as well as the current condition of the vegetation within the context of the historical disturbance regime. The disturbance data layers depict landscape changes that result from natural disturbances (e.g. wildfires and hurricanes) and management activities (e.g. prescribed fire and timber harvest), and are used to update the vegetation and fuel data layers over time (Nelson et al. 2013). Finally, the topographic data layers are required inputs to common geospatial fire behavior modeling systems and are used as base data for developing other LANDFIRE data layers. Modification of topographic data (elevation, slope, and aspect) is uncommon and therefore not discussed in this guide.

Table 2: LANDFIRE data products organized by data category.

Data Category	Abbreviation	Data Products
Vegetation	EVT	Existing Vegetation Type
	EVC	Existing Vegetation Cover
	EVH	Existing Vegetation Height
	SCLASS	Succession Class[a]
	ESP	Environmental Site Potential
	BpS	Biophysical Setting
	--	Vegetation Dynamics Models[b]
	LFRDB	LANDFIRE Reference Database[c]
Fuel	FBFM13	13 Fire Behavior Fuel Models
	FBFM40	40 Fire Behavior Fuel Models
	CFFDRS	Canadian Forest Fire Danger Rating System (AK only)
	FCCS	Fuel Characteristics Classification System Fuelbeds
	FLM	Fuel Loading Models
	CC	Forest Canopy Cover
	CH	Forest Canopy Height
	CBD	Forest Canopy Bulk Density
	CBH	Forest Canopy Base Height
Fire Regime	FRG	Fire Regime Groups
	MFRI	Mean Fire Return Interval
	PLS	Percent Low-severity Fire
	PMS	Percent Mixed-severity Fire
	PRS	Percent Replacement-severity Fire
	VCC	Vegetation Condition Class[d]
	VDEP	Vegetation Departure[e]
Disturbance	DYEAR	Disturbance 1999-2012
	FdistYEAR	Fuel Disturbance
	VdistYEAR	Vegetation Disturbance
	Events	Public Events Geodatabase[f]
Topography	ASP	Aspect
	DEM	Elevation
	SLP	Slope

[a]LANDFIRE groups succession class with its fire regime datasets because it is used to assess current vegetation condition, but in this guide it is grouped with the vegetation datasets because it is created from a compilation of existing vegetation datasets.
[b]The Vegetation Dynamics Models are non-spatial products used as primary inputs for mapping the fire regime datasets, to provide rulesets for mapping succession classes and as an ancillary data source for mapping existing vegetation type, biophysical settings and fire behavior fuel models.
[c]A database with geo-reference plot information used for mapping the vegetation datasets.
[d, e]Vegetation condition class and vegetation departure were not created for LANDFIRE 2010.
[f]A geo-referenced collection of disturbance and management information used to create the disturbance datasets.

The remainder of this chapter presents general considerations about the critique and modification of LANDFIRE geospatial data. Subsequent chapters will provide greater detail about specific considerations in the vegetation, fuels, fire regime, and disturbance categories.

Considerations of Scale

A primary consideration when evaluating a geospatial data layer is its scale. Traditionally map, or cartographic, scale is defined as the mathematical relationship between a given feature on a map and that same feature on the ground. For example, a typical topographic map from the U.S. Geological Survey's 7.5-minute quadrangle series has a map scale of 1 to 24,000 (1:24,000) meaning that one map unit is equivalent to 24,000 of the same units on the ground. Geospatial data do not have a map scale in the traditional sense. A geographic information system (GIS) stores the exact coordinates of every feature in a geospatial data layer, allowing users to zoom in and out on the monitor to view data at nearly any map scale, regardless of the precision of the underlying source data. This does not mean that geospatial data do not have a scale; rather, the scale of geospatial data may be difficult to discern.

In a more general sense scale may be defined as the spatial (or temporal) dimension of an object or a process, and is characterized by grain and extent (Turner et al. 2001). Grain is the finest level of resolution in geospatial data. For raster data, grain refers to cell size and for polygon data (i.e., vector data), grain refers to the minimum mapping unit. LANDFIRE raster data have a 30m x 30m cell size—that is, each data cell, or pixel, represents a $900m^2$ (approximately 0.22 acre) area on the ground. LANDFIRE data therefore have a 30-meter spatial resolution, or grain size. However, LANDFIRE data are not intended to be accurate or useful at the extent of an individual pixel or small group of pixels. The scale at which LANDFIRE data are applicable varies by product, intended use, and the location of interest.

With geospatial data there are no concrete rules that specify the required scale for a given application. Different analyses require data at different scales. For example, the scale needed to identify threatened and endangered species habitat is different than the scale needed to distinguish forests from grasslands. The critical question is, are the data good enough to meet the analysis needs? Evaluating the data accuracy and resolution requirements of your analysis will help answer this critical question.

Considerations of Accuracy and Resolution

Evaluating the accuracy and resolution of LANDFIRE data will help determine its suitability for a given use. Two types of accuracy to evaluate are **positional accuracy**, or the ability of the data to reflect the true or accepted geographic location of features in space, and **content accuracy**, or the agreement between mapped units and the true or accepted value of those units. Likewise, evaluation of resolution includes **spatial resolution**, or the amount of ground area represented by a pixel, and **thematic resolution**, or the level of detail in the classification of map units. Issues with accuracy and resolution are not mutually exclusive—problems with one may result in problems with the other. Ultimately, the goal of understanding these issues is to evaluate the strengths and weaknesses of a geospatial data layer to determine its suitability for a particular analysis. Next we discuss considerations of accuracy and resolution relevant to LANDFIRE data.

Positional Accuracy

Positional accuracy refers to the ability of the data to reflect the true or accepted geographic location of features. There is little the end user of LANDFIRE data can do to improve issues of positional accuracy. Boundaries or distinctions between feature types (e.g., vegetation types) may not be precisely located solely due to the raster format of LANDFIRE data. The spatial resolution of raster data has a direct effect on positional accuracy: the larger the cell size the less accurate the location (Figure 1). However, these should be minor issues if applying LANDFIRE data at an appropriate scale, one in which the data meet the analysis needs. It is also worth noting that vector data, such as the LANDFIRE event polygons, and plot data from the LANDFIRE Reference Database, are not immune to error in the location of features. Issues of positional accuracy may arise due to errors in source data, precision of field measurements, or errors in data entry.

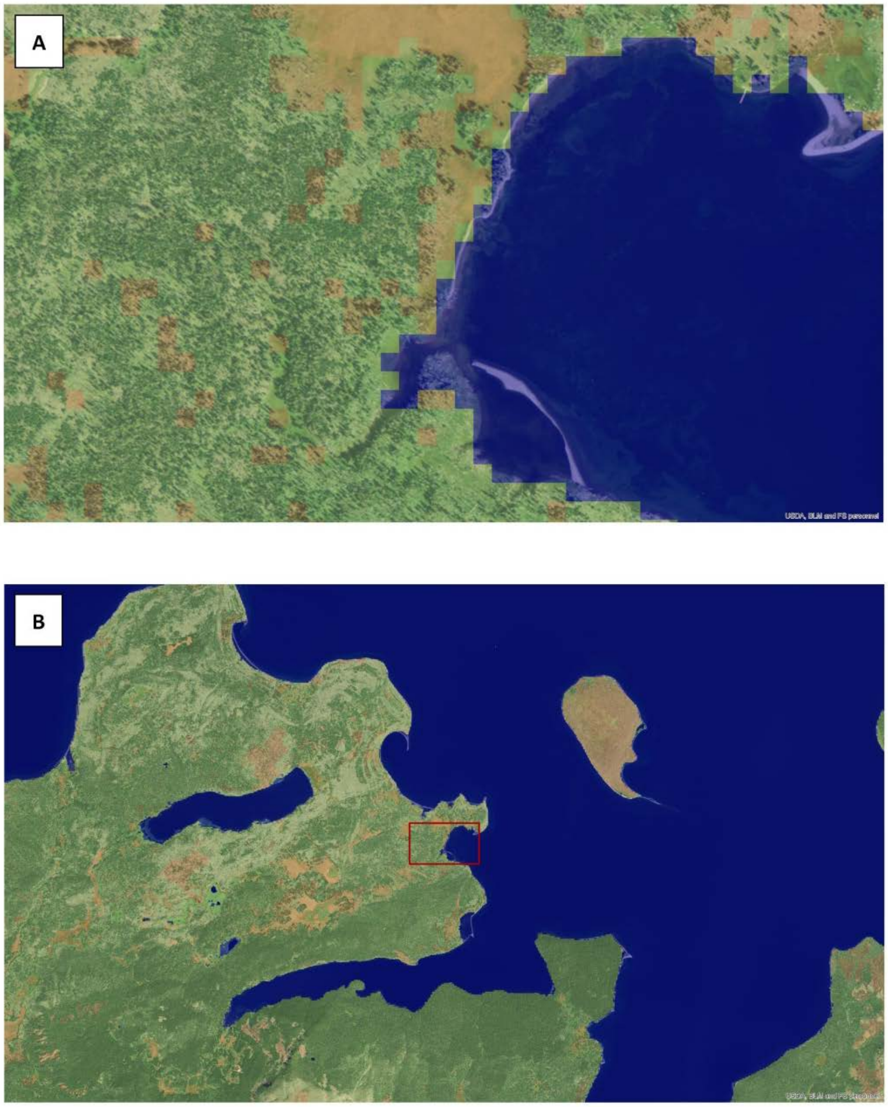

Figure 1. An example of how the spatial resolution of raster data has a direct effect on positional accuracy. LANDFIRE 30-meter resolution data does not precisely depict the shoreline or the boundary between grass (yellow shade) and forest (green shade) when viewed at a small extent (A), but at a broader extent (B), these differences are less apparent and less significant. The red rectangle in panel B shows the extent of panel A.

Content Accuracy

Content accuracy refers to the agreement between mapped units and the true or accepted value of those units. In other words, are the pixel values correct? There is much that can be done by end users of LANDFIRE data to improve issues of content accuracy based on local knowledge, additional data sources, and an understanding of the LANDFIRE data development process. This is the primary focus of this guide. Different types of errors that may affect content accuracy are described next.

Map Unit Errors

Errors in map unit assignments in LANDFIRE data may arise through errors or limitations in remote sensing data, field plots, statistical modeling, processing logic, or a combination of these and other factors. Due to variation in data sources, this error is typically not systematic geographically. For example, the abundance and quality of plot data is inconsistent across the U.S., and cloud-free imagery is more difficult to acquire in certain areas of the country (e.g., Alaska) than others.

Data Currency Errors

One of the most obvious sources of error in vegetation and fuel data is the currency, or age, of the data. Vegetation and fuels change over time due to disturbance and vegetation growth. Disturbance may include the development of previously undeveloped land, natural disturbances, such as windthrow or wildfire, and management activities such as forest thinning or prescribed fire. Vegetation growth over time may result in changes to species composition, structure, and associated dead wood and surface matter. LANDFIRE updates its products accounting for both disturbance and vegetation growth every two years (Nelson et al. 2013), but by the time the data are delivered to the user, they are typically three or more years out-of-date. For example, LANDFIRE 2010 existing vegetation and fuel data were not available for the northwest and southwest United States geographical areas until May 2013.

The importance of updating for these temporal changes should ultimately be determined by the analysis objectives, but the need will also be influenced by the geography and vegetation dynamics of the analysis area. In areas where disturbance is uncommon or where vegetation growth is slow, less frequent updating will be required than in areas that experience frequent disturbances or rapid vegetation growth. For example, vegetation and fuel maps likely need more frequent updating in the south-eastern United States where vegetation growth is more rapid and human and natural disturbances are more frequent than in the desert portions of the southwest. In more mesic life zones, such as mid-elevation forest, the geospatial data layers likely need more frequent updating than in drier low-elevation shrub or grassland zones. Even within local areas there are typically management areas with higher wildland fire or other disturbance activities that require updating as compared to adjacent areas with low activity. Other factors to consider when assessing data currency are the type and size of disturbances that need to be reflected in the data to meet analysis objectives.

Processing or Logic Errors

In some cases, content accuracy issues are introduced during data processing. Unintentional or accidental errors may be difficult to find and correct, but a common source of content error in LANDFIRE products is the result of applying generalized mapping rule sets—a pixel's value is determined by a combination of values from other data as specified in a rule. For example, a rule may assign fire behavior fuel model TU5 (Very High Load, Dry Climate Timber-Shrub), when vegetation type equals mesic mixed conifer and canopy cover is less than 60%. Rule sets are developed and applied at the map zone level (Figure 2). While these rules may be appropriate at the scale of an entire map zone (LANDFIRE map zones range between 12 and 60 million acres in size in the conterminous U.S. and Alaska; Hawaii is a single map zone of 4 million acres), they may need to be refined for application at finer scales. In other words, the "best fit" for an entire map zone may be a compromise between different parts of the map zone. There are also often inconsistencies in mapping rules between adjacent map zones resulting in an "artificial edge" in the data. Many analysis areas often extend across two or even three map zone boundaries. On the ground these changes would start gradually near the boundary between map zones displaying continuous change across the boundary. However, accurately mapping this type of gradual transition is very difficult to achieve in a large national mapping program such as LANDFIRE.

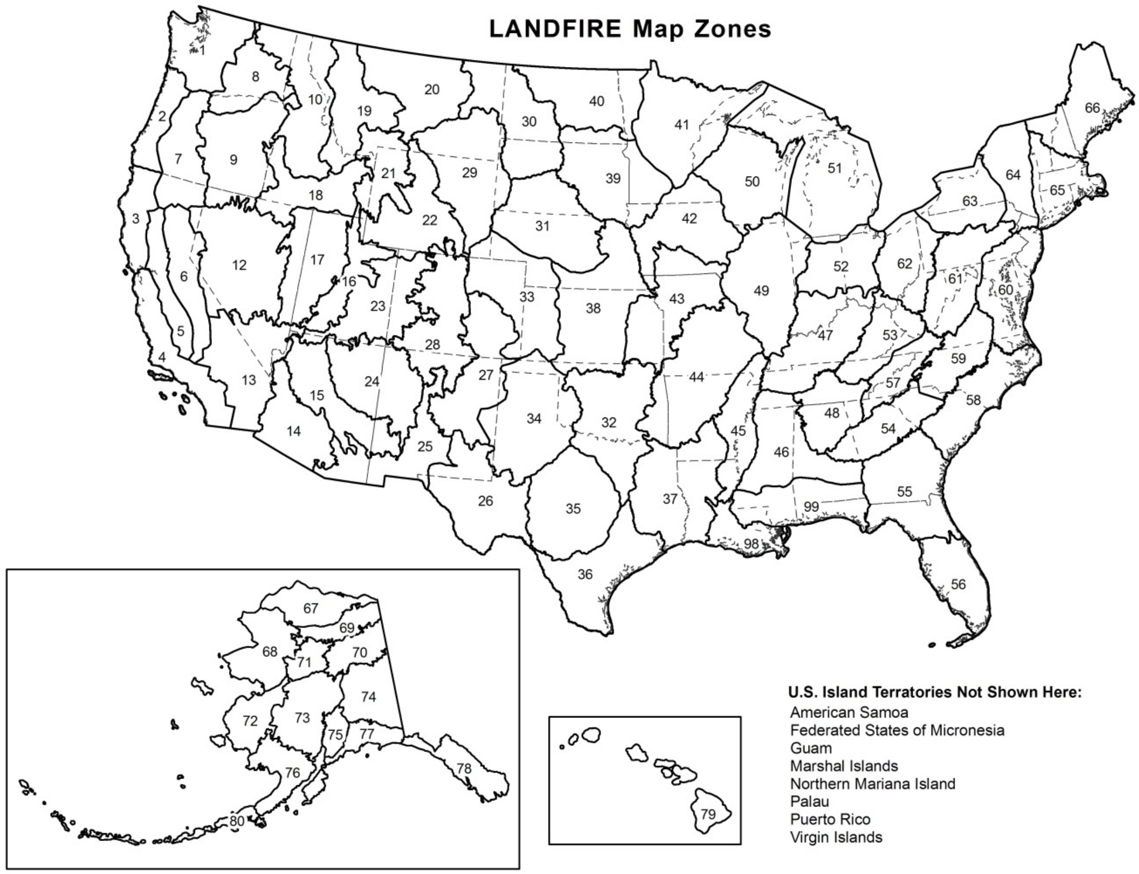

Figure 2. LANDFIRE map zones. There are 80 LANDFIRE map zones across the continental U.S., Alaska, and Hawaii, ranging in size from 4 to 60 million acres.

Content error may also arise due to incomplete knowledge and uncertainty. For example, LANDFIRE's pre-Euro-American fire frequency and severity data are created using a lookup table that links a biophysical setting with the results of a model used to simulate vegetation dynamics and estimate the mean fire frequency and fire severity distribution. The models are created using the best available literature and expert knowledge, but for many biophysical settings, the available information is far from complete. For example, there is considerably more information available to create vegetation dynamics models for biophysical settings that have economic value (e.g. productive forests) than biophysical settings that are rare or traditionally have had little economic value (e.g. arid shrublands; Blankenship et al. 2012). Greater uncertainty about historical fire regime characteristics is also associated with biophysical settings where evidence of historical fires is sparse, non-existent, or just harder to acquire, such as in stand-replacement or very long-interval fire regimes.

Spatial Resolution

As mentioned above, the spatial resolution of raster data is defined as the amount of ground area represented by a pixel. LANDFIRE data are based on Landsat satellite imagery, which have a 30m x 30m pixel size. In other words, each individual pixel represents an area of 30m x 30m, or 900m^2 (about .22 acres), on the ground.

Spatial resolution can be adjusted if necessary to meet analysis objectives. Decreasing spatial resolution by increasing pixel size (e.g., resampling 30m resolution data to 270m resolution) is sometimes done to: reduce processing time for computationally intensive analyses; decrease file storage space requirements; speed up display time; and/or, reduce the "pixelated" look of a map by absorbing isolated cells into larger patches. While it is possible to adjust resolution the other way, that is to change from coarser to finer resolution, greater map detail can only be achieved if finer resolution geospatial data are incorporated into the resampling process. That is, resampling to a finer resolution without additional finer-scale information gives a false sense of accuracy (see sidebar).

Resampling Raster Data Layers

Resampling is the process of changing the resolution of a dataset. Raster data may be made coarser by aggregating adjacent pixels. Some users of LANDFIRE data who perform national summaries of the data have resampled LANDFIRE grids from 30m to 270m. At this broad extent, resampling may have little impact on the results but can greatly increase computer processing efficiency.

Resampling to a finer resolution is sometimes referred to as downscaling and is often associated with the process of obtaining local level climate data from global climate models. Resampling to a finer resolution is possible using the resample techniques available in ArcGIS, but these techniques will not change the accuracy of the underlying data.

There are several resampling methods available in ArcGIS software, and the resampled raster values will differ depending on the method used.

Thematic Resolution

Thematic resolution refers to the level of detail in the map units. The thematic resolution of LANDFIRE data varies by data product. The most common reason that an end user of LANDFIRE data might change thematic resolution is to ensure that the level of detail in the map units aligns with the level of detail needed to achieve the analysis objectives.

Thematic resolution can be changed to achieve either coarser or finer map units by grouping or splitting map units respectively. Grouping map units is accomplished by aggregating similar map units or by choosing a higher or coarser level within a classification hierarchy (Table 3). One advantage of grouping map units is that it may improve the content accuracy because fewer and more broadly defined units can be mapped, thus minimizing potential error. Splitting map units to achieve higher thematic resolution requires more detailed ancillary data such as maps, plots, higher resolution imagery, or other geospatial data that can be used to distinguish units at a finer level than the original geospatial data layer.

Table 3. Hierarchy of LANDFIRE biophysical setting and existing vegetation type map units. Users can choose the level that best fits their needs or create a hybrid classification by aggregating units. Note that the Society of Americana Foresters and Society of Range Management map units that are provided in the existing vegetation type data layer attribute table is for reference only. This "cover type based" map unit classification is not equivalent to the NatureServe ecological systems classification used by LANDFIRE (see Chapter 4).

Data Layer	Map Unit Level	Example
Biophysical Settings	BpS Name	Central Mixed Grass Prairie
	Group Name	Bluebunch Wheatgrass-Big Bluestem-Little Bluestem-2
	Group Vegetation	Grassland
Existing Vegetation Type	EVT Name	Laurentian-Acadian Northern Hardwoods Forest
	System Group Physiognomy	Hardwood
	System Group Name	Yellow Birch-Sugar Maple Forest
	Society of American Foresters & Society of Range Management Cover Type	SAF 27: Sugar Maple
	National Vegetation Classification System Physiognomic Order	Tree-dominated
	National Vegetation Classification System Physiognomic Class	Closed tree canopy
	National Vegetation Classification System Physiognomic Subclass	Deciduous closed tree canopy

Reasons for Modifying LANDFIRE Data

The above considerations should be helpful in determining whether LANDFIRE data are appropriate for specific objectives and whether modifications are necessary. LANDFIRE geospatial data are commonly modified for the following reasons:

1. update for landscape changes that have occurred since the LANDFIRE version,
2. calibrate to local data and knowledge,
3. improve the thematic agreement (accuracy),
4. change the spatial or thematic resolution (e.g. lump or split map units),
5. modify the map unit classification,
6. create additional data versions that reflect temporal variability (e.g. peat soils being available for burning in drought situations, or exotic annual grasses being present in wet years but not dry years),
7. facilitate comparative analysis by creating data versions (e.g. analyzing pre- and post-treatment effects or comparing treatment alternatives),
8. analyze future conditions (e.g. modifying data to represent future conditions under a climate change scenario).

Conclusion

This chapter provided an overview of LANDFIRE data products, general considerations for critiquing LANDFIRE geospatial data products, and a list of common reasons why these geospatial data are modified for local applications. LANDFIRE's suite of products provides a rich set of data that have proven useful for addressing sub-regional, regional, and national level land management issues and research questions (e.g. Aycrigg et al. 2013, Cochrane et al. 2012, Reeves and Mitchell 2011, Swaty et al. 2011, Zhu et al. 2010). Through proper critique and modification by local natural resource and geospatial professionals, LANDFIRE data may also be appropriately applied to finer-scale, local applications. (e.g., Helmbrecht et al. 2012, Price et al. 2012, Scott et al. 2012, Tuhy et al. 2010). The importance of issues and the time and effort spent addressing them should be determined by the analysis objectives.

Chapter 2: Framework for Data Critique and Modification

This chapter presents a five-step conceptual framework for data critique and modification (Figure 3). The framework begins with defining objectives. Having a clear understanding of objectives will provide a foundation for the remaining steps of the framework. The process is iterative, as findings in one step of the framework may require reevaluation of a previous step. The framework is meant to be flexible and some steps may be combined, depending on the analysis objectives, processes being performed, and experience of the analyst. Certain tools may facilitate the integration of steps. For example, the LANDFIRE Total Fuel Change tool (LFTFCT 2011) allows the analyst to critique, modify, and analyze certain aspects of fuel mapping simultaneously. The framework is typically applied by a team, wherein specialists with expertise in various disciplines (e.g., fire/fuels, silviculture, ecology, and GIS) are involved in the process.

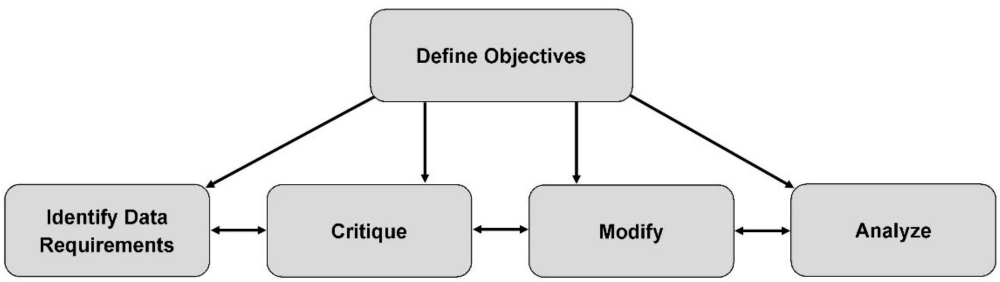

Figure 3. A conceptual framework for data critique and modification. The five-step framework begins with defining clear project objectives. The objectives will dictate the data requirements, influence the type of critique performed, dictate the types of modifications that are needed and determine the analysis performed. The framework is meant to be flexible and in some cases the process may be iterative.

Define objectives

The first step in the data critique and modification process is to define the team's objectives. Clear objectives will be a guiding principle for every other step in this process. For a given analysis determine what is needed from the data (and why), and its intended use. Defining objectives will help determine the data used, the landscape extent, the type of critique to do, and the type and level of modifications necessary.

Identify data requirements

With clear objectives in mind, the next step is to identify the data required to achieve those objectives. For example, if the objective is to assess vegetation departure from a historical reference condition, data is required that characterizes both the historical and current vegetation condition. If the objective is to assess potential wildland fire behavior, data is required that characterizes the fuels and topography of the area of interest.

As will be discussed in subsequent chapters, it is important to understand the linkages among LANDFIRE datasets, as well as the dataset creation method. Resolving issues with data that are mapped using a rule-based methodology, such as fire behavior fuel model or succession class, may require critiquing the data from which those data are derived, such as vegetation type, cover, and height or biophysical setting, thereby increasing the data requirements.

Critique

After identifying data requirements, the critical question is: are the data are good enough to meet the analysis objectives? Data need not be perfect to be useful. Ask what the important characteristics of the data are, and answer this question being mindful of the considerations discussed in Chapter 1. For the given objective: is the scale appropriate, are the data current, are the map units appropriate, and is the spatial resolution (pixel size) too coarse, or too fine? This is an iterative step; the critique may identify the need for additional data and that data will also need to be critiqued. For example, if the data are obsolete due to a recent disturbance, and that disturbance needs to be represented in the data to meet the objectives, then acquire and critique the disturbance data as it will be used to update the original data set.

Modify

Modification of data is the technical step and where GIS skills are mandatory. Subsequent chapters will provide examples of methods for conducting common modification tasks. This is also an iterative step. After modifying the data, critique it once again to be sure the desired result is achieved.

Analyze

The type of analysis performed is determined by the analysis objectives. Common analyses with LANDFIRE data include fire behavior modeling, vegetation departure assessment, and comparative analysis between land management alternatives. It is not uncommon for the results of a particular analysis to reveal data issues or requirements overlooked the first time through the framework. This step may be integrated with the previous step depending on both the analysis type and the experience of the analyst (Chapter 7).

Conclusion

This chapter presented a conceptual framework for critiquing LANDFIRE data for use in local applications. The following chapters discuss specific considerations for critiquing and modifying data from four of the five LANDFIRE data categories: disturbance, vegetation, fuels, and fire regime. Modification of topographic data (elevation, slope, and aspect) is uncommon and therefore not discussed in this guide; however, know that errors may still exist in these data. Having a thorough understanding of the assumptions and limitations of the data is of primary importance in data critique. Therefore, each of the following chapters begins with an overview of how LANDFIRE develops the data products of each category. Next are primary considerations for critiquing the data in each category and examples of why these considerations are important to local applications. Chapter 7 introduces common tools and techniques used for critiquing and modifying LANDFIRE data through interpreted examples.

Chapter 3: Disturbance

Landscape change due to planned and unplanned disturbances is continuously occurring across the United States. Updating LANDFIRE geospatial data for recent disturbances to vegetation and fuels is therefore a common modification task users of LANDFIRE data will encounter: this discussion of data critique and modification considerations thus begins with the disturbance data category. Additional considerations about updating for disturbance as it pertains specifically to vegetation, fuels, and fire regime data will be discussed in subsequent chapters.

LANDFIRE Disturbance Mapping Process

LANDFIRE maps the location, extent, type, and severity of both planned and unplanned disturbances. These data are used for determining vegetation transitions over time, and subsequently updating vegetation and fuel data products. As of LANDFIRE version 1.3.0 (LANDFIRE 2012), yearly geospatial disturbance data are available from 1999 through 2012. The yearly disturbance data are also compiled into two composite disturbance data layers—vegetation disturbance and fuel disturbance—representing disturbances occurring over the previous ten year time period. A time-since-disturbance attribute is recorded in the composite disturbance layers (Figure 4).

Yearly Disturbance Value Attribute Table

Rowid	VALUE *	COUNT	DIST_YEAR	DIST_TYPE	TYPE_CONFI	SEVERITY	SEV_CONFID	SOURCE1	SOURCE2	SOURCE3	SOURCE4	
3	13	13953	2009	Wildfire	High	Medium	High	MTBS				MTBS mapped wildfire.
4	14	6430	2009	Wildfire	High	High	High	MTBS				MTBS mapped wildfire.
5	15	156	2009	Wildfire	High	Increased Green	High	MTBS				MTBS mapped wildfire.

Figure 4. Yearly and composite disturbance data attribute tables. The yearly disturbance data layers are attributed with the year, type, and severity of the disturbance as well as up to four input data sources, type and severity confidence levels, and a synopsis of the data and reasoning used to determine the map unit classification. The yearly disturbance data are compiled into a composite disturbance data layer. The

disturbance year (dist_year) is classified into a time-since-disturbance category (d_time) in the composite layer.

LANDFIRE disturbance data are developed through a multistep process that incorporates Landsat satellite imagery, disturbance polygons derived from local agencies, and other ancillary data. The remainder of this section provides a general overview of the LANDFIRE disturbance mapping process (Figure 5). More detailed information is available on the LANDFIRE website and in the literature cited below.

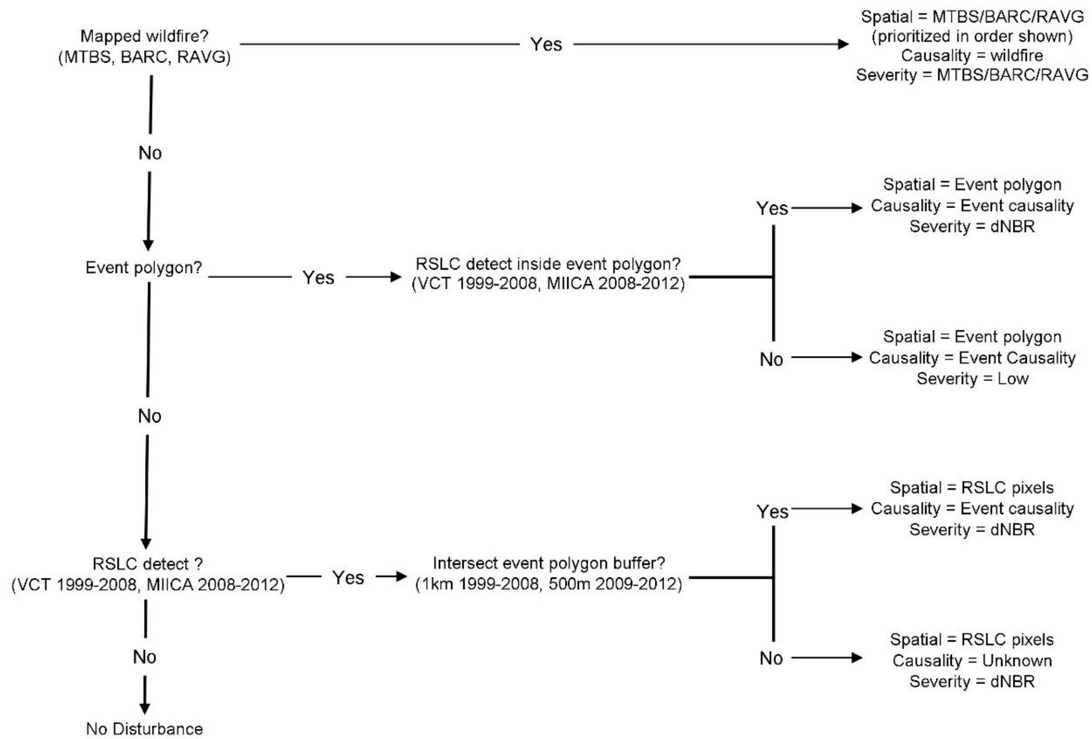

Figure 5. The LANDFIRE disturbance mapping process. LANDFIRE disturbance data are developed through a multistep process that incorporates Landsat satellite imagery, local agency derived disturbance polygons, and other ancillary data.

The first step in this process is to detect when and where disturbances have occurred. Three sources of information are used to accomplish this task: wildfire severity data from the Forest Service Remote Sensing Applications Center (RSAC), event polygons from the LANDFIRE events geodatabase, and change detection data derived from Landsat satellite imagery.

Wildfire Severity Data

RSAC manages three wildland fire severity mapping programs: Monitoring Trends in Burn Severity, Burned Area Emergency Response, and Rapid Assessment of Vegetation Condition after Wildfire. The data from these programs differ in the date of post-fire imagery and/or the severity mapping methodology used to create them. LANDFIRE uses all three datasets to map the extent and severity of wildfires.

LANDFIRE Events Data

Polygon data of vegetation and fuel management activities comprise the LANDFIRE events geodatabase. These data are obtained from federal, state, local, and private organizations and are compiled by LANDFIRE analysts. Events on national forest system lands rely heavily on data from the USDA Forest Service, Forest Activities Tracking System (FACTS). Regardless of the source, all events are crosswalked to one of 22 (including the exotic plants map unit) LANDFIRE event types (USFS 2013).

Change Detection

Lastly, LANDFIRE has incorporated two landscape change detection methodologies that apply Landsat satellite imagery in the development of the disturbance data. In the LANDFIRE 2008 mapping effort, a vegetation change and tracking process referred to as the Vegetation Change Tracker (VCT; Huang et al. 2010) was used. Beginning with the LANDFIRE 2010 mapping effort, the program adopted a new process called Multi-Index Integrated Change Analysis (MIICA; Jin et al. 2013). The MIICA process improves detection of disturbances in non-forest vegetation types, whereas VCT primarily identified disturbances in forested vegetation (D. Long, personal communication, July 23, 2013). MIICA was used to detect 2008 disturbances not identified through the VCT process, and all disturbances in 2009 through 2012. MIICA was not retroactively applied to the individual year disturbance data prior to 2008.

The second step in the disturbance mapping process is to assign causality, or disturbance type, to an identified disturbance. If the causality is know, that is, it is a mapped wildfire or LANDFIRE event, the causality is recorded in the yearly disturbance data attribute table. If the disturbance is identified through the change detection process, two additional sources of information are used to assign the likely causality: the National Gap Analysis Program's Protected Area Database and the USDA Forest Service, Pacific Northwest Research Station's SmartFire information system. Yearly disturbance layers are attributed with up to 19 of the 22 LANDFIRE event types plus an "unknown" class. This class indicates a disturbance occurred but the causality is uncertain (Table 4).

Table 4: Comparison of disturbance type attributes between LANDFIRE individual year and composite disturbance data layers. The composite vegetation disturbance (VDist) information is used to inform updates to the existing vegetation type data layer. The composite fuel disturbance (FDist) information is a subset of the VDist used to inform updates to fuel data layers.

LANDFIRE Event Type	Yearly Disturbance	VDist	Description	FDist	Applicable FDist Lifeforms
Wildfire	Wildfire	Fire	A catch-all term used to describe any non-structure fire that occurs in the wildland.	Fire	Herbaceous, Shrub, Tree
Wildland Fire Use	Wildland Fire Use				
Prescribed Fire	Prescribed Fire				
Wildland Fire	Wildland Fire				
Mastication	Mastication	Mechanical Add	A mechanical activity by which fuel is added to the natural fuelbed or in which the natural fuel structure is changed from a vertical to horizontal arrangement (e.g., mastication).	Mechanical Add	Shrub, Tree
Other Mechanical	Other Mechanical				
Clearcut	Clearcut	Mechanical Remove	A mechanical activity in which fuel is not added to the natural fuelbed (e.g., whole-tree harvesting) or in which natural fuels are removed.	Mechanical Remove	Shrub, Tree
Harvest	Harvest				
Thinning	Thinning				
Weather	Weather	Windthrow	Weather related event that results in loss of vegetation such as blowdown, hurricane, or tornado.	Windthrow	Tree
Insects	Insects	Insects-Disease	Infestations of insects and/or disease that can affect vegetative health and structure.	Insects-Disease	Shrub, Tree
Disease	Disease				
Insects/Disease	Insects/Disease				
Insecticide	Insecticide	Chemical	Application of a chemical substance such as herbicide.	NA	NA
Herbicide	Herbicide				

LANDFIRE Event Type	Yearly Disturbance	VDist	Description	FDist	Applicable FDist Lifeforms
Chemical	Chemical				
Biological	Biological	Biological	The use of living organisms, such as predators, parasites, and pathogens, to control weeds, pest insects, or diseases.	NA	NA
Development	Development	Development	Conversion of natural lands into housing, commercial, or industrial building sites. Involves permanent land clearing.	NA	NA
Exotic Plants	Exotics	Exotics	The presence of non-native species.	Exotics	Herbaceous, shrub
Planting	NA	NA	NA	NA	NA
Reforestation	NA	NA	NA	NA	NA
Seeding	NA	NA	NA	NA	NA
NA	Unknown	NA	Sources indicate that a disturbance occurred but causality is uncertain.	NA	NA

The final step in the disturbance mapping process is to map the disturbance severity. Information for determining disturbance severity may come from any one of the three data sources described above: RSAC wildfire severity, LANDFIRE events geodatabase, or remotely sensed change detection methods. Disturbance severity is assigned to one of three classes: low, moderate, or high (Table 5).

Table 5: LANDFIRE disturbance severity classes.

Severity	Description
Low	Less than 25% above-ground biomass removed.
Moderate	25 – 75% above-ground biomass removed.
High	Greater than 75% above-ground biomass removed.

The flow chart shown in Figure 5 may be used as an aid to understand this process. Where a wildfire has been mapped by one or more of the RSAC wildfire severity mapping programs, the information is used to determine the extent, year, causality (i.e., wildfire), and severity of the fire. In areas where a wildfire has not been mapped by one of the RSAC programs, but a LANDFIRE event has been mapped using other methods, the extent and causality of the event polygon are used. If the change detection process also detected the disturbance, severity is derived from the remote sensing data using the differenced Normalized Burn Ratio methodology (Key and Benson 2005). If no disturbance was detected via change detection, the year attributed to the event polygon is used and severity is set to low. Finally, if neither a wildfire or event is mapped to an area but a change is detected via remote sensing, the extent, year, and severity are determined by inference. This is done through analysis of the change detection data and assignment of causality based on proximity to event polygons and other ancillary data such as the National Gap Analysis Program's Protected Area Database and buffered SmartFire points. In addition to year, type, and severity, the yearly disturbance data layers are attributed with input data sources, type and severity confidence levels, and a synopsis of the data and reasoning used to determine the map unit classification (Figure 4).

The yearly disturbance data layers are then integrated into two composite data layers representing disturbances occurring over the previous ten year time period. In instances where multiple disturbances from different years overlap, the type and severity of the most recent disturbance is used in the composite data layer. An exception to this rule is in the case of a fire disturbance type (prescribed or wildfire) which overrides other disturbance types and is assigned to the composite layers regardless of when the fire occurred in the series of events. The disturbance type attribute of the yearly disturbance layers is reclassified into one of nine disturbance type map units in the final composite *vegetation* disturbance layer (Table 4). The year of the disturbance is classified into one of three time-since-disturbance classes: one year, two to five years, or six to ten years.

The composite *vegetation* disturbance layer is used to inform updates to the existing vegetation type, cover, and height data layers (Chapter 4). Both the yearly disturbance and composite vegetation disturbance layers are compiled from "raw" disturbance data. As such, direct comparison with existing vegetation data may reveal illogical combinations (e.g., fire and water mapped to the same pixel). When vegetation transition rules are applied to update the vegetation data layers, illogical combinations are filtered out.

The composite *fuel* disturbance layer is used to inform updates to fuel data layers (Chapter 5). The composite *fuel* disturbance layer is a subset of the composite *vegetation* disturbance layer and does not include chemical, biological, or development map units (see comparison in Table 4). The reasoning for this is that the composite fuel disturbance data layer is only applied in cases where both the post-disturbance vegetation characteristics *and* the disturbance that created those characteristics influence the post-disturbance fuels. For example, an herbicide application may cause a transition in vegetation type, cover, and/or height; and a fire behavior fuel model would be assigned based on these post-disturbance vegetation characteristics. The fact that the change was caused by the application of an herbicide does not factor into the assignment of the fuel model. This is in contrast to what would occur in a forested vegetation type after a wildfire, for example, where the post-disturbance vegetation characteristics *and* the fact that fire consumed dead wood and surface organic matter would both need to be taken into consideration in assigning the post-disturbance fuel model (Chapter 5). The composite fuel disturbance layer undergoes additional filtering to remove inconsistent disturbance/lifeform combinations (e.g., windthrow in herbaceous- or shrub-dominated landscapes, Table 4).

Considerations

Time-Since-Disturbance

LANDFIRE periodically updates the geospatial data products it develops to represent change due to disturbances; however, the update process itself takes two to three years to complete. Under the current update schedule, LANDFIRE data are typically 3–5 years out of date for any given year. In regards to the vegetation and fuel disturbance data layers, the time-since-disturbance attribute may therefore be out of date. For example, LANDFIRE 2012 data reflects conditions through the end of 2012. Thus, a disturbance that occurred in 2012 would be assigned to the one year time-since-disturbance class in the LANDFIRE 2012 data. However, the LANDFIRE 2012 data were released in the later months of 2014. For application in 2015, the original 2012 disturbance is 3 years old putting it in the 2–5 year time-since-disturbance class (Table 6). Likewise, disturbances that occurred in 2008 and 2009 should be shifted from the 2–5 year time-since-disturbance class to the 6–10 year class in 2014.

Table 6: Comparison of time-since-disturbance (TSD) between currency and release dates. For application in 2015, LANDFIRE 2012 disturbance data in the one year TSD class should be updated to the two to five year class. Likewise, disturbances that occurred in 2008 and 2009 should be updated to the six to 10 year TSD class.

Disturbance Year:	2003	2004	2005	2006	2007	2008	2009	2010	2011	2012	2013	2014
Data TSD (Years)	10	9	8	7	6	5	4	3	2	1	--	--
Current (TSD) Years	12	11	10	9	8	7	6	5	4	3	2	1

Whether this is of concern or not depends on the particular data products, their intended use, and the location of your assessment. For example, the assignment of fire behavior fuel model for use in fire behavior simulation is sensitive to the time-since-disturbance attribute. This is especially true in areas of the country where vegetation growth and fuel accumulation are rapid.

Disturbance Type

Disturbance type, or causality, is assigned to the vegetation disturbance and fuel disturbance data layers by pairing remote sensing data with information from the LANDFIRE Events Geodatabase. Individual disturbances are first classified into one of 22 LANDFIRE event types. Nineteen of these event types, plus an "unknown" class, are used to attribute the yearly disturbance data layers. The event types of the yearly layers are then reclassified into one of nine disturbance types in the composite vegetation disturbance layer and six types in the composite fuel disturbance layer (Table 4). Two disturbance types in particular—mechanical add and mechanical remove—can be especially challenging to assign from the information available in the events data but are very important for determining post-disturbance fuel. Whether the surface fuels (e.g., branches, needles, bark) generated from a forest management activity are added, rearranged, or removed from a site is highly dependent on factors such as site characteristics, management techniques, and management objectives. The management techniques and objectives are strongly influenced by law, regulations, and policies (local through national). These factors are highly variable in both location and time. For example, in more humid areas of the United States where downed wood decomposes quickly, activity fuel may be left on site to decompose and provide valuable nutrients to the soil. Conversely, in drier climates where this fuel takes years to decades to decompose, local, regional and/or national regulations or policy may dictate that activity fuel be removed from the site.

The information in the events data is typically not specific enough to discern these differences and LANDFIRE updates must therefore resort to the broad definitions of mechanical add/remove shown in Table 4. For local applications however, local resource professionals often have the institutional knowledge and/or ancillary information to critically critique, and update if necessary, disturbance type attributes.

Most Recent Disturbance Rule

As discussed above, in instances where multiple disturbances from different years overlap, the composite disturbance data layer is assigned the attributes of the most recent disturbance. The only exception to this rule is if fire is one of the disturbances, in which case the severity and time-since-disturbance of the fire is assigned to the composite layer regardless of when it occurred in the series of events. Multiple entries in the same treatment unit are quite common (e.g., a thinning treatment followed by treatment of activity fuels). In areas where timber harvesting is common, four or more entries may be found in short succession (e.g., a pre-treatment, one or more harvest entries, a fuel treatment, and site-preparation for planting or natural regeneration). A harvest treatment is also common, as timber salvage, after a fire.

In these situations the "most recent disturbance" rule, or "fire overrides other disturbances" rule, can lead to issues of content accuracy in the composite disturbance layers. For example, consider a high-severity harvest, such as a clearcut or shelterwood cut, followed by a low-severity disturbance, such as site-preparation or piling activity fuels. If these subsequent activities are at least a year apart, the composite data layer will be assigned "low-severity," even though all or most of the overstory vegetation was removed.

New Disturbances

The above considerations about time-since-disturbance and disturbance type attributes were presented in the context of critiquing disturbances that were already mapped and included in the LANDFIRE disturbance data products. As discussed previously, the composite disturbance data may be 3–5 years out of date upon time of version release. Updates are therefore often necessary, especially in actively managed landscapes or landscapes in which natural disturbances have occurred after the currency date of the latest LANDFIRE version. New disturbances may be added to the vegetation and fuel disturbance data layers using a variety of geospatial techniques and tools. The most appropriate technique may be influenced by the availability of recent disturbance data, the thematic and spatial detail of the data, and the experience of the analyst. For example, recent disturbance data may be in the form of a polygon shapefile depicting the location, extent, and type of disturbance without information on severity (e.g., locally developed prescribed fire burn unit map), or in the form of a raster data layer representing multiple classes of severity (Figure 6 e.g., RSAC wildfire severity data). Regardless of the techniques applied, new disturbances must be attributed with type, severity, and time-since-disturbance to be added to the vegetation disturbance and fuel disturbance data layers.

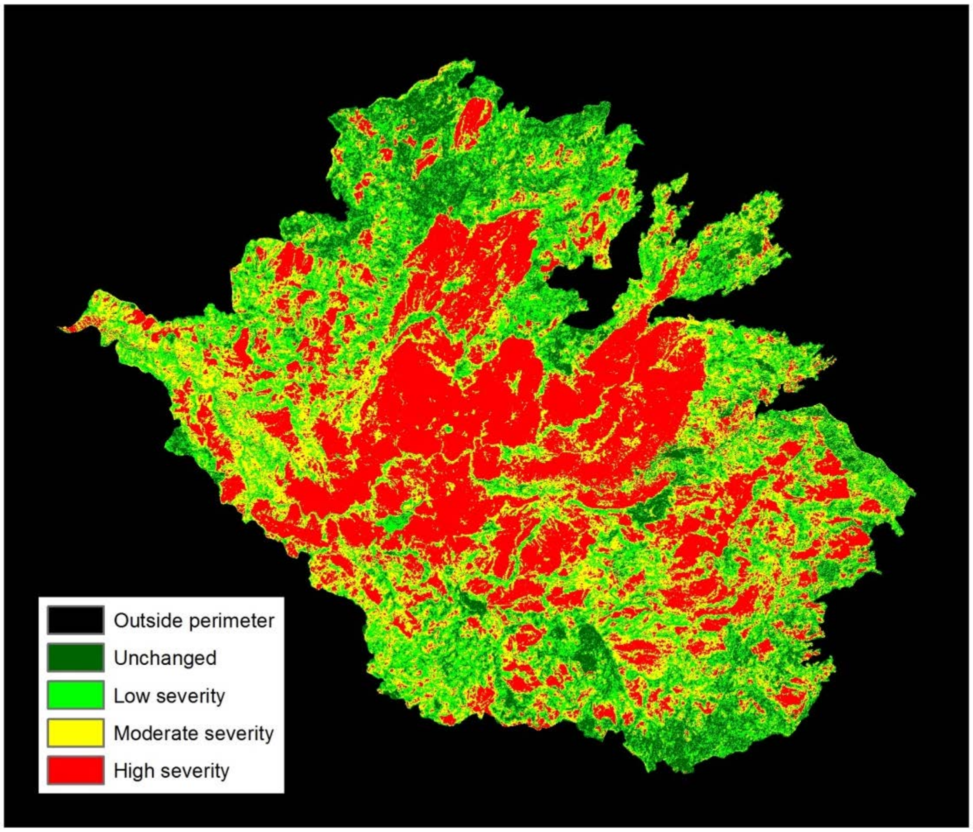

Figure 6. Four class severity classification of the 2013 Rim fire in California. Data were acquired from the U.S. Forest Service Remote Sensing Applications Center, Rapid Assessment of Vegetation Condition after Wildfire program.

Chapter 4: Vegetation

LANDFIRE develops geospatial data of potential and existing vegetation. The potential vegetation products include environmental site potential and biophysical setting. In contrast to the environmental site potential, the biophysical setting reflects potential for the historically dominant vegetation. The existing vegetation products include existing vegetation type, existing vegetation cover, existing vegetation height, and succession class. These six vegetation products are foundational to the development of other LANDFIRE geospatial data depicting fuel and fire regime characteristics.

This chapter presents an overview of the LANDFIRE vegetation mapping process, common considerations for critiquing LANDFIRE vegetation data, and examples of common pitfalls.

Vegetation Mapping Process

Potential Vegetation

Potential vegetation refers to the vegetation that could be supported at a given site based on the site's biophysical environment. LANDFIRE maps two representations of potential vegetation: environmental site potential and biophysical setting. Environmental site potential represents the late successional vegetation community that may become established at a site in the absence of disturbance. Biophysical setting represents the vegetation community that may have been dominant at a site prior to Euro-American settlement based on both the biophysical environment and an approximation of the historical disturbance regime.

Potential vegetation is mapped by LANDFIRE using a predictive modeling approach referred to generally, as *classification and regression tree* (CART; Figure 7) analysis, in conjunction with rule-based mapping techniques. First, field plot data (available in the LANDFIRE Reference Database; LFRDB [n.d.]), are keyed to environmental site potential classes based on the presence and abundance of indicator plant species that identify the biophysical conditions of the site. These plots are then intersected and attributed with information from biophysical gradient data layers (e.g., soil depth, average temperature, and average daily precipitation). The gradient layers are modeled from climate, soil, and topographic data and indirect topographic gradients such as elevation, slope, and indices of slope position. The information gathered from plot locations is then used as training data to develop the CART model—a statistical model used to predict a dependent variable (environmental site potential class) based on correlation with the independent variables (biophysical gradients). The CART model is then applied spatially to create a draft map of the environmental site potential of every pixel across the landscape based on combinations of the biophysical gradient data. The draft product is then refined using rule sets derived from the Nature Serve

Ecological Systems map unit descriptions and expert review.

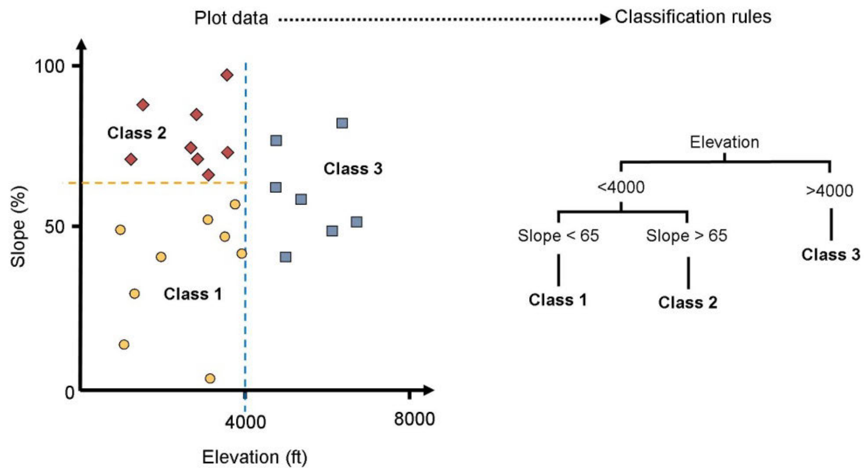

Figure 7. Classification tree conceptual diagram. In this simplified example, three classes of vegetation are plotted in respect to two biophysical gradients: elevation and slope (left side of figure). The relationship between the three vegetation classes and two biophysical gradients are then translated into classification rules (right side of figure), which are then in turn used to build spatial data layers. Approximately 40 biophysical gradients are used in the creation of the LANDFIRE potential vegetation data layers**.**

The environmental site potential data layer becomes the starting point for mapping Biophysical Settings. Environmental site potential units are associated with biophysical setting units using rule sets based on assumptions pertaining to vegetation dynamics and disturbance regimes. For example, an environmental site potential that is dominated by shade-tolerant species such as Douglas-fir or grand fir in the absence of disturbance may be mapped as a ponderosa pine- or western larch-dominated biophysical setting in an area with a frequent low-severity fire regime that would favor species that are less shade-tolerant and more fire-adapted. In other cases, alternate CART models were built to map biophysical settings from General Land Office survey data and Natural Resource Conservation Service Ecological Site Descriptions.

Existing Vegetation

Existing vegetation refers to the vegetation that is currently present on a given site. LANDFIRE maps four characteristics of existing vegetation: type, cover, height, and succession class. Existing vegetation is mapped using a predictive modeling approach similar to that used for potential vegetation; the primary difference is the input data. Like potential vegetation, methods for mapping existing vegetation type apply geospatial data of biophysical gradients and information from field plots. Because plot data can sometimes be many years old and vegetation characteristics may change rapidly, an additional filtering process is applied to ensure that current data are being used to develop the CART models. The existing vegetation type mapping process also includes data derived from Landsat satellite imagery as input. The base Landsat imagery used by LANDFIRE to derive existing vegetation products was acquired in the years 1999–2003, with newer imagery brought in to detect changes over time due to disturbance during the disturbance update process (Chapter 3).

Existing vegetation cover represents the area of the ground covered by a vertical projection of the canopy: in other words, the area of the ground covered if one were to look straight down from above (Figure 8). This is not to be confused with canopy closure, which is the proportion of the sky hemisphere obscured by vegetation when viewed from a single point (Jennings et al. 1999). Cover is mapped separately for herbaceous, shrub, and tree lifeforms using a predictive modeling approach based on plot data, satellite imagery, and biophysical gradient data layers. The canopy cover of each lifeform is binned into ten-percent classes[1] and then merged into a composite data layer in which the upper-layer lifeform's cover is assigned to the pixel. The training data for each lifeform are based on plot-level, ground assessments. However for the tree lifeform, plot canopy cover is modeled using a stem-mapping approach developed by Toney et al. (2009). This method was applied to the LANDFIRE 2001 data and is being applied to subsequent versions as an improvement over the canopy cover mapping in LANDFIRE National, which tended to over-predict tree canopy cover (Nelson et al. 2013, USFS [n.d.], Forest Canopy Cover…).

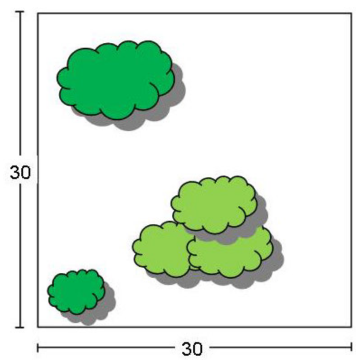

Figure 8. Vertically projected canopy cover. Existing vegetation cover represents the vertically projected canopy cover of the dominant lifeform for a pixel. In this example, the canopy cover within a 30-by-30 meter pixel is approximately 25%.

The existing vegetation height product represents the average height of the dominant lifeform. Like canopy cover, canopy height is mapped separately for herbaceous, shrub, and tree lifeforms using plot data, satellite imagery, and biophysical gradient data layers in a predictive modeling approach. The height of each lifeform is binned into classes and then merged into a composite data layer in which the upper-layer lifeform's height is assigned to the pixel (Table 7). For forests, a Shuttle Radar Topography Mission (SRTM) derived vegetation height product (Kellendorfer et al. 2004) is added to the other data sources for predictive modeling in LANDFIRE 2001 (Toney et al. 2012). The addition of the SRTM data provides a vertical structure measurement unavailable from the two-dimensional Landsat imagery which improved forest height mapping (Nelson et al. 2013, LANDFIRE 2008). Existing vegetation height for forests represents the average height of the dominant and co-dominant trees (weighted by basal area) for the pixel (Toney et al. 2012). In other words, the height value does not represent the average height of all individual trees, nor does it represent the average height of only the dominant trees. For non-forest areas, existing vegetation height represents the average height of the dominant lifeform. This is determined from species height weighted by species cover composition.

[1] For Alaska, tree and shrub cover is binned into three classes: 10%-25%, 26%-60%, and > 60%; herbaceous cover is binned into two classes: 10%-60% and > 60%.

Table 7: LANDFIRE height classes by lifeform and geographic area.

Lifeform:	Height Class (m) CONUS and HI	Height Class (m) Alaska
Herbaceous	0 - 0.5	0 - 0.5
	0.5 - 1	> 0.5
	> 1	
Shrub	0 - 0.5	0 - 0.5
	0.5 - 1	0.5 – 1.5
	1 – 3	> 1.5
	> 3	
Tree	0 - 5	No difference
	5 - 10	
	10 - 25	
	25 - 50	
	> 50	

The final characteristic of existing vegetation mapped by LANDFIRE is succession class. Succession class represents the current stage of vegetation development within an individual biophysical setting. It is very important to understand that the succession class should not be used independent of its biophysical setting. **Without its biophysical setting the succession class has no definition**. LANDFIRE maps up to seven succession classes using a rule-based approach—for each biophysical setting, a succession class is assigned based on rules that define specific combinations of existing vegetation type (primarily lifeform), existing canopy cover, and existing canopy height (Figure 9). Up to five of the seven succession classes are used to represent development stages characteristic of those found under the historical disturbance regime. Two classes are used to represent uncharacteristic conditions. Uncharacteristic native identifies native vegetation conditions that would be unlikely to occur under the historical disturbance regime, such as excessive canopy cover for a biophysical setting succession class with a frequent low-severity fire regime. Uncharacteristic exotic identifies areas in which exotic species have partially or completely replaced the native species.

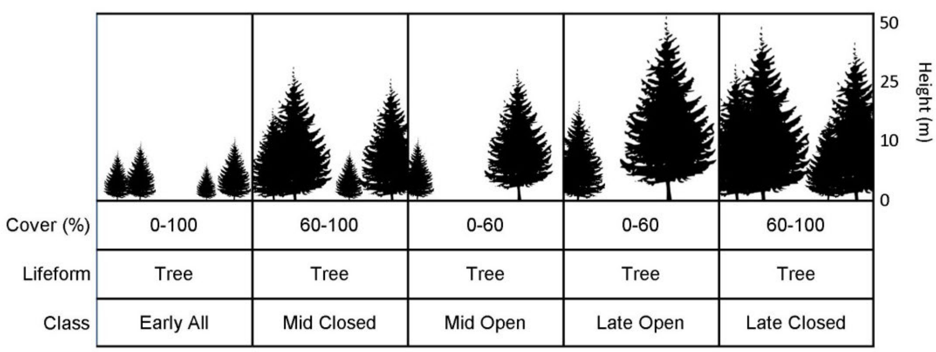

Figure 9. Typical five-class model for a forested biophysical setting, demonstrating succession class assignment based on vegetation characteristics. LANDFIRE maps up to seven succession classes using a rule-based approach—for each biophysical setting, a succession class is assigned based on rules that define specific combinations of existing vegetation type (primarily lifeform), existing canopy cover, and existing canopy height.

Updating Existing Vegetation

The existing vegetation products are periodically updated for changes due to disturbances and growth. The disturbance updating process was discussed in Chapter 3. Changes due to growth are incorporated in the mapping process after the disturbance update through a series of transition rules. Rules for updating the non-forest vegetation type for growth are developed based on the vegetation dynamics development models and the judgment of LANDFIRE analysts and other regional experts. Transition rules for forest vegetation type, cover, and height were developed based on forest growth simulations for Forest Inventory and Analysis plots modeled in the Forest Vegetation Simulator (FVS, Dixon 2002; Nelson et al. 2013). In Hawaii and Alaska (except southeast AK), where Forest Inventory and Analysis data are not available, forest transitions were developed by LANDFIRE analysts and other regional experts (Nelson et al. 2013). In LANDFIRE 2008 and 2010 the vegetation products were updated for both disturbances and growth. In LANDFIRE 2012, the vegetation products were updated for disturbance only. The transition rules are documented in databases available from the LANDFIRE Program website.

Considerations

One Classification, Three Interpretations

LANDFIRE uses the same map unit classification and naming system for the environmental site potential, biophysical setting, and existing vegetation type data layers. However, each of these layers must be interpreted differently, since they have different definitions and processing methods. A first step in identifying and mitigating possible vegetation type mapping issues (existing or potential) is to have a thorough understanding of this map unit classification and naming system and how it is used in the LANDFIRE existing vegetation type, environmental site potential, and biophysical setting data layers.

LANDFIRE uses NatureServe's Ecological Systems classification (Comer et al. 2003) as the primary map units and naming system for its existing vegetation type, environmental site potential, and biophysical setting products. The Ecological Systems classification units are intended to represent *existing* vegetation communities that persist for anywhere from 50 to hundreds of years, but LANDFIRE applies this concept in three different ways. In the existing vegetation type data layer, Ecological Systems are used as they were designed—to classify existing vegetation communities. For the environmental site potential data layer, LANDFIRE uses Ecological Systems to classify potential vegetation communities that could exist on a site given its biophysical characteristics in the absence of disturbance. Environmental site potential classes are modified to map LANDFIRE's biophysical setting concept which represents vegetation communities that may have been present prior to European-American settlement based on the biophysical environment and the historical disturbance regime. These are major differences and can have substantial effects on interpreting the data. For example, the same pixel classified as a Douglas-fir/grand fir forest environmental site potential based on the physical environment could be classified as a ponderosa pine forest biophysical setting, because of its historical fire regime, and a grass- or shrub-existing vegetation type due to a recent high-severity fire event. In rangeland, the same pixel classified as pinyon-juniper environmental site potential could be classified as a grassland biophysical setting, because of its historical fire regime, and a shrub existing vegetation type due to reduction in fire frequency.

Another important consideration specific to LANDFIRE existing vegetation type is that the NatureServe Ecological Systems map units represent vegetation communities that are typically comprised of groups of species. Most existing vegetation map users are more familiar with the concept of cover types. Cover types, in contrast to Nature Serve Ecological Systems map units, represent one or more dominant species at a single point in time. NatureServe Ecological Systems map units are not equivalent to cover types. The LANDFIRE existing vegetation type attribute table provides a crosswalk to the Society of American Foresters (SAF) and Society for Range Management (SRM) cover types classes as a guide to help users better understand LANDFIRE’s map units. However, because SAF and SRM map units represent cover types and LANDFIRE’s units represent systems, the crosswalk should not be interpreted as an exact match.

Potential vs. Existing Vegetation Type Rectification

The LANDFIRE potential vegetation data layers (environmental site potential and biophysical setting) were mapped using a predictive modeling approach based on plot data and biophysical gradient data layers, but did not incorporate imagery or use the existing vegetation type to modify the mapping process. This results in the potential vegetation data layers being inherently coarser in concept than the existing vegetation type data layer, which integrates Landsat satellite imagery. However, due to time and budgetary constraints, the LANDFIRE program has not been able to rectify either environmental site potential or biophysical setting with existing vegetation as to the inclusion or exclusion of specific existing vegetation types that would better depict site potential, thus improving content accuracy. Therefore, the user may find illogical combinations of these data layers and existing vegetation type for the same pixel, such as an existing vegetation type mapped to the same pixels as a biophysical setting that would not support the vegetation type due to moisture or topo-edaphic (i.e., soil) constraints. An example of this would be a riparian existing vegetation type, such as upper montane riparian, mapped to a non-riparian biophysical setting, such as sagebrush steppe. In the vegetation departure data products (Chapter 6) this situation may falsely indicate ecological departure. In these situations it can be difficult to determine which data layer is correct, but it is typically assumed that the existing vegetation type data layer is more likely to accurately depict the site because it integrates satellite imagery, and plot data go through additional filtering in its development.

Map Zone Boundaries

Because LANDFIRE vegetation data were mapped independently by map zone (Figure 2), differences or abrupt changes are sometimes found along map zone boundaries. For example, where map zone boundaries coincide with ecological division boundaries (Comer et al. 2003), there may be a change in the existing vegetation type map unit for similar vegetation types, such as Colorado Plateau pinyon-juniper woodland (Intermountain Basins ecological division) to Southern Rocky Mountain pinyon-juniper woodland (Rocky Mountain ecological division) (Figure 10). This does not necessarily indicate a mapping issue; however, secondary data products for which existing vegetation type is a variable in their mapping methodology—such as succession class (below), fire behavior fuel model (Chapter 5), and the fire regime and vegetation departure products (Chapter 6)—may be influenced by the difference in vegetation type map unit.

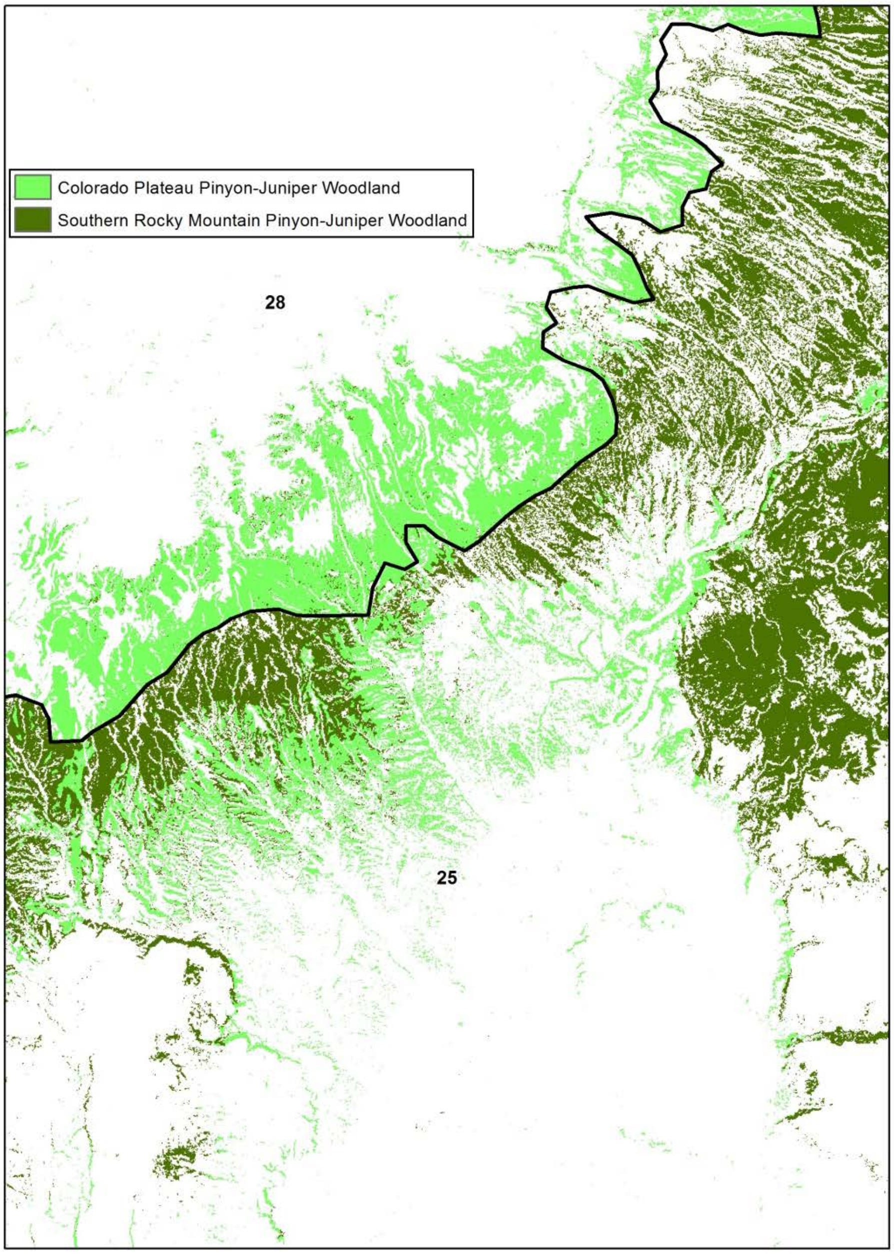

Figure 10. Comparison between the Colorado Plateau pinyon-juniper woodland existing vegetation type (Intermountain Basins ecological division) and the Southern Rocky Mountain pinyon-juniper woodland existing vegetation type (Rocky Mountain ecological division) at the map zone 25 and 28 map zone boundary. Secondary data products for which existing vegetation type is a variable in their mapping methodology may be influenced by the difference in vegetation map units at the boundary.

Existing vegetation cover is a primary variable in mapping secondary data products (i.e., succession class, fire behavior fuel model, and vegetation departure products). An abrupt change in vegetation cover within the same existing vegetation type is sometimes found at map zone boundaries (Figure 11). This may occur if the satellite imagery used for the adjacent zones was collected in different years and those years received significantly different amounts of precipitation, especially in dry southwestern ecosystems, or if different configurations of plot data were used between the zones (D. Long, personal communication, July 6, 2015). This may lead to an artificial demarcation in secondary data products and subsequently the results of analyses that use these products such as fire behavior and vegetation departure.

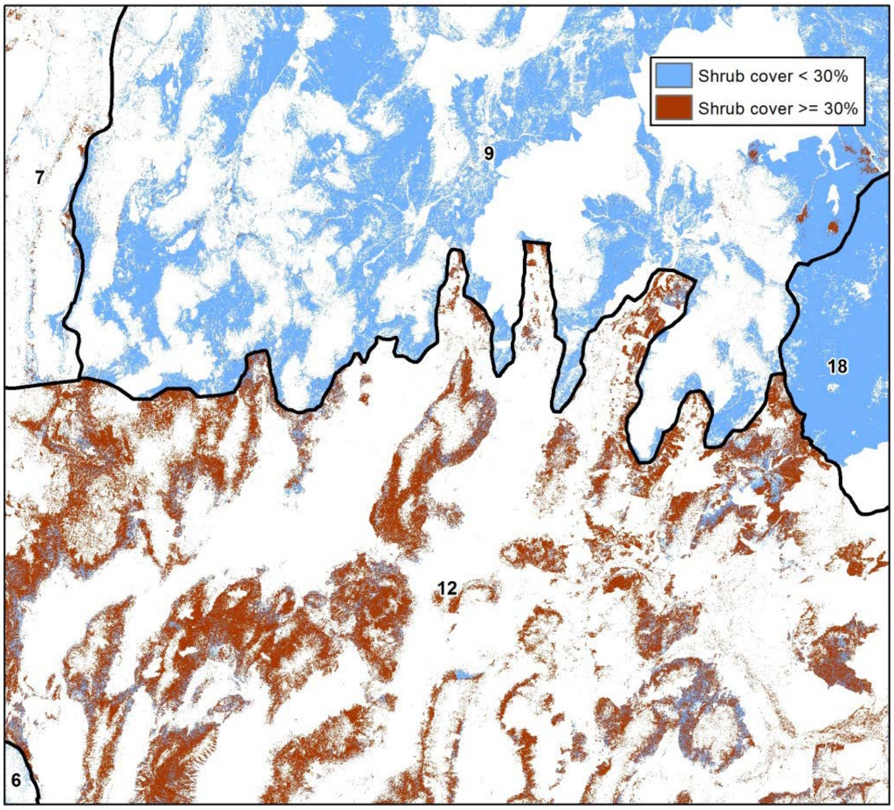

Figure 11. Abrupt change in canopy cover in the Inter-Mountain Basins Big Sagebrush Shrubland existing vegetation type at the boundary between map zones 9 and 12. This can have a profound effect on secondary data layers that use existing canopy cover as a mapping variable.

Succession Class Mapping Rules

LANDFIRE succession class is mapped using a rules-based approach. The mapping rules are based on unique combinations of biophysical setting and existing vegetation type, existing vegetation cover, and existing vegetation height. The rules were developed through a series of workshops by regional experts in vegetation dynamics and fire ecology (Rollins 2009) and are described in both the LANDFIRE vegetation dynamics model descriptions and vegetation dynamics model tracker database available for download from the LANDFIRE website.

One primary consideration in critiquing succession class mapping rules is that the modelers who developed the vegetation dynamics models sometimes emphasized species composition and structure in the definition of classes, while the mappers relied primarily on lifeform and structure to map the classes. As a result, in cases where species composition differentiates between classes of the same structure (Figure 12), LANDFIRE may not have mapped the succession classes appropriately. Post-processing in a GIS may be required to refine the succession class map based on species composition.

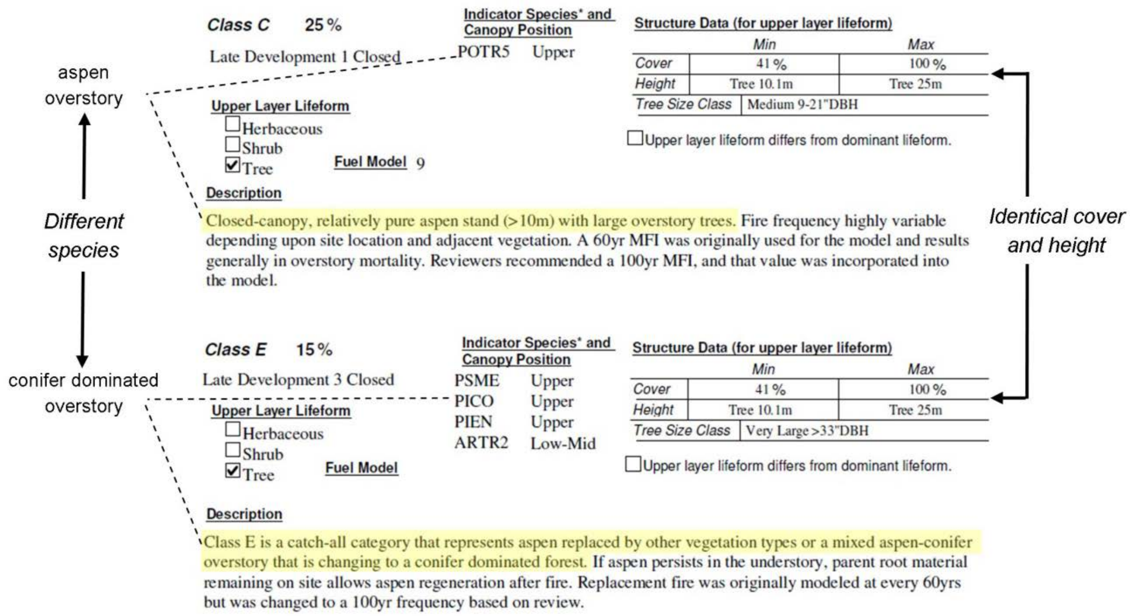

Figure 12. Example of a biophysical setting where species composition (not lifeform) is the primary variable for differentiating between succession classes. As of version 1.2.0 (LANDFIRE 2010) succession class E was not mapped for this biophysical setting in map zone 21 thus requiring GIS post-processing to map it.

Another consideration is that structure, as defined in the vegetation dynamics models, may be difficult to map using remote-sensing based techniques (as is done in mapping LANDFIRE existing vegetation). For example, although a rule may differentiate between succession classes based on whether herbaceous vegetation height is less than or greater than 0.5m, this level of precision is difficult to map accurately using the satellite-based predictive modeling approach described above (Riano et al. 2002). Conversely, the existing vegetation height classes in forested vegetation (Table 7) may be too coarse to accurately differentiate between succession classes (e.g., 10m to 25m and 25m to 50m) or a poor surrogate for vegetative development stage altogether. Chapter 6 contains additional considerations for using the LANDFIRE succession class data layer in vegetation departure analyses.

Chapter 5: Fuels

LANDFIRE produces geospatial data depicting surface and canopy fuel characteristics. For surface fuel data we will focus on the 40 Scott and Burgan fire behavior fuel models data layer (Scott and Burgan 2005), as it is the most commonly used LANDFIRE surface fuel data product. However, the concepts presented in the Considerations section of this chapter are applicable to the other LANDFIRE surface fuel products as well—13 Anderson fire behavior fuel models (Anderson 1982), Canadian forest fire danger rating system fuel types, fuel characteristic classification system fuelbeds, and fuel loading models.

In combination with forest canopy cover, forest canopy height, and topographic data (slope, aspect and elevation), LANDFIRE fire behavior fuel model and canopy fuel data (canopy base height and bulk density) can be used to create a “landscape” file (LCP) required by common geospatial fire behavior modeling systems used in the United States, such as FlamMap (Finney 2006), FARSITE (Finney 1998), and FSPro (USDAFS 2009). Although an LCP file may be downloaded directly from the LANDFIRE data distribution website, we do not discuss the critique or modification of these data in the LCP file format.

This chapter presents an overview of the LANDFIRE fuel mapping process and common considerations for critiquing LANDFIRE fuel data with examples relevant to local applications.

Fuel Mapping Process

Surface Fuels

Technically, a fire behavior fuel model—Anderson (1982) or Scott and Burgan (2005)—is a set of fuelbed inputs required by fire behavior modeling systems that use the Rothermel (1972) fire spread model. More practically speaking, a fire behavior fuel model represents a range of fuelbed conditions (e.g., load, depth, surface-area-to-volume ratios) in which fire behavior may be expected to respond similarly to changes in fuel moisture, slope, and wind speed (Figure 13). In this sense, a fire behavior fuel model is not so much a model of fuels as it is a model of fire behavior.

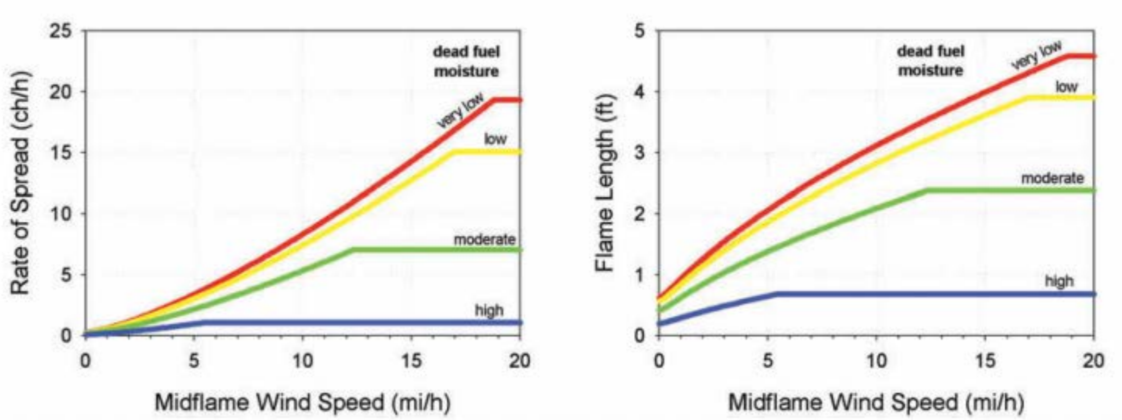

Figure 13. Differences in rate of spread and flame length by dead fuel moisture content and wind speed for fuel model Timber-Understory 1 (Low Load Dry Climate Timber-Grass-Shrub; Scott and Burgan 2005).

Like succession class (Chapter 4), all LANDFIRE surface fuel data products are mapped using an expert-opinion, rule-based approach, where mapping rules are based on unique combinations of: existing vegetation type, cover, and height; biophysical setting; and disturbance (Chapters 3 & 4). Fire behavior fuel model mapping rules were developed by fire and fuel specialists through a series of fuel calibration workshops held across the United States. The purpose of these workshops was to elicit regional expertise about fire behavior characteristics (i.e., how fire burns) in various vegetation types and structures. The calibration workshops were conducted at the extent of a LANDFIRE map zone or multiple adjacent zones. There are 80 LANDFIRE map zones across the continental U.S., Alaska, and Hawaii, ranging in size from 4 to 60 million acres (Figure 2).

The LANDFIRE total fuel change tool (formally known as ToFu Δ) (LFTFCT 2011) is a custom ArcGIS toolbar that links to the national fuel mapping rules through a Microsoft Access database (Figure 14). This tool, originally developed for use in the national calibration workshops, can now be downloaded from the [Wildland Fire Management Research, Development and Application] website and is highly useful in local LANDFIRE fuel data critiques.

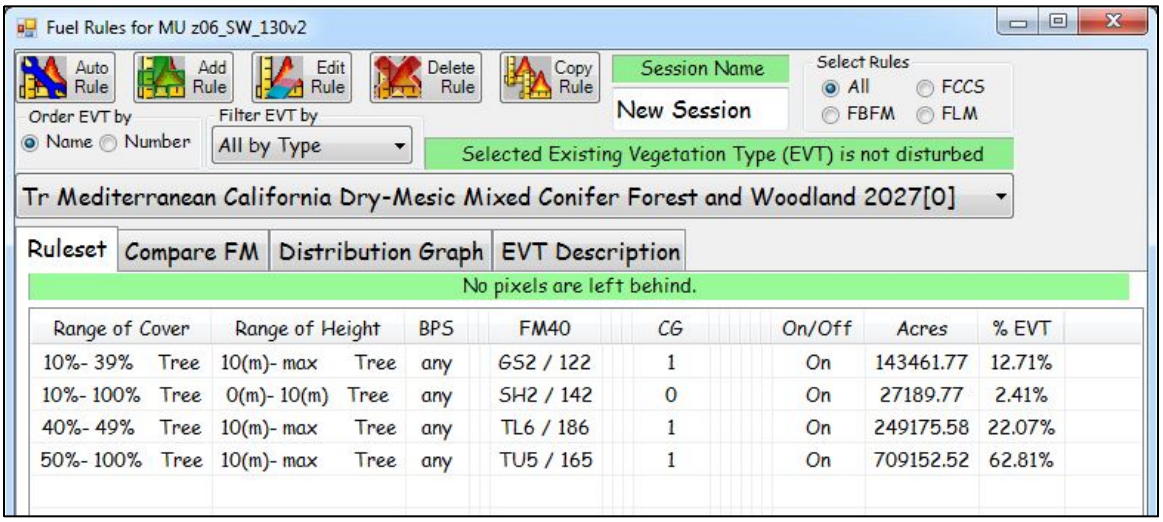

Figure 14. Example LANDFIRE Total Fuel Change Tool (LFTFCT) rule set. The LFTFCT is a custom ArcGIS toolbar that links to the LANDFIRE fuel mapping rules through a Microsoft Access database.

Canopy Fuels

The LANDFIRE canopy fuel data products include canopy base height, canopy bulk density, forest canopy cover, and forest canopy height. Forest canopy cover and canopy height values represent the midpoint of the existing vegetation cover and height data layer classes, respectively. These values are used in some fire behavior modeling systems as variables in predicting dead woody fuel moisture, wind reduction, and crown fire spotting potential. All four variables are required to model crown fire behavior using U.S. fire behavior modeling systems.

Canopy base height is defined as the lowest height above the ground at which there is sufficient available fuel (i.e., ≤ 0.25 inch diameter) to propagate fire vertically through the canopy. It is important to differentiate canopy base height—which is a property of the group of trees represented by the pixel—from *crown* base height, which is a property of an individual tree. Canopy base height is an important variable for fire behavior modeling, as it is used to predict whether crown fire initiation is possible under a given set of environmental conditions (Scott and Reinhardt 2001; Scott 2012). Prior to LANDFIRE 2012, canopy base height was mapped based on plot level averages. Various combinations of existing vegetation type, cover, and height values were crosswalked to an average canopy base height value of associated plots. For the LANDFIRE 2012 canopy base height data layer, a predictive modeling approach was implemented where field referenced plot data were used to develop regression equations based on statistical relationships between canopy base height and existing vegetation type, cover, and height (USGS 2010).

Canopy bulk density is the mass of available canopy fuel per unit canopy volume (Scott and Reinhardt 2001). Like canopy base height, canopy bulk density is a property of a group of trees—*crown* bulk density is a property of an individual tree. In fire behavior modeling, canopy bulk density is used to predict whether an active crown fire is possible under a given set of environmental conditions assuming that a crown fire has initiated (Scott and Reinhardt 2001; Scott 2012). LANDFIRE maps canopy bulk density using a predictive modeling approach based on forest canopy cover, forest canopy height, and membership to a pinyon-juniper existing vegetation type as input to a generalized linear model (Reeves et al. 2009).

In deciduous forest vegetation types—typically not considered prone to crown fire—LANDFIRE assigns canopy base height and canopy bulk density values that prevent fire behavior modeling systems from predicting crown fire. Forest canopy cover and forest canopy height values are still mapped to account for the canopy's effect on fuel moisture and wind reduction.

Fuel Updates

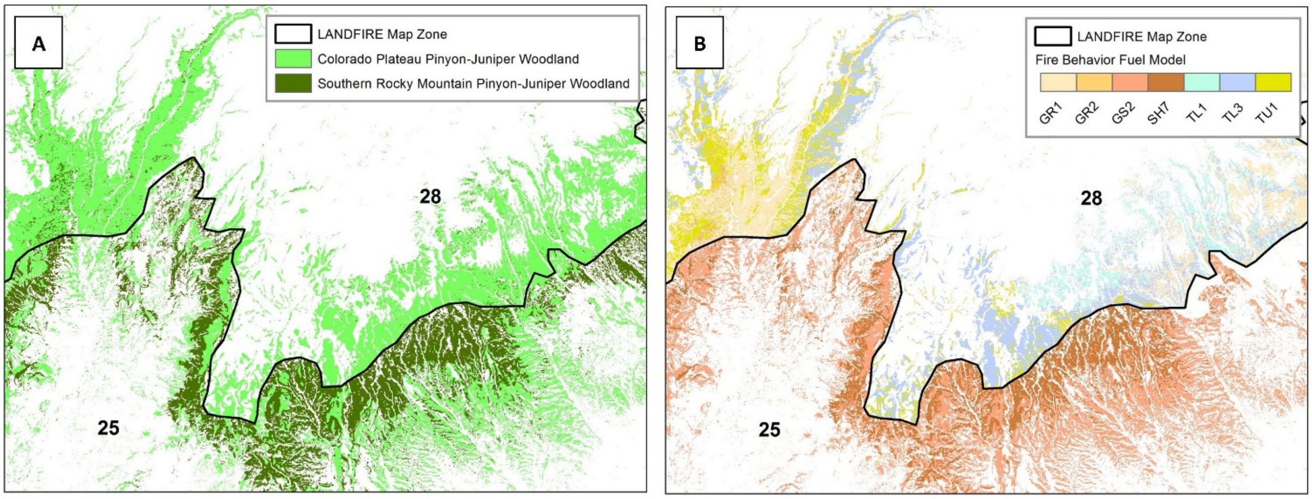
Because surface and canopy fuel mapping rules are tied to existing vegetation type, cover, and height, updates to existing vegetation data due to growth and vegetation succession automatically account for updates to fuels in non-disturbed areas. Whether an update to the fuel data layers occurs or not depends on the magnitude of the change and the threshold values in the mapping rules.

Rules for disturbed areas are independent of rules for non-disturbed areas so that the disturbance type, severity, and time-since-occurrence can be taken into account in combination with the post-disturbance vegetation characteristics, including unique lifeform and species specific disturbance response as discussed in the previous sections. The one-year time-since-disturbance category is used by LANDFIRE to update the immediate post-fire effects to canopy fuels but not used in the assignment of post-disturbance fire behavior fuel model. Fire behavior fuel model is the same for the one-year and two- to five- year time-since-disturbance categories, which are considered to represent the second growing season after the event (C. Martin, personal communication, July 10, 2015).

Considerations

Map Zone Boundaries

As mentioned earlier, fire behavior fuel model mapping rules are developed for individual map zones or groups of adjacent zones based on unique combinations of existing vegetation type, cover, and height; biophysical setting; and, disturbance. It is common to find differences in mapping rules between adjacent map zones that may lead to an "artificial edge" at the zone boundary (Figure 15). In situations where your analysis area overlaps more than one LANDFIRE map zone, a primary consideration is whether there are differences in mapping rules between the zones. If so, determine whether those differences are legitimate or if the rules from one zone more appropriately fit the analysis area as a whole. If working in an area with pinyon-juniper vegetation types, a specific mapping rule issue to watch for is whether or not there are differences between zones in the assignment of canopy fuels. In some cases, the rules for one map zone will consider the canopy fuels in pinyon-juniper vegetation types as part of the surface fuel model, while the rules for an adjacent map zone will not. This may lead to prediction of crown fire on one side of the zone boundary and surface fire on the other. The discrepancies are due to differences in mapping methodology rather than actual fire behavior potential. There may be valid reasons for each case but consistency should be strived for when an analysis area intersects multiple map zones, to ensure consistent interpretation of the results across the entire analysis area.



Existing Vegetation Type	Zone 28				Zone 25			
	Tree Cover (%)	Tree Height	FM	CG	Tree Cover (%)	Tree Height	FM	CG
Colorado Plateau Pinyon-Juniper Woodland	10-29	Any	GR1	1	10-19	Any	GR2	0
	30-39	Any	TU1	1	20-49	Any	GS2	0
	40-59	Any	TL3	1	50-100	Any	TL3	1
	60-100	Any	TL1	1	-	-	-	-
Southern Rocky Mountain Pinyon-Juniper Woodland	10-19	Any	GR2	1	10-29	Any	GS2	0
	20-59	Any	GS2	1	30-49	Any	SH7	0
	60-100	Any	TL3	1	50-100	Any	TL3	1

Figure 15. Example of variation in fire behavior fuel mapping rules by existing vegetation type and map zone. Panel A shows the existing vegetation type at the map zone boundary; panel B shows the fire behavior fuel model. FM refers to the standard Fire Behavior Fuel Model (Scott and Burgan 2005). CG refers to the canopy guide feature in the LANDFIRE Total Fuel Change Tool that controls how canopy fuels are mapped.

Multiple inconsistencies between map zones can be seen in Figure 15. The predominant pinyon-juniper existing vegetation type in map zone 28 is Colorado Plateau pinyon-juniper woodland; in map zone 25 it is southern Rocky Mountain pinyon-juniper woodland (Figure 15A). The fire behavior fuel model mapping rules for these two vegetation types vary both by type and by map zone, resulting in the obvious difference in fuel model seen at the boundary (Figure 15B). Furthermore, in map zone 28, the rules for both vegetation types include the assignment of canopy fuels (i.e., canopy guide of 1); in map zone 25 the rules do not assign canopy fuels to pixels with less than 50% canopy cover, indicating that the trees are part of the surface fuel stratum. This inconsistency forces a different interpretation of fire behavior modeling results for each map zone.

Application Scale and Location

As stated earlier, fire behavior fuel model mapping rules were developed at regional workshops for application to individual, or groups of adjacent, map zones. While these rules may be appropriate at this scale, they may need to be adjusted for application at finer scales. In other words, the "best fit" for an entire map zone may be a compromise between different parts of the zone. For finer-scale applications, fire behavior fuel model mapping rules should be locally critiqued whenever possible. We recommend doing this in a workshop setting, where local specialists with expertise in local fire behavior critique the national mapping rules and make adjustments as needed. Remember, the objective is to choose the fire behavior fuel model that most appropriately simulates the observed or expected fire behavior under a range of fire-environment conditions. It is therefore invaluable to have workshop participants who have seen fire burn under a range of conditions in the local vegetation types.

Another consideration common in more arid locations is whether the fuel models that are appropriate under a typical, or average, yearly weather scenario are appropriate in an atypical scenario. For example, in a typical year, fire behavior in many desert ecosystems may be best represented using a shrub fire behavior fuel model. However, in a year when an unusually wet winter is followed by an influx of annual grasses, the primary carrier of fire will be the herbaceous component and thus fire behavior would be better represented using a grass or grass-shrub fuel model. In this case, two separate versions of fuel data layers could be created to represent the different fuel scenarios.

Similarly, areas with a heavy deciduous tree component may experience very different fire behavior depending on the time of year. In fall, winter, and spring the leaves have fallen from deciduous trees, therefore adding to the load and structure of the surface fuels and associated surface fire behavior. As mentioned above, in deciduous forest vegetation types, LANDFIRE assigns pseudo canopy-fuel values that prohibit the simulation of crown fire in fire behavior modeling systems but retain the actual forest canopy cover and height values for modeling the influence of canopy cover on wind-reduction and fuel moisture. However, in mixed deciduous-conifer existing vegetation types LANDFIRE does not account for the proportion of deciduous-to-conifer cover; canopy bulk density is estimated from the total forest canopy cover. Depending on the proportion of conifer and deciduous trees, canopy bulk density may therefore be overestimated in these stands throughout the year, and wind-reduction and shading may be overestimated during the leaf-off times of the year.

Disturbance

Disturbances may affect both surface and canopy fuels depending on their type and severity. As with undisturbed fuels, the fuel mapping rules for disturbed areas should be critiqued by local fire specialists before application to finer-scale analyses.

In grass and shrub vegetation types the post-disturbance fire behavior fuel model is influenced by the affected species' response to disturbance. For example, wildfire in grass vegetation types is typically high-severity by nature—consuming all of the above-ground biomass. Most grasses, however, return to their pre-fire condition relatively quickly (i.e., one or two growing seasons) and in some cases will respond with increased biomass compared to the pre-fire condition due to an influx of nutrients and more favorable growing conditions. In shrub vegetation types, low-severity fire (less than 25% overstory mortality) may have little effect on the fuel load, fuelbed depth, and other components of a shrub-based fire behavior fuel model, whereas high-severity fire (greater than 75% overstory mortality) may result in immediate resprouting of shrubs or conversion to grass for some period of time, all dependent on the particular species' response to fire.

In tree-dominated vegetation types, low-severity fire will, generally speaking, consume litter (small dead branches and needles on the forest floor) and grass with minimal effect on understory shrubs and small trees. Moderate-severity fire may have a wide range of effects on litter and understory vegetation, but at the pixel level can generally be assumed to have consumed most of the litter and understory vegetation. By LANDFIRE severity definitions, moderate-severity fire in forested vegetation types results in 25% to 75% overstory tree mortality. High-severity fire results in greater than 75% mortality of the overstory trees. The mortality of overstory trees will influence the availability of light, water, and nutrients to understory vegetation, as well as contribute litter (through needle and branch fall) and large woody debris (as dead trees fall) as surface fuels over time.

These same principles apply to non-fire disturbance types. Ask yourself what is the response of the vegetation to the particular disturbance, what influences will this response have on post-disturbance fuel, how fire burns in the disturbed area, and what is the effect of time-since-disturbance.

As discussed in Chapter 3, the generalization of mechanical disturbance types to two categories—mechanical add and mechanical remove—may lead to a misrepresentation of effects. Critique of the LANDFIRE events polygon and individual year disturbance data by local experts can often confirm or provide additional information about the disturbance's effect on fuels.

The effect of time-since-disturbance varies by location and fuel type. Time-since-disturbance is split into three categories, the first of which is "one year". The need for the one year time-since-disturbance category can be evaluated based on your location, how you plan to apply the data, and how frequently you plan, or need, to update it.

Modeling

In-depth discussion of wildfire behavior modeling concepts is beyond the scope of this guidebook. Scott (2012) provides a comprehensive review of the topic in his *Introduction to Wildfire Behavior Modeling* guide. Nevertheless, a few considerations warrant discussion here. Wildfire behavior modeling requires an understanding of how the interaction among vegetation, fuels, and topography—as characterized in LANDFIRE data—influences modeling results. Wildfire analyst support may therefore be desired when critiquing and updating fuel data, depending on local wildfire behavior modeling expertise.

First, there is no direct, repeatable method for measuring canopy base height in the field, and multiple observers will often estimate significantly different values in the same stand. Methods exist to indirectly estimate canopy base height from plot data (Sando and Wick 1972; Cruz et al. 2003; Reinhardt and Crookston 2003; Scott and Reinhardt 2005), but canopy base height is challenging to map at a landscape scale because it is not well-related to characteristics that can be measured by remote sensing techniques. Canopy base height may include ladder fuels such as lichen, dead branches, needle drape, small trees, and shrubs. However, if shrubs and small trees are being considered as part of the fire behavior fuel model, they should not also be included in the canopy base height.

Next, understanding the interaction of fire behavior fuel model and canopy base height on modeling results is crucial in critiquing fuel data. The fire behavior fuel model predicts the surface fire intensity under a given set of environmental conditions (e.g., wind speed, slope steepness, fuel moisture). The lower the canopy base height, the milder these conditions can be in order to initiate crown fire. Given the difficulty of measuring and mapping canopy base height, working backwards— that is, adjusting canopy base height based on the conditions expected to initiate crown fire—is an effective way to critique canopy base height in relation to other variables. Tools such as NEXUS (Scott 1999) and BehavePlus (Andrews 2013) can provide information on the torching index—20' wind speed required for crown fire initiation—under various fuel and fire environments. The LFTFC tool also includes an option for calculating the critical canopy base height needed for crown fire initiation for different combinations of fire behavior fuel model, fuel moisture, and wind speed (Figure 16).

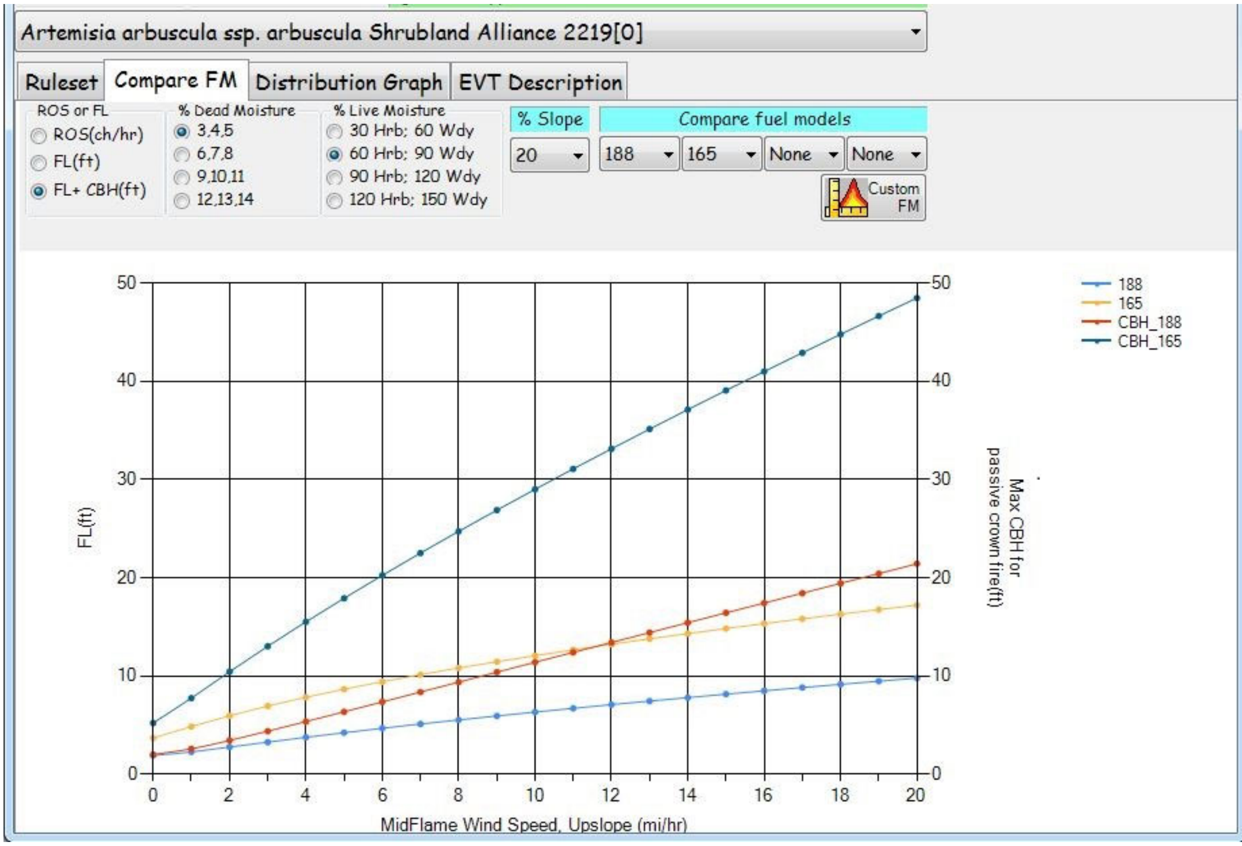


Figure 16. LANDFIRE Total Fuel Change Tool compare fuel model tab. This allows the user to calculate the critical canopy base height needed for crown fire initiation for different combinations of fire behavior fuel model, fuel moisture, and wind speed.

Lastly, in fire behavior modeling, canopy bulk density is a factor in determining whether an active crown fire can be sustained once initiated. Since the existing vegetation height classes used to predict canopy bulk density are rather coarse, they influence the resulting precision of the canopy bulk density values as well. Again, tools such as NEXUS and BehavePlus can be useful in determining if the data will predict the expected fire behavior under various conditions. Analysts are also encouraged to run geospatial fire behavior modeling systems to see if patterns in the results reveal any potential calibration issues that warrant a closer look. This is the *analyze* component of the data critique and modification framework discussed in Chapter 2.

Chapter 6: Fire Regime and Vegetation Departure

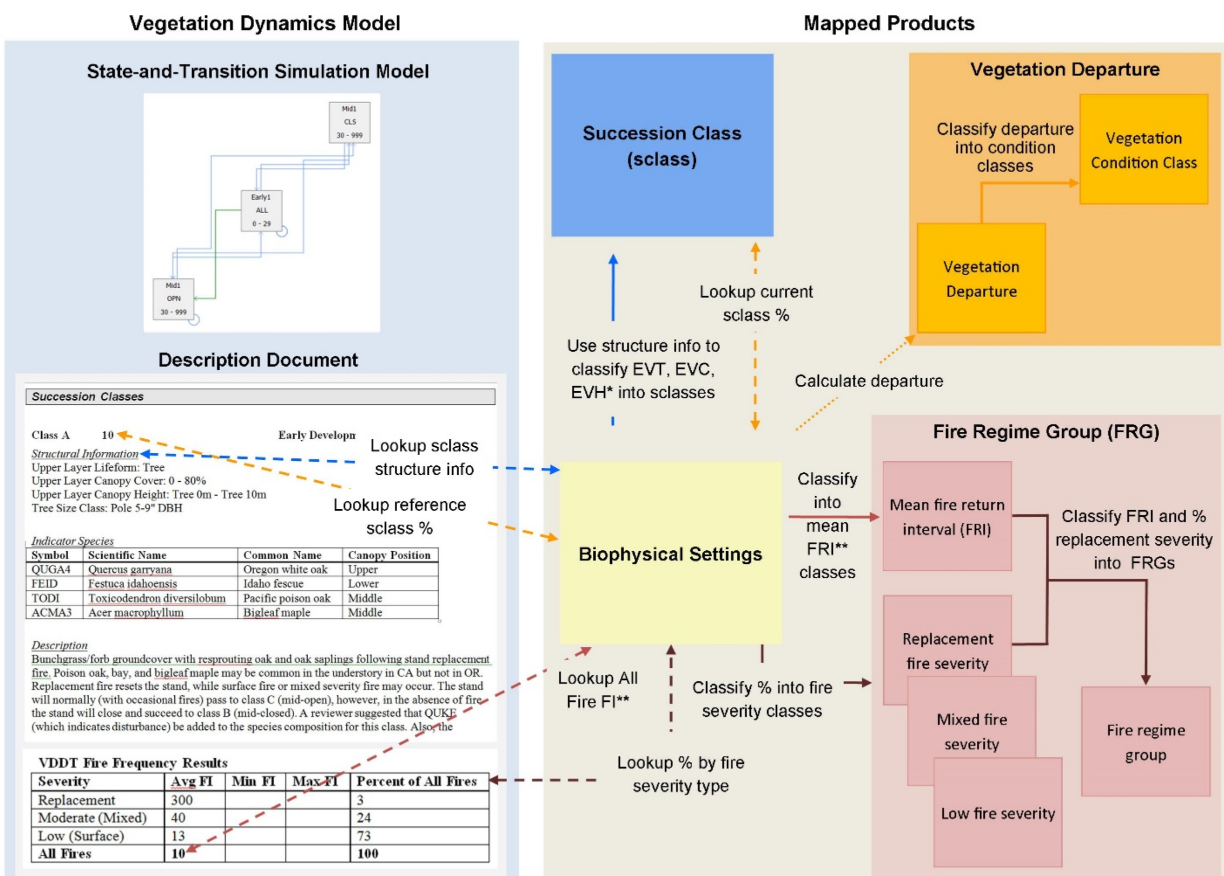
The fire regime and vegetation departure products are useful for understanding historical fire regimes and the current condition of vegetation on the landscape within the context of the historical disturbance regime. The fire regime products include fire regime group, mean fire return interval, percent low-severity fire, percent mixed-severity fire, and percent replacement-severity fire. The vegetation departure products include vegetation departure and vegetation condition class. The departure products were created for the LANDFIRE National, 2001, 2008 and 2012 versions but not for LANDFIRE 2010.

This chapter begins with an overview of the vegetation dynamics models, which form the basis of the fire regime and vegetation departure products, and then describes how those products are mapped by LANDFIRE. The chapter concludes by presenting common considerations for critiquing these data layers and provides examples of common pitfalls.

Fire Regime Mapping Process

Vegetation Dynamics Models

The foundation of the fire regime and vegetation departure products is a set of models that describe the vegetation dynamics and reference conditions of each biophysical setting mapped by LANDFIRE (Figure



*Existing vegetation type (EVT), cover (EVC) and height (EVH)

**Fire Interval (FI) and Fire Return Interval (FRI) refer to the average fire frequency modeled.

17). This section therefore begins with a brief overview of the models and how they relate to the fire regime and vegetation departure products. More information on the vegetation dynamics models can be found on the LANDFIRE program website.

Figure 17. The fire regime and vegetation departure products are created through crosswalks that link each BpS on the BpS data layer to the reference condition values modeled in the corresponding vegetation dynamics model.)

LANDFIRE collaborated with vegetation and fire ecology experts to create a vegetation dynamics model to estimate the reference (i.e., pre-Euro-American settlement) condition for each biophysical setting. The models were created in the Vegetation Dynamics Development Tool (VDDT, ESSA Technologies Ltd. 2007). A model represents a single biophysical setting and consists of five or fewer successional states, or classes, that compose the biophysical setting (Figure 18). Each state is equivalent to a succession class and each succession class is mapped in the succession class data layer (Chapter 4). A state has an age range that indicates how long it typically persists before it transitions to the next state. Disturbance pathways between states are used to represent the impact of important disturbances, and each pathway is defined by a probability that describes how often it occurs. The models were attributed based on scientific literature, available data, and the experience and judgment of the modelers (Rollins 2009).

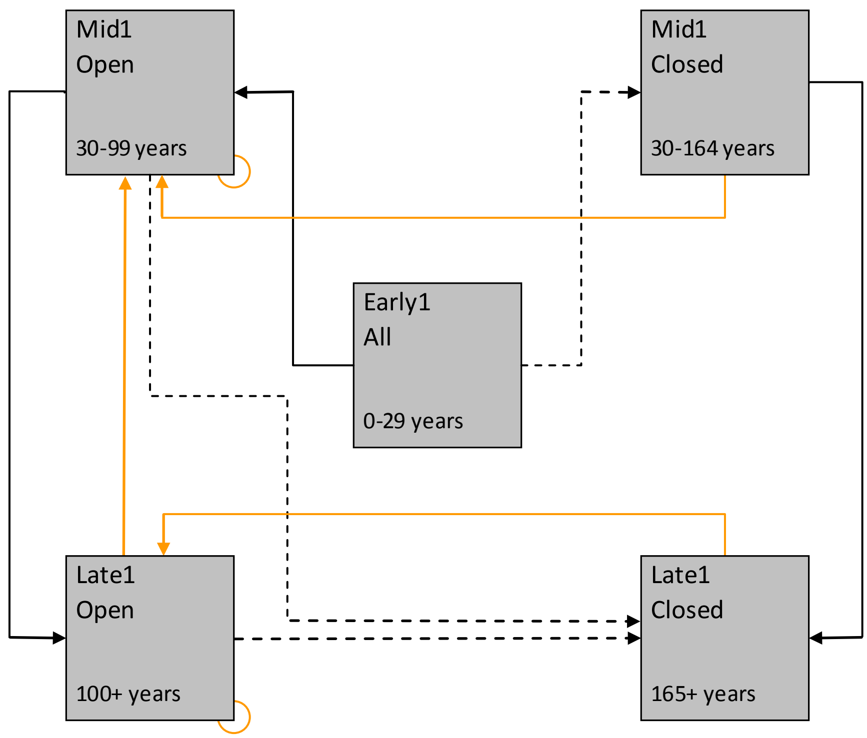


Figure 18. State-and-transition model of the Pacific Northwest Mixed Conifer BpS. This model is comprised of five successional states (boxes). Each state has an age range and is linked to other states through main successional pathways (solid lines), alternative succession pathways (dashed lines) and disturbance pathways (yellow line represent mixed fire transitions).

Once attributed, each model was run for ten 1,000-year simulations, in VDDT, and the results were averaged to estimate the biophysical setting reference conditions. The reference conditions include:

- the fire frequency expressed as a mean fire return interval,

- the fire severity expressed as the relative percent of low-, mixed-, and replacement-severity fire, and
- the relative amount represented by each succession class expressed as a percent.

The reference conditions are published in the LANDFIRE model descriptions along with the VDDT models available from the LANDFIRE website (Figure 19).

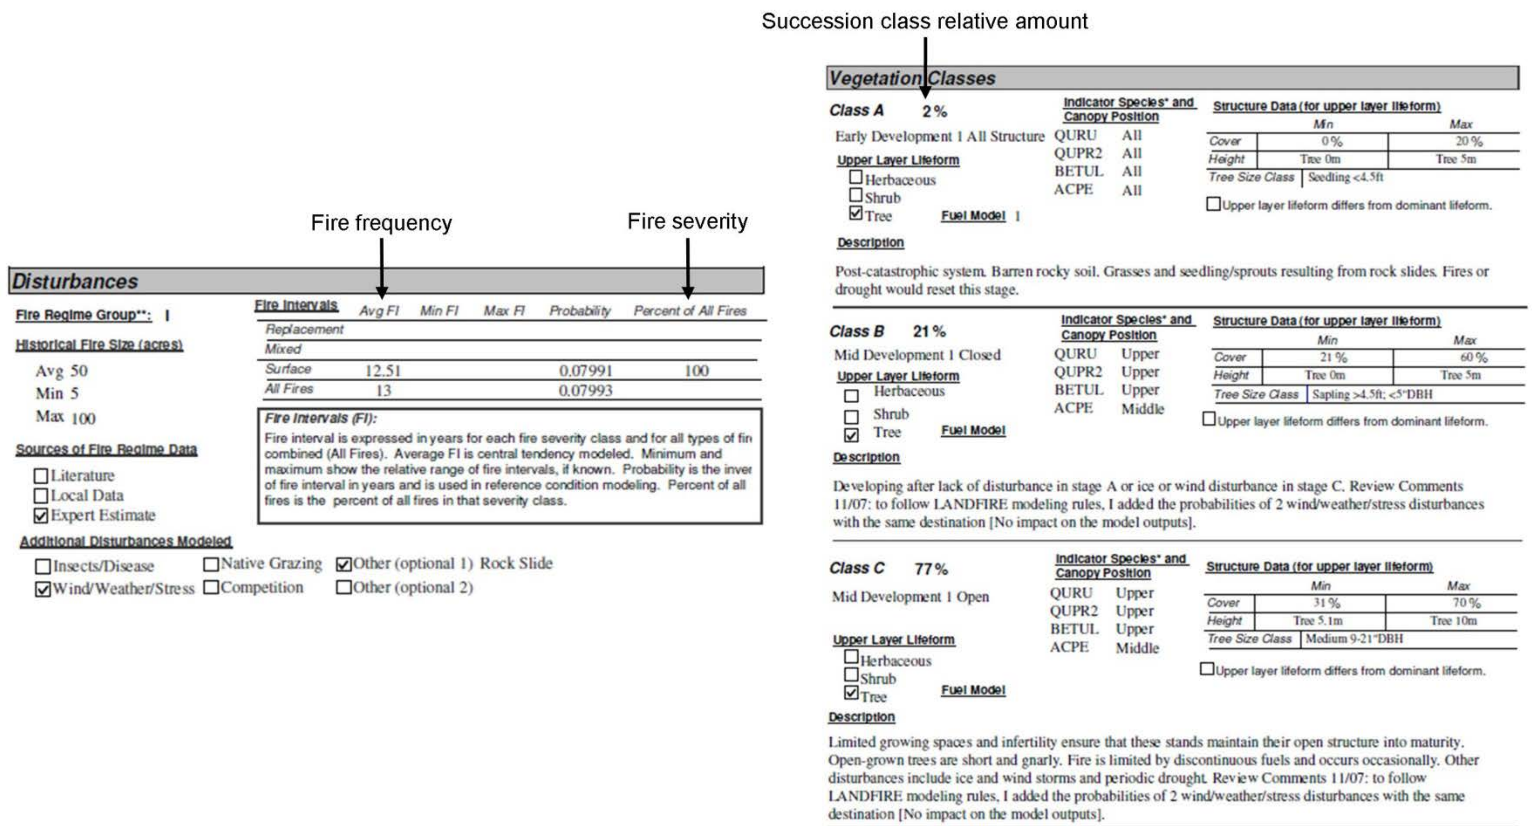

Figure 19. The biophysical setting model descriptions contain the reference conditions. The fire frequency and severity are found in the Disturbances section. The relative amount represented by each succession class is expressed as a percent and is found after the class letter name in the upper left of each vegetation class description.

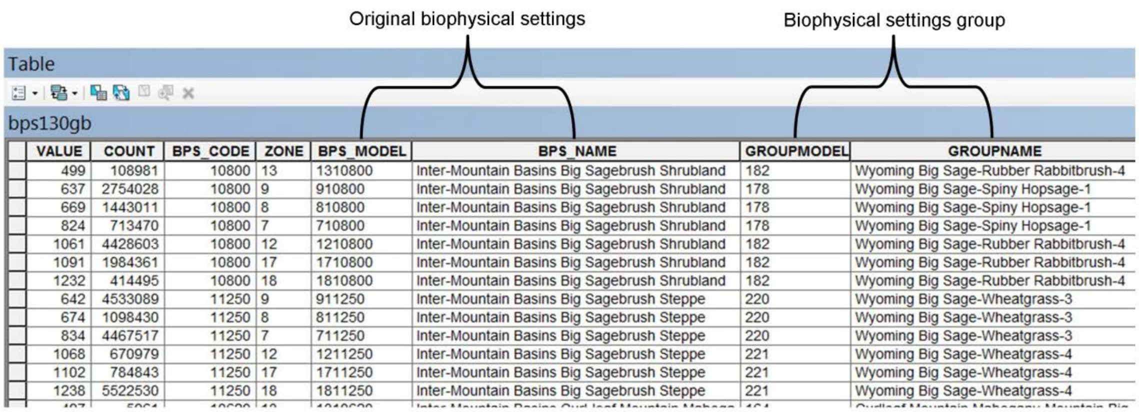
Vegetation Dynamics Models and Biophysical Setting Map Units

The LANDFIRE biophysical setting data layer contains attributes for two nested map units: biophysical setting and biophysical setting groups. The biophysical setting attribute is the original biophysical setting classification based on NatureServe's Ecological Systems and described in the vegetation dynamics model description documents. LANDFIRE created biophysical setting groups to simplify the mapping of the fire regime products and to reduce the complexity of the vegetation dynamics model set for users. The original units were placed into groups based on similar vegetation and fire regime characteristics. Each biophysical setting group is represented by a single "exemplar" model chosen from the original model set. The fire regime products and the succession class data layer in LANDFIRE 2001 and 2008 are based on the biophysical setting groups and their associated exemplar models. All other LANDFIRE versions, including the most recent versions, use the original biophysical setting attribute. Although the biophysical setting and the biophysical setting groups are related, they can have different succession class definitions and different reference conditions, including different succession class proportions and fire frequency and severity values. Users need to pair the correct biophysical setting attribute in the biophysical setting data layer with the correct model based on the version of LANDFIRE data they are using. The relationship between biophysical setting and biophysical setting groups is described in the "BpS Groups Table" located on the LANDFIRE website (Figure 20).



VALUE	COUNT	BPS_CODE	ZONE	BPS_MODEL	BPS_NAME	GROUPMODEL	GROUPNAME
499	108981	10800	13	1310800	Inter-Mountain Basins Big Sagebrush Shrubland	182	Wyoming Big Sage-Rubber Rabbitbrush-4

1068	670979	11250	12	1211250	Inter-Mountain Basins Big Sagebrush Steppe	221	Wyoming Big Sage-Wheatgrass-4
1102	784843	11250	17	1711250	Inter-Mountain Basins Big Sagebrush Steppe	221	Wyoming Big Sage-Wheatgrass-4
1238	5522530	11250	18	1811250	Inter-Mountain Basins Big Sagebrush Steppe	221	Wyoming Big Sage-Wheatgrass-4

Figure 20. LANDFIRE biophysical settings were placed into groups based on similar vegetation and fire regime characteristics. Each biophysical setting group is represented by a single "exemplar" model chosen from the original model set. For example, in the table above notice that the seven original Inter-Mountain Basins Big Sagebrush Shrubland biophysical settings models were lumped into two groups: Wyoming Big Sage-Rubber Rabbitbrush-4 and Wyoming Big Sage-Spiny Hopsage-1.

Fire Regime: Frequency, Severity, and Fire Regime Group

The mean fire return interval data layer depicts the presumed historical fire frequency for each biophysical setting. The layer is created by linking the biophysical setting to the VDDT-modeled fire frequency results described in the vegetation dynamics model description document. The mean fire return interval is classified into 22 categories that vary in length to provide greater temporal resolution for frequently burned biophysical settings and less temporal resolution for biophysical settings that burn infrequently.

The fire severity data layers depict the relative percent of low-, mixed-, and replacement-severity fire under the presumed historical fire regime for each biophysical setting. Fire severity is defined as the percent mortality of the overstory vegetation: less than 25% mortality is classified as low-severity, 25-75% mortality is classified as mixed-severity, and greater than 75% mortality is classified as high-severity. The layer is created by linking the biophysical setting to the VDDT-modeled relative amount of each fire severity type as reported in the vegetation dynamics model description document. The results range from 0-100% and they are classified and mapped in 5% increments.

The fire regime group data layer characterizes the presumed historical fire frequency and percent replacement severity fire for each biophysical setting in five classes (Table 8). The fire regime group layer is created by linking the biophysical setting to the fire frequency and severity results described in the vegetation dynamics model description document.

Table 8: Fire regime group mapping rules. The fire regime group layer is created using a rule set that classifies combinations of fire frequency and relative percent replacement severity fire into one of five fire regime groups for each biophysical setting.

Fire Regime Group	All Fire Frequency (years)	Relative Percent Replacement Severity Fire
I	0-35	<66%
II	0-35	>=66%
III	36-100	<80%
	101-200	<66%
IV	36-100	>=80%
	101-200	>=66%
V	>=201	Any fire severity

All of the fire regime products include additional map units for water, snow/ice, barren, and sparsely vegetated systems which are mapped from the existing vegetation type data layer. The value "indeterminate fire regime characteristics" identifies a biophysical setting without fire disturbance in its associated vegetation dynamics model. These are typically biophysical settings that are either too wet or too dry to carry fire (e.g., Alaskan Pacific Maritime Sitka Spruce Forest biophysical setting).

Vegetation Departure

LANDFIRE provides geospatial data that characterize two metrics of vegetation departure: stratum vegetation departure and stratum vegetation condition class. Vegetation departure and vegetation condition class are calculated following the methodology described in the FRCC Guidebook (Barrett et al. 2010) and the FRCC Mapping Tool User's Guide (Jones and Ryan 2012). Both metrics describe the overall departure of the current vegetation conditions from the historical, or reference, vegetation conditions across all succession classes within a particular biophysical setting (i.e., stratum). The historical proportion, or relative amount, of each succession class in a biophysical setting is based on the average proportion modeled in the vegetation dynamics model and reported in the model description document (Figure 17). Current succession class proportions are calculated directly from the succession class data layer.

Stratum vegetation departure is calculated by determining the succession class "similarity" (the smaller of the reference, or the current proportion, for each succession class), summing the similarities, and then subtracting from 100. This provides the percent departure for a biophysical setting and that value is mapped in the vegetation departure data layer. To create the vegetation condition class data layer, the percent departure is classified into three classes: 0-33% departure in condition class 1, 34-66% departure in condition class 2, and 67-100% departure in condition class 3 (see sidebar).

Calculating Vegetation Departure

Stratum vegetation departure is calculated by comparing the reference distribution of succession classes (i.e., the proportion that each contributes to the whole expressed as a percent) to the current distribution of succession class for individual biophysical settings. In the table below, departure is calculated for a biophysical setting with three reference succession classes (A, B, and C), which are defined in its vegetation dynamics model. The Uncharacteristic succession class only includes a current value because by definition it does not occur under the reference condition. The uncharacteristic class proportion is the sum of the uncharacteristic native and uncharacteristic exotic proportions.

The first step in calculating stratum vegetation departure is to determine the succession class similarity (i.e., the lower of the reference or current percent) of each succession class. Next, stratum similarity is calculated by summing the succession class similarity values. Then, the current stratum vegetation departure is calculated by subtracting the stratum similarity value from 100. This is the value mapped in the LANDFIRE vegetation departure grid. Finally, the vegetation condition class is calculated by classifying the current stratum vegetation departure value into the three condition classes (1 = ≤ 33%, 2 = > 33% to ≤ 66%, 3 = > 66%). This is the value mapped in the LANDFIRE Vegetation Condition Class grid:

Succession Class (S-Class)	Reference Percent	Current Percent	S-Class Similarity
A-Early	15	3	3
B-Mid	40	25	25
C-Late	45	31	31
Uncharacteristic	0		
Stratum Similarity	**59**		
Current Departure	**41**		
Vegetation Condition Class	**2**		

Departure is calculated for a specific geographic area referred to as the landscape summary unit. For LANDFIRE National, departure was calculated for ecological subsections (Cleland et al. 2005) within a LANDFIRE map zone. In LANDFIRE 2001 and 2008 departure was calculated within nested hydrologic unit codes (HUCs; Seaber et al. 1987). Departure for biophysical settings in fire regime groups I and II was calculated at the sub-watershed level (HUC 12); biophysical settings in fire regime group III were calculated at the watershed level (HUC 10); and biophysical settings in fire regime groups IV and V were calculated at the sub-basin level (HUC 8). In LANDFIRE 2012 the landscape summary unit was defined as a biophysical setting with identical reference condition values regardless of map zone. To understand this, imagine that a biophysical setting is mapped in map zones 1, 2, and 3 and that zones 1 and 2 have identical reference conditions in their associated vegetation dynamics models but that zone 3 has a unique set of reference conditions. In this case, the departure would be calculated using the biophysical setting's extent in zones 1 and 2 as one summary unit and zone 3 as another summary unit.

Considerations

Understanding the Source Data

All of the fire regime and vegetation departure products are derived from other LANDFIRE products. Any assumptions, limitations, and issues associated with the source data are inherited by the fire regime and vegetation departure products. To understand and critique these products, the user must therefore understand the source data. The fire frequency, fire severity, and fire regime group values come from the vegetation dynamics models. Vegetation departure and vegetation condition class results are derived from the modeled reference conditions, the biophysical setting data layer, the succession class data layer, (which is itself derived from the biophysical setting, existing vegetation type, existing vegetation cover, and existing vegetation height data layers; see Chapter 4), and the landscape summary unit. The information from other chapters in this guide will help the user critique these geospatial data inputs. For more information on critiquing the vegetation dynamics models, refer to the *Reviewing and Modifying LANDFIRE Vegetation Dynamics Models* (The Nature Conservancy 2011a) user's guide.

Knowledge Uncertainty

The quality of the fire regime and vegetation departure products depends to a great extent on the quality and quantity of the information used to create the vegetation dynamics models. In general, there are more data to attribute models for economically valuable and heavily studied biophysical settings, such as forested ecosystems, than there are for biophysical settings with little economic value and those that are rare (Blankenship et al.2012). The quantity and quality of fire regime information also varies considerably based on the characteristics of the vegetation comprising the biophysical setting. Fire history from recent centuries tends to be most reliably documented in systems where the evidence of low- and moderate-severity fires is recorded and persists within the annual rings of long-lived tree species (Swetnam et al. 1999) such as longleaf pine and ponderosa pine, and/or where the time since the last stand-replacing fire can be determined from the stand age. In non-forested systems, little direct evidence persists for inferring the characteristics of historical fire regimes (Swetnam et al. 1999) although historical records, charcoal and pollen records, and dependence or sensitivity of long-persisting species provide clues to the fire frequency and severity. The vegetation dynamics model description documents often provide information about the sources and the quality of the information on which they are based and can provide users with valuable information for evaluating the fire regime products derived from them.

Map Zone Boundaries

The vegetation dynamics models were developed to apply at the level of a LANDFIRE map zone (Figure 2). Sometimes the same biophysical setting may have different succession class mapping rules, succession class reference proportions, and fire frequency and severity information in different map zones. This can lead to abrupt changes in the fire regime and vegetation departure products at map zone boundaries, even for the same biophysical setting. Users performing an independent departure analysis can address this issue (see Vegetation Departure Analysis below).

Changes in Departure Methods

The methods LANDFIRE used to create the departure products have changed between versions (Table 9). Users should be cautious when comparing the departure products (vegetation departure and vegetation condition class) between different LANDFIRE versions because changes in the biophysical setting map units and the landscape summary unit discussed above, as well as the source of the reference conditions, can change the departure score. Theoretically the LANDFIRE 2001 and 2008 departure data layers are comparable because they were calculated using the same method, but it may be too short a time period to see substantial change across broad areas. LANDFIRE 2001, 2008 and 2012 departure data layers are not comparable to LANDFIRE National because of the changes in the methods (USFS [n.d.] Fire Regime Data…).

Table 9: Comparison of the methods and input data used to create the LANDFIRE departure data products by data version.

Version	Departure Products Mapped	Departure BpS Unit[a]	Summary Unit	Reference Condition Source[b]
National	Yes	BpS	Ecological Subsections within Mapzones	VDDT & LANDSUM
2001	Yes	BpS Group	Nested Hydrologic Unit Codes	VDDT
2008	Yes	BpS Group	Nested Hydrologic Unit Codes	VDDT
2012	No	BpS	Unique Combination of BpS Code and BpS Model	VDDT

[a]Vegetation departure products were calculated for the biophysical setting (BpS) or the BpS groups depending on the version. In versions where departure products were not mapped, the Departure BpS Unit refers to the units used to map the fire regime and succession class layers.
[b]The reference conditions were derived from the Vegetation Dynamics Development Tool (VDDT) and the Landscape Succession Model (LANDSUM). For LANDFIRE versions 2001 and greater the reference condition source is as described in this guide. The reference conditions source for the National version is described in the document "Developing the LANDFIRE Fire Regime Data Products" on the LANDFIRE Program website.

Vegetation Departure Analysis

Rather than use the LANDFIRE vegetation departure products as-is, many users prefer to complete their own, local, departure analysis. Performing an independent departure analysis allows users to address the issues discussed above, critique and refine the succession class mapping rules, and integrate ancillary data (e.g., locally mapped invasive species distribution). The Fire Regime Condition Class Mapping Tool also allows for the calculation of additional vegetation departure metrics beyond stratum vegetation departure and stratum vegetation condition class, as well as fire *regime* departure analysis. In addition to the considerations listed above, there are some considerations specific to an independent departure analysis using LANDFIRE data.

Biophysical Setting Thematic Resolution

Users performing an independent departure analysis may want to consider the thematic resolution (Chapter 1) of the biophysical setting data layer in relation to their analysis objectives (Chapter 2), especially if there are concerns about the source data or knowledge uncertainty as discussed above. Using the biophysical setting group attribute is one way to "coarsen" the biophysical setting data layer to a more appropriate thematic resolution, but careful critique of the "exemplar" vegetation dynamics model associated with the biophysical setting group is critical. In some cases, the user may want to choose a different "exemplar" model that better represents the biophysical setting group for their analysis location.

Biophysical setting classes may also be grouped using local, ancillary information. For example, in a vegetation condition analysis of Southern Sierra National Forests, analysts grouped models based on similarity of vegetation characteristics and fire regimes following a crosswalk between LANDFIRE biophysical setting and presettlement fire regime groups presented in Van De Water and Safford (2011), thus reducing the number of biophysical settings from 25 to 15.

If biophysical settings are grouped to coarsen the thematic resolution of the biophysical setting data layer, the user will usually be required to manually map succession class due to differences in succession class definitions between the original and chosen vegetation dynamics models. The guide *How to Map Successional Stages Using LANDFIRE Products* (The Nature Conservancy 2013) provides step-by-step instructions on how to do this.

Biophysical Settings that Cross Map Zone Boundaries

In situations where the analysis area overlaps more than one LANDFIRE map zone, a primary consideration is whether there are differences in the vegetation dynamics models between zones, and if such differences reflect reality. If the map zone boundary reflects an ecological transition, then differences between models for the same biophysical setting may be acceptable and necessary. However, if the map zone boundary creates an artificial demarcation in the analysis area, users will want to choose the model that best fits the analysis area and make the appropriate modifications to the related geospatial data. If a new biophysical setting model is chosen, the succession class data layer will need to be adjusted so that it reflects the succession class mapping definitions of the new model (the guide *How to Map Successional Stages Using LANDFIRE Products* provides instructions for re-mapping succession classes) (The Nature Conservancy 2013).

Succession Class Mapping Rules

It is particularly important to critique the succession class mapping rules because the vegetation departure calculation is very sensitive to the amount of area mapped to each succession class. The LANDFIRE succession class data layer is created by applying rule sets to combinations of biophysical setting, existing vegetation cover, existing vegetation height, and to a lesser extent existing vegetation type (Chapter 4). Any problems in the input data layers will carry through to the succession class data layer. Three general concerns with the succession class mapping rules that can impact departure assessments are: 1) the mappability of the classes; 2) the completeness of the succession class rule set; and, 3) the classification of uncharacteristic types.

> *Mappability of Succession Classes*. Succession class is a concept that can be difficult to translate into mappable criteria. Height and cover, the primary variables LANDFIRE uses to map succession class, may not always be the best surrogate for vegetative development and can be difficult to map (Chapter 4). In particular, the height classes for shrub and herbaceous lifeforms are difficult to discern using LANDFIRE's two dimensional satellite imagery. For example, it may be difficult to distinguish 0.5m tall grass from 1.0m tall grass using Landsat data, but some succession classes are mapped based on this distinction. In forests, the height classes tend to be mapped more accurately (see Chapter 4 - Existing Vegetation), but they may be too coarse to adequately differentiate succession classes (e.g., 10 to 25m and 25 to 50m).

> *Completeness of the Rule Set.* Ideally, the succession class rule sets would cover all possible mapped combinations of existing vegetation type, existing vegetation cover, and existing vegetation height for every biophysical setting without gaps or overlaps. In other words, the rules should be mutually exclusive and exhaustive, but this is not the case for all LANDFIRE succession class rules.

Take, for example, a hypothetical shrub biophysical setting with two succession classes defined as follows:

A - shrubs 10-100% cover and height < 1m

B – shrubs 50-100% cover and height > 0.5m

In this case shrubs .5-1m tall with >50% cover could be classified in either succession class A or B; the rule set is not mutually exclusive.

Take another hypothetical example of a tree-dominated biophysical setting:

A – trees 0-100% cover and < 5m height; or herbs or shrubs 0-100% cover and "any" height

B – trees 0-100% cover and 5-10m height

C – trees 0-100% cover and 10-25m height

In this example, if trees are not established or trees are less than 5m in height, the pixel is mapped as succession class A. Trees that are 5-10m in height are mapped as succession class B and trees 10-25m in height are mapped to succession class C. What about trees greater than 25m in height? Did the model developers intend for this condition to be mapped as uncharacteristic? In many cases this is not the intent; rather, the rule was developed before the geospatial data were mapped and the modelers chose the most reasonable height class without knowledge of the possible mapped height range. When the rules are not exhaustive and/or mutually exclusive, pixels can be mapped into an inappropriate class.

Users also should watch for rules that overlap in structure (cover and height) but differ by species composition. Some vegetation dynamics model descriptions use existing vegetation type as criteria for distinguishing between succession classes, but it was not a primary variable used in mapping—although this varies by biophysical setting and data version. In these cases the succession class assigned by LANDFIRE may not be in agreement with the vegetation dynamics model description. For example, in LANDFIRE map zone 21, the Rocky Mountain Aspen Forest and Woodland vegetation dynamics model differentiates between succession classes C and E by species composition (Figure 12). Both classes have the same structural criteria but succession class C represents a "relatively pure aspen stand," whereas succession class E represents "aspen replaced by other vegetation types or a mixed aspen-conifer overstory that is changing to a conifer dominated forest." These classes should be differentiated by existing vegetation type, but as recent as LANDFIRE 2010 no pixels were mapped to succession class E because existing vegetation type was not used in the succession class mapping process.

If manually mapping succession class, the existing vegetation type data layer can be used to mitigate this issue. For instance, where the structural criteria are met, succession class C would be assigned to pixels classified as the Rocky Mountain Aspen Forest and Woodland existing vegetation type; succession class E would be assigned to pixels classified as an aspen-mixed conifer or a pure conifer existing vegetation type.

Classification of Uncharacteristic Types. LANDFIRE classifies uncharacteristic vegetation as either uncharacteristic native or uncharacteristic exotic (Chapter 4). The uncharacteristic native class indicates that the existing characteristics (i.e., cover, height, and composition) of native vegetation are outside the reference condition range. When conducting a local vegetation departure analysis users may want to critique the mapping rule thresholds for local relevance. For example, if the maximum canopy cover in the vegetation dynamics model is 40%, any cover greater than 40% will be mapped as uncharacteristic native. Does local research of reference conditions corroborate the 40% threshold? Another instance in which the succession class might be mapped as uncharacteristic native is when a *native* riparian existing vegetation type is mapped to a non-riparian biophysical setting. As discussed in Chapter 4 this situation may be due to differences in the mapping methodologies for biophysical setting and existing vegetation type (see Chapter 4 - Potential vs. Existing Vegetation Type Rectification). Users may wish to further critique the data in such situations.

The uncharacteristic exotic class indicates that an exotic species has become established in an area. Succession class is mapped as uncharacteristic exotic wherever an "introduced" existing vegetation type is mapped (e.g., introduced upland vegetation-perennial grassland and forbland). A consideration related to the presence of exotic species is that LANDFIRE classifies less than 10% vegetation cover as "sparsely vegetated." For some analysis objectives, it may be important to identify sparse cover of exotics, such as cheatgrass (*Bromus tectorum)*, and this may require ancillary data sources (Provencher et al. 2009).

Landscape Summary Unit

Independent vegetation departure analyses are not tied to the landscape summary units used by LANDFIRE. The key criterion for landscape delineation is that the summary unit needs to be large enough to encompass the full range of succession classes expected under the historical disturbance regime (Barrett et al. 2010). Careful consideration should be given to the choice of the landscape summary unit using the guidance in the Fire Regime Condition Class Guidebook and Fire Regime Condition Class Mapping Tool User's Guide, keeping in mind that departure scores may vary with changes in the summary unit. If the landscape summary unit is so small that it would not contain the full range of succession classes under the historical disturbance regime, misleading departure scores can result, and lead to errors in the subsequent planning process (Barrett et al. 2010). In contrast, summary units that are too large may make it difficult to discern changes in departure due to planned (e.g., restoration treatments) and unplanned disturbances (Barrett et al. 2010). This may be the case for some biophysical settings under the LANDFIRE 2012 methodology for mapping departure, in which the full extent of the biophysical setting in one or multiple map zones is used as the summary unit to calculate departure. However, it is the intent of the off-the-shelf LANDFIRE products to assess departure at a much broader scale than that of a typical local analysis.

Chapter 7: Interpreted Examples

In this chapter, we (the authors) illustrate the data critique and modification process in two example applications. The first example critiques LANDFIRE data for use in fire behavior analysis of the Rogue Basin located in southwest Oregon (Figure 21). The second example focuses on the critique of LANDFIRE data for use in vegetation departure analysis in the southern Sierra Nevada Mountains of California (Figure 21).

Figure 21. Project area boundaries for interpreted examples.

There are multiple approaches and tools available for critiquing and modifying geospatial data. In these examples we demonstrate the use of common approaches and tools that are available to most natural resource professionals. The following examples summarize the concepts and considerations for modifying LANDFIRE data discussed in previous chapters and therefore should be beneficial to all readers regardless of expertise in working with geospatial data. Details on geospatial analysis and data manipulation tasks, however, are beyond the scope of this document and are only outlined here.

Example 1: Critiquing LANDFIRE data for local fire behavior analysis

Define objectives

For this example we turned to the 3.3 million-acre Rogue Basin in southwest Oregon, where the Southern Oregon Forest Restoration Collaborative and its partners are undertaking the development and implementation of a cohesive forest restoration strategy. A key component in the development of this strategy was an understanding of the current wildfire hazard and associated risk to the Basin's natural resources and assets. Our objective was to conduct a wildfire hazard analysis using LANDFIRE data and geospatial wildfire behavior modeling software.

Identify data requirements

Eight geospatial data layers are required inputs for simulating the full range of wildfire behavior—surface through active crown—in the geospatial fire modeling systems used in this analysis. These layers characterize surface fuels (fire behavior fuel model), canopy fuels (canopy base height and canopy bulk density), forest canopy structure (canopy cover and canopy height), and topography (elevation, aspect, and slope). Each geospatial data layer is available from LANDFIRE.

Given our objective to geospatially analyze wildfire hazard, it was important that the geospatial data represent the fuels and wildfire potential as appropriately as possible for the scale of the analysis. To evaluate the LANDFIRE fuels data we would use the LANDFIRE Total Fuel Change Tool (LFTFCT 2011), which allows for the critique, modification, and analysis of fuel mapping rules and their effect on simulated fire behavior within the tool itself. Because LANDFIRE fuel data (Chapter 5) are derived from existing vegetation type, cover, and height (Chapter 4), biophysical setting (Chapter 4), and disturbance (Chapter 3), the tool requires these geospatial data layers as input, thus increasing our data requirements. We downloaded the additional data layers using the LANDFIRE Data Access Tool (Figure 22, LFDAT 2012).

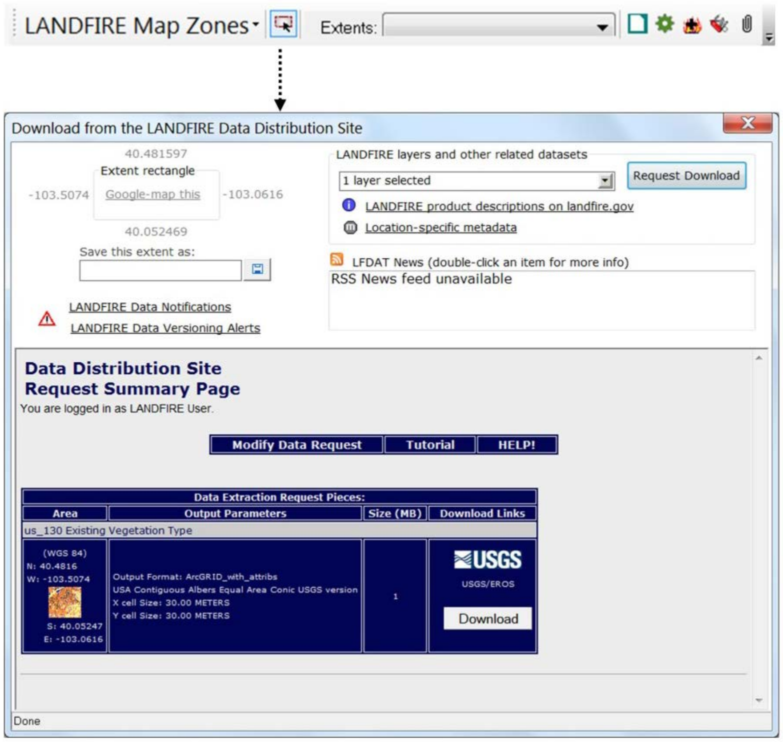

Figure 22. The LANDFIRE Data Access Tool (LFDAT). The LFDAT is a custom ArcGIS toolbar that links to the LANDFIRE Data Distribution Site.

Critique

The fundamental question of our critique was whether LANDFIRE data would be appropriate for simulating wildfire behavior at the analysis location and scale. The LANDFIRE Total Fuel Change Tool would be used to assess the fuel mapping rules in addressing this question; however, *data currency* and *map unit accuracy* (Chapter 1) are also important to accurately simulate the current wildfire hazard so we began our critique there.

The wildfire analysis component of this project began in January 2015, just after LANDFIRE version 1.3.0 (LANDFIRE 2012) data were released for the region. This meant the data were two years out-of-date at the time of acquisition. A critical first task was therefore to determine how much the landscape had changed in the preceding two years.

Approximately 200,000 acres of wildfire and 11,500 acres of mechanical disturbance had occurred over 2013 and 2014 within the wildfire simulation landscape. Given this information, it was clear that currency updates to the LANDFIRE vegetation and disturbance data inputs would be required prior to critiquing the fuel mapping rules with the LANDFIRE Total Fuel Change Tool.

The input data were also critiqued for map unit accuracy. Upon field review, local resource managers felt that oak woodland ecological systems were underrepresented in the LANDFIRE existing vegetation type data layer and that ancillary data would be required to address this issue. In critiquing the LANDFIRE disturbance data, local resource specialists also determined that certain disturbance type assignments were not correct for the local area. For example, the assignment of mechanical remove to all silvicultural treatments (i.e., clearcut, harvest, thinning) was not appropriate for the Rogue Basin because not all local harvesting methods are accompanied by activity-fuel treatments such as hand-pile burning or biomass extraction. Similarly, there were activities assigned to the "other mechanical" event type (a mechanical-add disturbance) that participants felt should be assigned to mechanical-remove. In addition, participants felt that although mastication event types add fuel to the surface fuelbed, they should be differentiated from the other mechanical add disturbances due to the effect of the structure and compactness of masticated fuel on fire behavior.

Finally, as discussed in Chapter 3, LANDFIRE does not currently use a cumulative effect approach to assign disturbance attributes in the composite fuel disturbance data layer. Rather, if multiple treatments occurred in the same location within the update period, the attributes of the most recent treatment are assigned (except where fire has occurred; see Chapter 3). This was also a potential cause of inaccurate map unit assignment.

To summarize, the following information was gathered from the data critique and used to modify the geospatial data inputs to the LANDFIRE Total Fuel Change Tool.

- Data is not current through 2014.
- Oak woodland ecological systems are underrepresented.
- Some disturbance type map unit assignments are inaccurate due to generalization of treatment types at the national scale and/or incorrect accounting of cumulative treatment effects.
- Grouping of mastication treatments with other mechanical add disturbances does not represent the unique fire behavior of masticated fuel.

Modify LANDFIRE Total Fuel Change Tool inputs

As discussed above, the LANDFIRE Total Fuel Change Tool requires geospatial data layers of: existing vegetation type, cover, and height; biophysical setting; and disturbance as inputs. The amount of updating required for these layers varies depending on analysis objectives. The following sections describe the modifications that were made, or why modification was determined to be unnecessary, for each of the required geospatial data layers based on our data critique.

Disturbance

Data Currency

Because the LANDFIRE 2012 composite fuel disturbance data layer only represents conditions through 2012, two data currency updates were required to create an up-to-date 2014 disturbance layer: 1) the time-since-disturbance attribute needed to be updated to reflect the two additional years that had passed, and 2) new disturbances—those that occurred in 2013 and 2014—would need to be added. The following methods were used to create the updated disturbance layer.

First, we determined the years for which the time-since-disturbance attribute would need to be updated (Table 6). Disturbances that occurred from 2005-2007 would remain in the 6-10 year time-since-disturbance class. Likewise, disturbances that occurred in 2010 and 2011 would remain in the 2-5 year time-since-disturbance class. However, disturbances that occurred in 2008 and 2009 would need to be updated to the 6-10 year class and disturbances that occurred in 2012 would need to be updated to the 2-5 year class.

The 2003 and 2004 disturbances would now be greater than ten years old. LANDFIRE removes disturbances greater than ten years old from the composite vegetation and fuel disturbance data layers (Chapter 3) and may also update existing vegetation layer map units to reflect a vegetation transition based on the ecology of the region. For example, a forested, existing vegetation type that experienced a high-severity wildfire, and was subsequently reassigned as an herbaceous or shrub existing vegetation type, may be reassigned to a forest vegetation type after ten years if reestablishment of trees is expected. More information on LANDFIRE vegetation transition rules is available on the program's website. Based on our analysis objectives we determined that we could leave the 2003 and 2004 disturbances in the 6-10 year time-since-disturbance class since we were only concerned with the fuel data layers required for wildfire hazard analysis and therefore not required to update existing vegetation layers.

Next, we downloaded the individual-year disturbance data layers for the years 2008-2012 using the LANDFIRE Data Access Tool. These layers were used to create two "geospatial masks" using the ArcGIS Spatial Analyst extension—one representing the 2008-2009 disturbances and one representing the 2010-2012 disturbances (Figure 23). Masks are used in geospatial analysis to constrain operations to certain pixels within a raster dataset. In our case, we used the masks to identify and update the time-since-disturbance of pixels where a disturbance had occurred in 2008 or 2009 without subsequent disturbances in 2010-2012. As in the LANDFIRE mapping process, if a fire disturbance occurred prior to 2008 we retained the time-since-disturbance of the fire (Chapter 3).

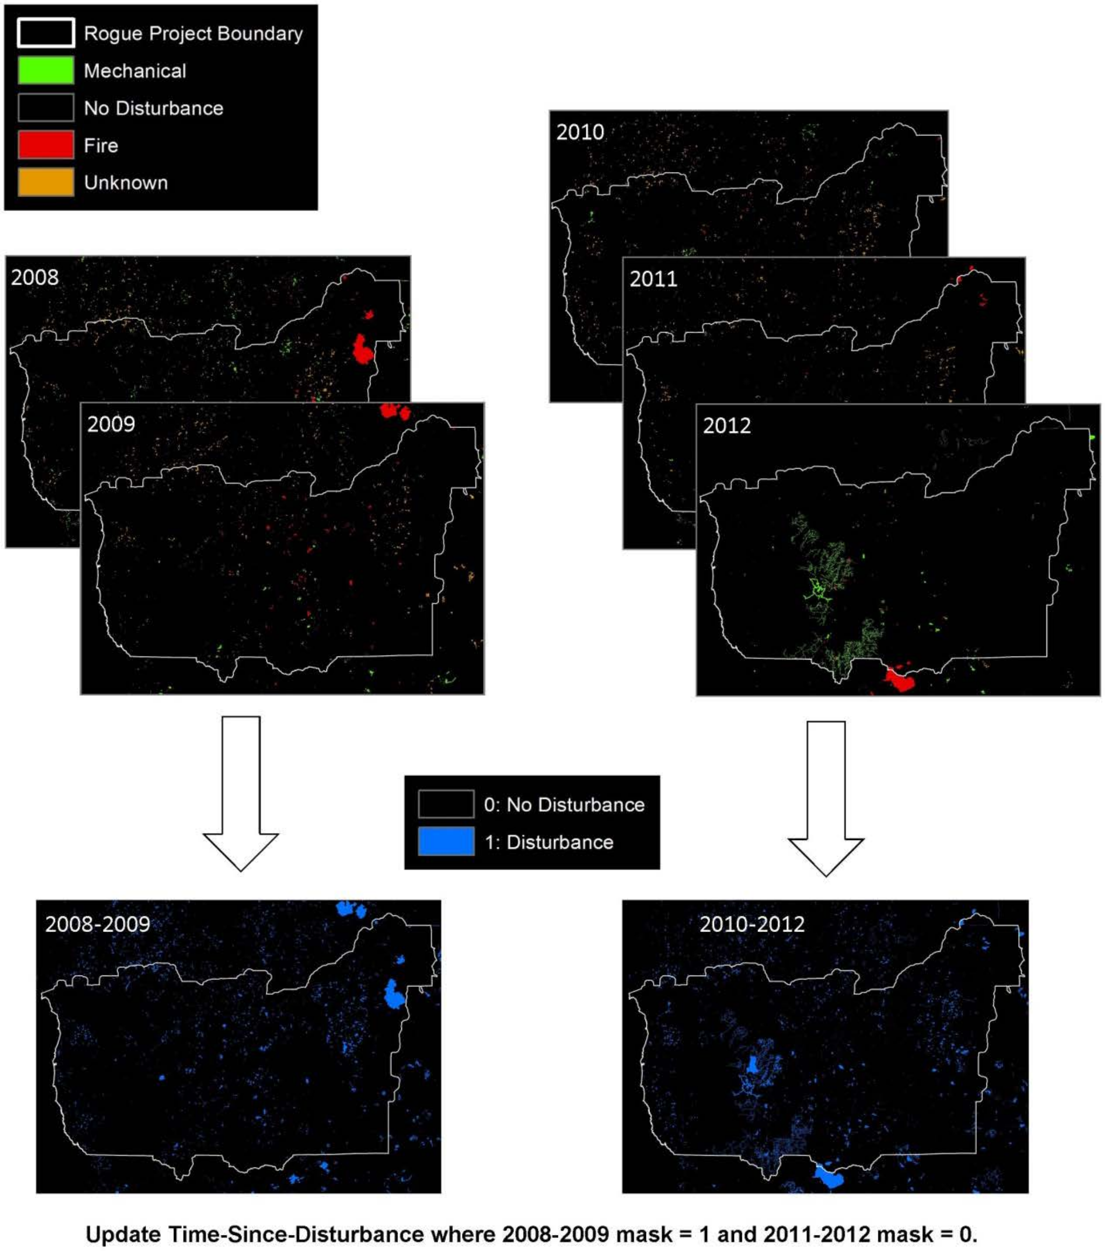

Figure 23. Updating time-since-disturbance. Two geospatial masks were created from the LANDFIRE individual year disturbance layers: one representing disturbances from 2008-2009 and the other representing disturbances from 2010-2012. Time-since-disturbance was updated from the 2-5 year class to the 5-10 year class only where disturbances occurred in 2008-2009 without subsequent disturbance in 2010-2012

With the time-since-disturbance updates complete, we next needed to incorporate 2013 and 2014 disturbances into our updated composite fuel disturbance layer. To reflect large wildfires (> 1,000 acres), we acquired wildfire severity data from the Forest Service Rapid Assessment of Vegetation Condition after Wildfire (RAVG) program website. Recall from Chapter 3 that the LANDFIRE disturbance severity classes represent the effect of disturbances on the vegetation cover of the dominant lifeform. The RAVG program produces a raster data layer representing canopy cover reduction, as a result of fire, through a process that correlates percent change in canopy cover to a remote sensing change detection protocol (Miller and Thode 2007, Miller et al. 2009). We used this data layer to further update the composite fuel disturbance layer based on the percent canopy cover reduction using the ArcGIS Spatial Analyst Extension *Reclassify* tool (Figure 24).

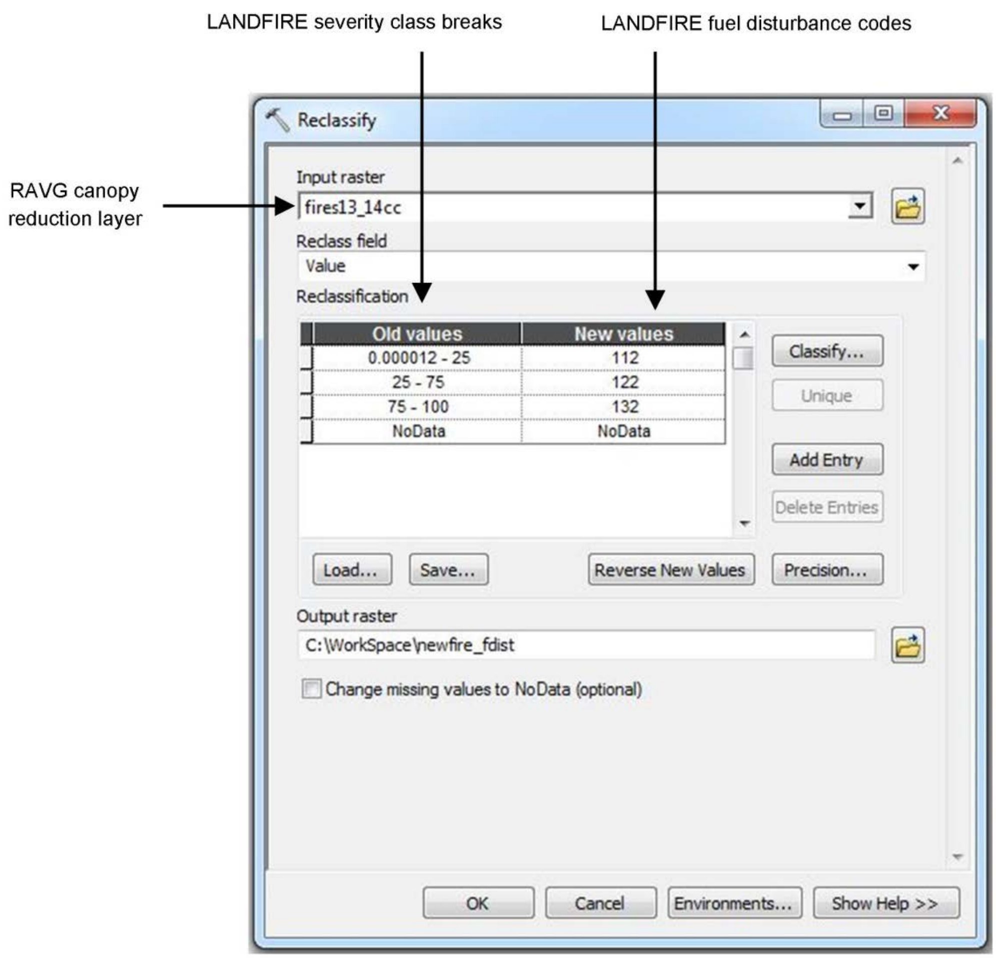

Figure 24. Reclassification of canopy cover reduction estimates from the Rapid Assessment of Vegetation of Condition after Fire (RAVG) program data to LANDFIRE fuel disturbance codes.

We followed a similar process for non-wildfire disturbances. First we acquired 2013 and 2014 Forest Service activities data from the agency's Forest Activities Tracking System (FACTS) and Bureau of Land Management activities from the National Fire Plan Operations and Reporting System (NFPORS). Forest Service and Bureau of Land Management personnel assigned the LANDFIRE disturbance type (mechanical add, mechanical remove, or prescribed fire), severity, and time-since-disturbance codes to each of the activity polygons. If subsequent activities occurred in the two-year time frame, the cumulative effect of those activities was used to determine the most appropriate disturbance attributes. We converted the polygon data to raster format and used ArcGIS Spatial Analyst Extension tools to further update the composite fuel disturbance layer.

Map Unit Accuracy

As mentioned above, our data critique identified two map unit accuracy issues in the disturbance data layer: 1) disturbance type map unit assignments were inaccurate due to generalization of treatment types at the national scale and/or incorrect accounting of cumulative treatment effects, and 2) the grouping of mastication treatments with other mechanical add disturbances does not represent the unique fire behavior of masticated fuel.

We used the ArcGIS Spatial Analyst *combine* function to combine the composite fuel disturbance layer with the individual disturbance layers from 2003-2012. The combine function creates a new raster where each unique combination of values from the input layers represents a single row in the attribute table. Using this table we were able to identify four unique situations and make adjustments based on local resource specialist input (Table 10).

Table 10: Adjustments made to mechanical disturbance type based on local input.

Criteria	Acres	Adjustment
Silvicultural treatments only	200,039	Disturbance type was changed from mechanical remove to mechanical add.
Mastication treatments only	9,188	Created a mask of mastication only pixels and changed the final fuel model values to a "post-mastication" fuel model within the mask during post-processing.
'Other mechanical' treatments only	75,936	Modified disturbance type only if local resource specialists felt the cumulative effect of the treatments was incorrectly assigned.
Combination of mechanical treatment types	289,248	Typically a combination of "other mechanical" and silvicultural treatment. Modified disturbance type only if local resource specialists felt the cumulative effect of the treatments was incorrectly assigned.

Biophysical Setting

Since the biophysical setting data layer represents potential vegetation based on the biophysical characteristics and historical disturbance regime of the site (Chapter 4), disturbances by definition do not have an effect on this layer[2]. Furthermore, because biophysical setting criteria are infrequently used in the LANDFIRE fuel mapping rules for the Northwest Geographic Area, we did not critique this layer for content accuracy.

Existing Vegetation Type

As mentioned above, our data critique identified that oak woodland ecological systems were underrepresented in the existing vegetation type layer. We therefore acquired ancillary geospatial vegetation data developed by the Landscape Ecology, Modeling, Mapping, and Analysis team (LEMMA). We extracted the oak woodland vegetation cover types from this data and augmented the LANDFIRE existing vegetation type data layer using ArcGIS Spatial Analyst tools.

Disturbances may result in a change to the existing vegetation type. For example, tree- or shrub-dominated vegetation may transition to herbaceous-dominated vegetation as a result of high-severity fire. If the existing vegetation type layer was to be used for purposes beyond the critique and development of fuel data, a separate data layer would need to be created to account for any post-disturbance effects to the existing vegetation type. However, since we were only concerned with post-disturbance effects on fuels, we were able to omit this step and rely on our updates to canopy structure and the *canopy guide* feature of the LANDFIRE Total Fuels Change Tool (see below) to correctly assign post-disturbance fuel attributes.

Existing Vegetation Cover

Two updates to the existing vegetation cover layer were required based on our data critique. First, because we used the LEMMA cover type data to augment our existing vegetation type data layer for oak woodland, we also updated the existing vegetation cover layer with LEMMA canopy cover values to ensure consistency across layers. That is, wherever existing vegetation type was updated with LEMMA data, we also updated existing vegetation cover with LEMMA data. Second, we needed to update existing vegetation cover to reflect the 2013 and 2014 disturbances added to the composite fuel disturbance layer.

The structural characteristics of existing vegetation are what the fire behavior fuel model mapping rules are keyed to (Figure 14). We were therefore required to adjust the existing vegetation cover for the new (i.e., 2013 and 2014) disturbances we added to the composite fuel disturbance layer. The post-disturbance canopy cover of forested vegetation types is also required for calculating post-disturbance canopy base height and canopy bulk density.

For the 2013 and 2014 large wildfire disturbances we used the RAVG canopy cover reduction data layer directly to adjust existing vegetation cover. For the non-wildfire disturbances we first assigned a canopy cover reduction value to each severity class midpoint (low severity: 12.5%, moderate severity: 50%, high severity: 87.5%). We did not allow values to be reduced below the lowest canopy cover class (10%-20%) because with few exceptions (e.g., clearcuts), even high-severity disturbances leave some cover. In the case of forested vegetation, leaving 15% forest canopy cover allows for simulating a slight effect of shading and wind reduction to surface fuel from the standing dead trees.

Existing Vegetation Height

[2] Although there are exceptions that could lead to a biophysical setting type conversion, such as those influenced by climate change, uncharacteristic disturbances, and/or exotic species, these occurrences are rare and even if present would have little effect on the assignment of fuel model in this analysis area—that is, biophysical setting criteria are infrequently used in the LANDFIRE fuel model mapping rules in the western states.

As with existing vegetation cover we first updated the existing vegetation height with the LEMMA data in the oak woodland vegetation type.

LANDFIRE existing vegetation height represents the basal-area weighted average of the dominant and co-dominant trees (Chapter 4). In forested vegetation types it is therefore typically not necessary to reduce forest canopy height due to disturbance, as most disturbances would not change the average height significantly enough to reduce existing vegetation height to a lower height class (Table 7). Certain silvicultural methods that target dominant trees, such as clearcuts or thinning from above, are exceptions. For high-severity wildfire, we retained the pre-disturbance canopy height. In combination with the low canopy cover value we assigned, retaining a canopy height value would allow us to simulate a slight effect of the standing dead trees on shading and wind reduction to surface fuel. We were able to prohibit crown fire from being predicted in the post high-severity fire pixels through use of the LANDFIRE Total Fuel Change Tool "canopy guide" function (see below).

Integration of steps with the LANDFIRE Total Fuel Change Tool

With the preliminary critique and updates to the required vegetation and disturbance data layers complete, we then critiqued the LANDFIRE fuel mapping rules using the LANDFIRE Total Fuel Change Tool. A user's guide, tutorial, and information on training for this tool are available on the Wildland Fire Management Research Development and Application – Fuels and Fire Ecology Program website. In this section we will highlight key features of the tool that were used to critique and update fuels for the Rogue Basin analysis.

The LANDFIRE Total Fuel Change Tool provides users the ability to critique and modify the LANDFIRE fire behavior fuel model mapping rules. Additionally, the tool will create canopy fuel data layers (canopy base height and canopy bulk density) using LANDFIRE's methodology, or allow users to "hardcode" base height and bulk density values to unique combinations of vegetation and disturbance attributes. This allows the user to "fine-tune" the interaction of fuel model, canopy base height, and canopy bulk density that is so critical to accurately simulating wildfire behavior.

Critique and Modification of Fire Behavior Fuel Model

The fuel critique was done in a workshop setting where local fire and vegetation specialists from the Forest Service, Bureau of Land Management, and The Nature Conservancy participated. This collaborative approach not only provides a wide range of local knowledge and expertise but also facilitates a sense of ownership and confidence in the end product.

We critiqued the fire behavior fuel model mapping rules for each of the major existing vegetation types in the analysis area. For each existing vegetation type, we first reviewed its description and where it was mapped. If photos were available they would be displayed to provide further context. Next, we discussed which factors—canopy cover; canopy height (a surrogate for stand age); biophysical setting; and disturbance type, severity, and time-since-occurrence—influenced the surface fuels and reviewed how the mapping rules used different combinations of these variables.

Adjustments to the fuel model mapping rules can be made in one of two ways, either to the fuel model assignment itself or to the combination of variables that define a rule (Figure 25). Adjustments to the fuel model assignment were made if workshop participants felt the specified fuel model didn't represent the expected surface fire behavior for the vegetation type and structure identified (that is, if the flame length was too high/low or the rate of spread was too fast/slow). The LFTFC tool provides an interface for comparing the flame length and rate of spread of different fuel models under varying combinations of fuel moisture, slope, and wind speed (Figure 26) as an aid to making modification decisions. Adjustments to the canopy cover and height thresholds, or addition of biophysical setting criteria will influence the spatial distribution and proportion of area assigned to each fuel model. We modified these criteria if participants felt the location or distribution of fuel models did not reflect on-the-ground conditions.

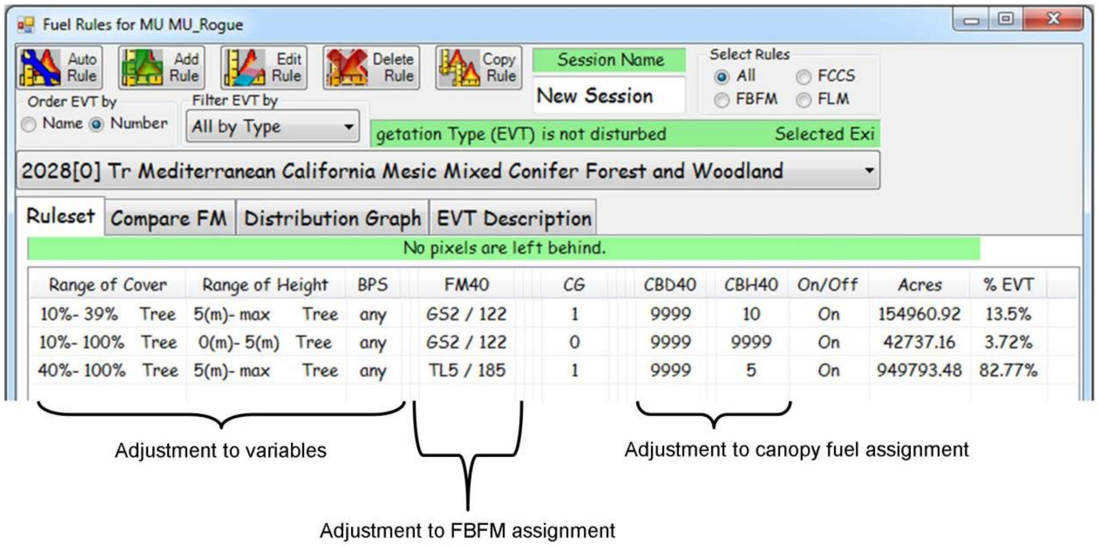

Figure 25. LANDFIRE Total Fuel Change Tool rulesets. Adjustments can be made to the range of variables, fire behavior fuel model (FBFM), and canopy fuel.

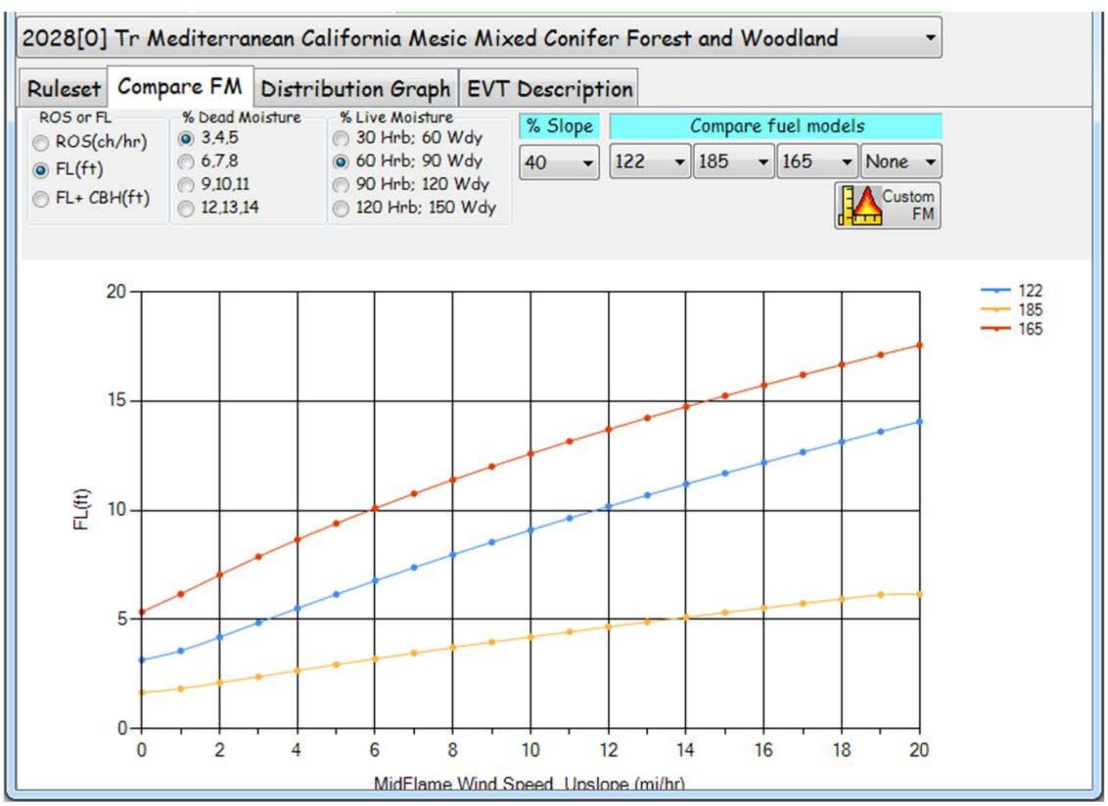

Figure 26. Comparing fuel models. The LANDFIRE Total Fuel Change Tool has built-in functionality to compare fire behavior between fuel models under a variety of fuel moisture and slope conditions.

Finally, for areas where a mastication treatment occurred we assigned the fire behavior fuel model outside of the LANDFIRE Total Fuel Change Tool using ArcGIS Spatial Analyst tools.

Critique and Modification of Canopy Fuels

There are two ways a user has control over how canopy fuels are mapped with the LANDFIRE Total Fuel Change Tool. The first is to use the tool's canopy guide feature; the second is to "hardcode" canopy fuel values. The canopy guide options are as follows:

- 0: No forest canopy structure characteristics (i.e., cover and height) or fuels are assigned. In forested existing vegetation types this may be used to represent a disturbance that removes the forested canopy (e.g., clearcut) or when the "forested" canopy is already considered in the fire behavior fuel model assignment (e.g., short trees).
- 1: The standard LANDFIRE methodologies (Chapter 5) are used to calculate canopy structure and canopy fuel values.
- 2: The canopy base height and canopy bulk density are artificially set to a point where crown fire—passive, active, or conditional (Scott and Reinhardt 2001)—will not be simulated (canopy base height of 10m and canopy bulk density of 0.012 kg/m-3). This value may be used in cases where canopy height and canopy cover values are still desired due to their influence on reducing wind speed and dead fuel moisture content through shading (Chapter 5) but where crown fire is unlikely (e.g., broadleaf forests).

We set the canopy guide value to 2 for all high-severity fire disturbances. As discussed previously, this technique allows for the standing dead trees to still have some, albeit minimal, influence on dead fuel moisture content and wind reduction, but eliminates crown fire and spotting from being modeled in fire behavior modeling systems. The use of a canopy guide value of 2 also served as an alternative to modifying the existing vegetation type due to high-severity fire. That is, by "turning off" crown fire and assigning the appropriate fire behavior fuel model for the expected change in the dominant vegetative lifeform, we accomplished the same goal.

For non-disturbed, and low- and moderate-severity fire disturbances, we assessed the effect of fire behavior fuel model and the LANDFIRE default canopy base height values on crown-fire initiation using the NEXUS (Scott 1999) fire modeling system (Figure 27). Canopy base height values were "hardcoded" (Figure 25) in the fuel rules if workshop participants felt that simulated crown-fire initiation didn't accurately represent expected crown-fire initiation. There are many factors to consider when assigning a canopy base height value. Knowledge of local wind patterns and/or analysis of the wind data that will be used in your analysis are paramount. We accepted the LANDFIRE default canopy base height assignments for all mechanical disturbances.

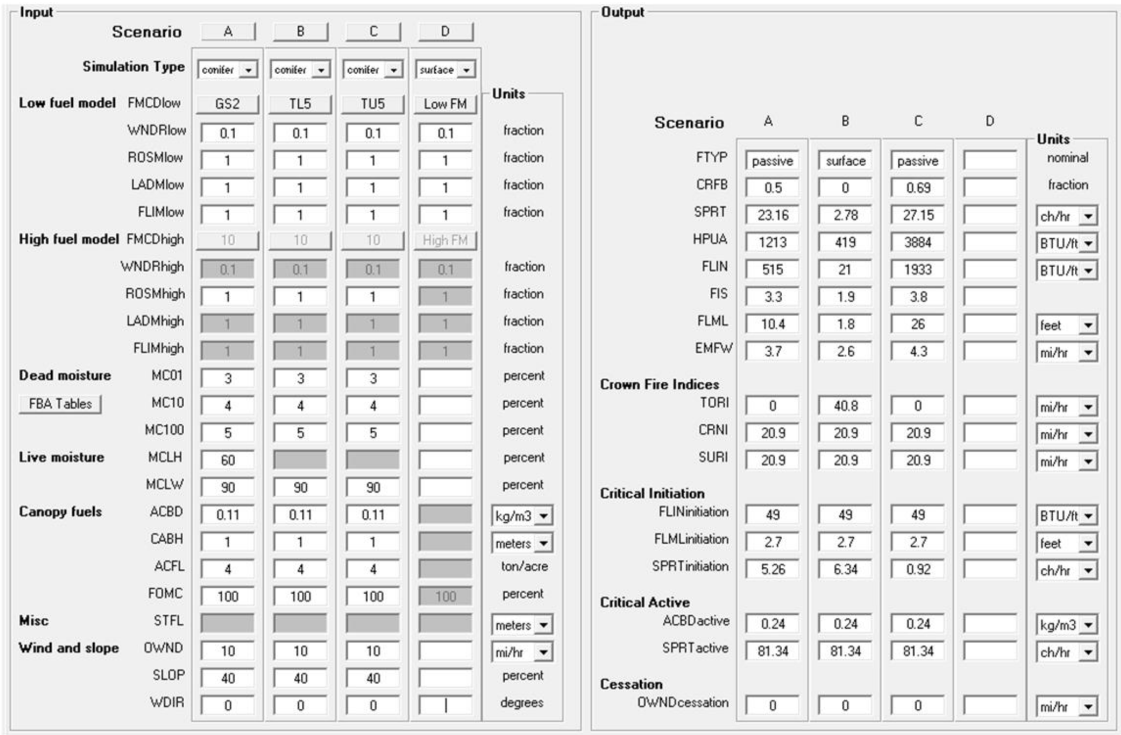

Figure 27. NEXUS fire modeling system. NEXUS facilitates in depth fire behavior critique and is particularly useful in assessing the environment conditions required to transition surface fire to crown fire based on fire behavior fuel model and canopy base height values.

Analysis

We created a new fire behavior modeling landscape (i.e., LCP file) based on our updated disturbance data layers and fuel model mapping rules. We then used this LCP to run basic fire behavior simulations as an additional critique. This final analysis step was used to highlight issues that were possibly overlooked or might have been hard to detect during the fuel calibration, thus necessitating further data modifications. After completion of this final step, the modified fuel data layers were used to analyze wildfire hazard in the Rogue Basin.

Example 2: Using LANDFIRE for local vegetation departure analysis

In this example we illustrate the data critique and update tasks conducted as part of an analysis of vegetation departure in the southern Sierra Nevada Mountains. The 12.5 million-acre planning area includes the Inyo, Sequoia, and Sierra National Forests; Sequoia and Kings Canyon National Parks; and portions of Yosemite and Death Valley National Parks (Figure 21). Because LANDFIRE provides wall-to-wall geospatial vegetation data, it was an obvious choice for vegetation departure analysis at such a broad spatial extent.

Define objectives

The objective of this project was to conduct a vegetation departure analysis using the FRCC Mapping Tool (Hutter et al. 2012) and LANDFIRE data. The results of this analysis would be further integrated into a wildfire hazard and risk assessment. The analysis was conducted in the fall of 2013.

Identify data requirements

Vegetation departure analysis requires data that characterize both the historical and current vegetation condition. LANDFIRE vegetation dynamics models (Chapter 6) would be used to describe the baseline historical conditions for each biophysical setting mapped to the analysis extent. LANDFIRE vegetation data would be used to characterize the current vegetation composition and structure. LANDFIRE 2008 vegetation data layers were acquired and updated for disturbance through 2012 by USDA Forest Service regional office geospatial analysts.

Critique and modification

We began our critique by listing biophysical settings by analysis area acreage from largest to smallest. A team of regional ecologists, vegetation specialists, and GIS and remote sensing specialists reviewed the data list to determine which biophysical settings to assess for departure. Biophysical setting classes comprising insignificant acreage, those that were difficult to accurately map (Chapter 6), and those determined not important to the analysis objectives were dropped. The review team further determined that the thematic resolution (Chapter 1) of the biophysical setting data layer was too fine, given local knowledge of historical vegetation dynamics and disturbance regimes (Chapter 6). Biophysical setting classes were therefore grouped (Table 11) based on recently developed presettlement fire regime groups that summarize presettlement fire frequency estimates for California ecosystems dominated by woody plants (Van de Water and Safford 2011).

Because the analysis area intersects multiple LANDFIRE map zones, we next reviewed the vegetation dynamics models for each of the biophysical settings for consistency across zones. It is common for the vegetation dynamics model to differ across zones for the same biophysical setting. If the map zone boundary reflects an ecological transition, then the differences between models may be appropriate (Chapter 6). However, if the map zone boundary creates an artificial demarcation in the analysis area, users will want to choose a single model that best fits the analysis area. The review team chose the most representative vegetation dynamics model for each biophysical setting or group of biophysical settings to be assessed. The LANDFIRE 2008 biophysical setting data layer was reclassified using the *reclassify* tool in the ArcGIS Spatial Analyst extension to the final 15 classes represented in Table 11.

Table 11: LANDFIRE biophysical setting (BpS) model groupings for the Southern Sierra vegetation departure analysis.

LANDFIRE Biophysical Setting Name	LANDFIRE BpS Code	Presettlement Fire Regime[a]	LANDFIRE Model Used in VCA[b]
Inter-Mountain Basins Big Sagebrush Shrubland	10800	Big Sagebrush	610800
Inter-Mountain Basins Big Sagebrush Steppe	11250		611260
Inter-Mountain Basins Montane Sagebrush Steppe	11260		
Great Basin Xeric Mixed Sagebrush Shrubland	10790	Black and Low Sagebrush	610790
California Mesic Chaparral	10970	Chaparral-Serotinous Conifers	611050
California Montane Woodland and Chaparral	10980		
Great Basin Semi-Desert Chaparral	11030		
Northern and Central California Dry-Mesic Chaparral	11050		
Sonora-Mojave Semi-Desert Chaparral	11080		
Mediterranean California Dry-Mesic Mixed Conifer Forest and Woodland	10270	Dry Mixed Conifer	610270
Sierra Nevada Subalpine Lodgepole Pine Forest and Woodland	10580	Lodgepole Pine	610581
Sierra Nevada Subalpine Lodgepole Pine Forest and Woodland - Wet	10581		
Mediterranean California Mesic Mixed Conifer Forest and Woodland	10280	Moist Mixed Conifer	610280
California Lower Montane Blue Oak-Foothill Pine Woodland and Savanna	11140	Oak Woodland	611140
Mediterranean California Mixed Oak Woodland[c]	10290	Mixed Evergreen	410140
Great Basin Pinyon-Juniper Woodland	10190	Pinyon-Juniper	610190
Mediterranean California Red Fir Forest - Cascades	10321	Red Fir	610321
Mediterranean California Red Fir Forest - Southern Sierra	10322		610322
Mediterranean California Subalpine Woodland	10330	Subalpine Forest	610330
Northern California Mesic Subalpine Woodland	10440		
Sierra Nevada Subalpine Lodgepole Pine Forest and Woodland - Dry	10582	Lodgepole Pine	
Inter-Mountain Basins Subalpine Limber-Bristlecone Pine Woodland	10200	Subalpine Forest	610200
Rocky Mountain Subalpine-Montane Limber-Bristlecone Pine Woodland	10570		
California Montane Jeffrey Pine(-Ponderosa Pine) Woodland	10310	Yellow Pine	610310
Mediterranean California Lower Montane Black Oak-Conifer Forest and Woodland	10300		

[a] Van de Water and Safford (2011) pre-settlement fire regime vegetation types shown for reference.
[b] Vegetation Condition Assessment.
[c] Based on local knowledge and ancillary vegetation data, workshop participants felt that areas mapped as a Mediterranean California Mixed Oak Woodland biophysical setting were incorrectly classified and should be classified as Central and Southern California Mixed Evergreen Woodland (BpS model 410140).

Next, the succession class mapping rules for each of the final vegetation dynamics models were assessed. Adjustments were made to ensure rules were *exhaustive* and *mutually exclusive*, and that uncharacteristic native conditions were appropriately represented for the local area (Chapter 6). Succession class was then remapped, accounting for the adjustments, using ArcGIS software (Figure 28). First, the existing vegetation type layer was reclassified to create an exotic vegetation mask, where exotic vegetation types were assigned a value of 1 and native vegetation types were assigned a value of 0. Next, the biophysical setting, existing vegetation cover, existing vegetation height, and exotic vegetation mask data layers were combined using the ArcGIS Spatial Analyst extension *combine* tool. A new field was then added to the output combine layer and populated with the new succession class values by first selecting combinations of the data layer attributes as defined in the mapping rules and using the *field calculator* function. Finally, after all combinations had been assigned a new succession class value, the ArcGIS Spatial Analyst extension *lookup* tool was used to create a new succession class data layer.

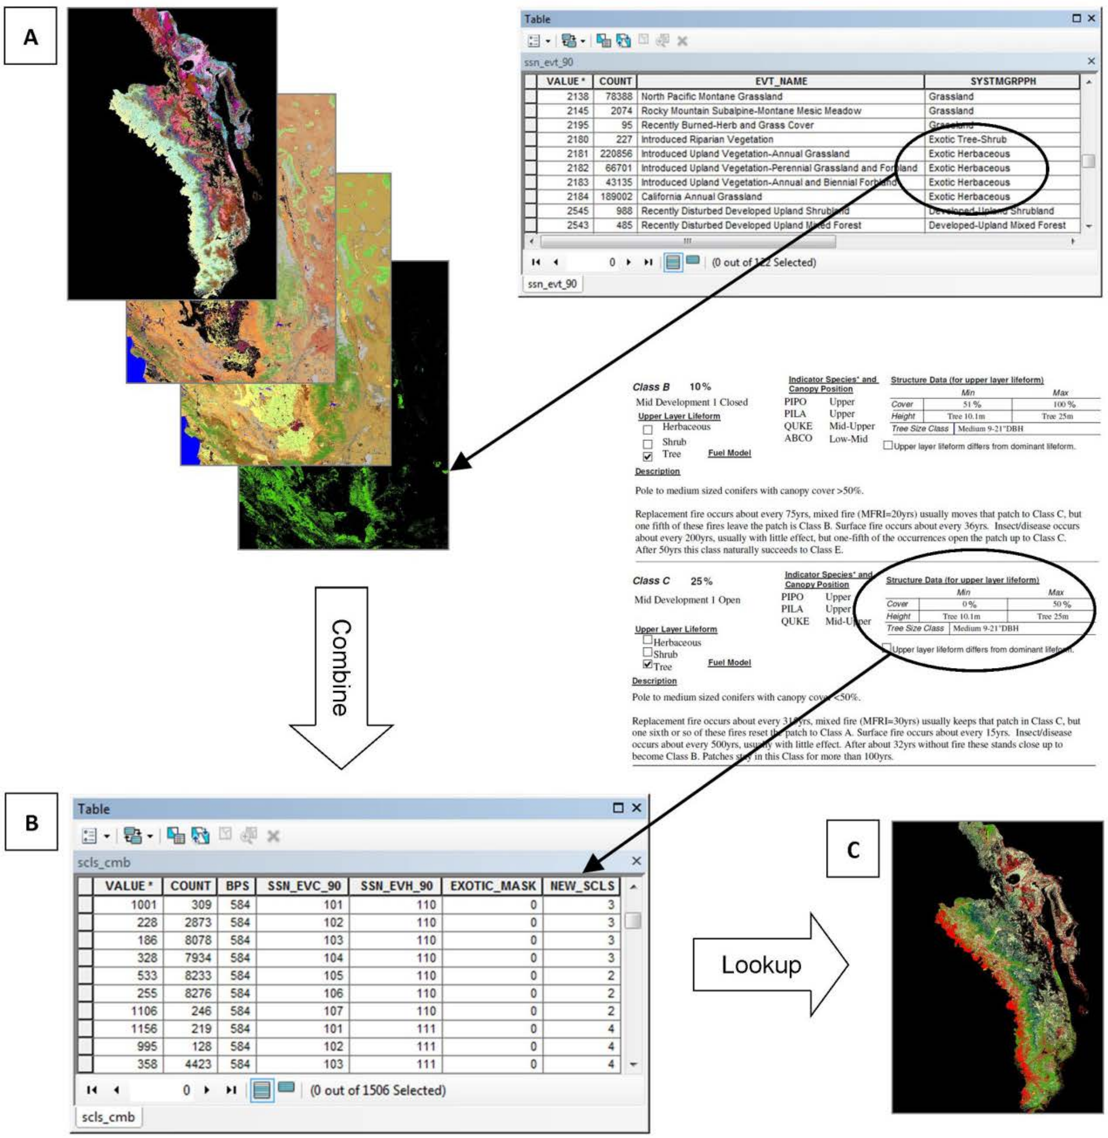

Figure 28. Succession class remapping process. (A) Biophysical setting, existing vegetation cover and height, and exotic vegetation data layers were combined using ArcGIS Spatial Analyst. (B) New succession class values were then assigned based on vegetation dynamics models and adjustments defined by local specialists. (C) Finally, the ArcGIS Spatial Analyst *lookup* tool was used to create a new succession class spatial data layer.

Analysis

We created a spatial landscape assessment unit data layer for conducting the vegetation departure analysis. Each biophysical setting was assigned to an assessment unit based on fire regime characteristics, including historical fire-size distribution (Barrett et al. 2010). Finally, we ran the Fire Regime Condition Class Mapping Tool and reviewed the results.

No issues were identified and the results informed managers where on the landscape specific vegetation development classes (i.e., succession class) were in either surplus or deficit in relation to their presettlement condition. As noted in Example 1 of this chapter, sometimes an analysis may highlight issues that were overlooked or hard to detect earlier in the data critique process that necessitate further data modifications. Analysis should be viewed as an iterative process.

ACKNOWLEDGMENTS

Funding for the production of this guide was provided by the Wildland Fire Management Research, Development, and Application program and the LANDFIRE Program through Cooperative Agreement 14-CA-11132543043. We thank the following people for their helpful review comments: Greg Dillon, Wendel Hann, Don Long, Charley Martin, James Napoli, Kurtis Nelson, Brianna Schueller, Tobin Smail, Jim Smith, Jenna Volpe, and Erin Noonan-Wright. We also thank Kim Ernstrom and Eva Strand for their project support and give a special thanks to our editor Joan Jones.

Abstract

Uncertainties about the consequences of natural resource management mean that managers are required to make difficult judgments. However, research in behavioral economics, psychology, and behavioral decision theory has shown that people, including managers, are subject to a range of biases in their perceptions and judgments. Based on an interpretative survey of these literatures, we identify particular biases that are likely to impinge on the operation and success of natural resource management. We discuss these in the particular context of adaptive management, an approach that emphasizes learning from practical experience to reduce uncertainties. The biases discussed include action bias, the planning fallacy, reliance on limited information, limited reliance on systematic learning, framing effects, and reference-point bias. Agencies should be aware of the influence of biases when adaptive management decisions are undertaken. We propose several ways to reduce these biases.

Introduction

Natural resource management is often a complex and uncertain process. The underlying environmental and physical processes are sometimes not well understood. Even when they are understood, there are likely to be uncertainties about the quantitative outcomes of management. The current actual status of the resource may be difficult to determine. Managers cannot always fully control which on-ground actions are undertaken due to lack of resources, legal powers, or capacities (Williams & Brown 2014).

These complexities and uncertainties mean that managers are required to make judgments. However, it has been shown that, in making judgments of these types, decision makers do not always undertake decisions "rationally." Simple rational decision-making models assume that agents always take decisions to maximize the achievement of their objectives, based on accurate knowledge of the outcomes, costs, and constraints. In reality, however, people have limited information, limited time, and limited cognitive capacity. As a consequence, they are restricted in formulating and solving complex problems, and they are susceptible to different types of biases (Arnott 2006; Tasic 2011)—beliefs that are inconsistent with reality (Chira *et al.* 2011) or behaviors that compromise the achievement of objectives. For example, Guthrie *et al.* (2000) found that some of the biases listed in Box 1 affect judges when they are making judicial decisions. Similarly, Hirshleifer (2008) found that financial regulators are subject to a different set of biases that influence their decisions, plans, and polices. The impacts of such biases can be substantial. For example, Kahneman (2012) reports on a 2005 study of rail projects worldwide undertaken between 1969 and 1998. Passenger usage of the rail system was overpredicted in 90% of cases. On average, planners overestimated passenger usage of new train lines by over 100%, reflecting a common bias known as the "planning fallacy."

Box 1: Selected behavioral biases with potential impact on adaptive management

- Action bias: Tendency to take actions even when it is better to delay action
- Framing effect: Tendency to respond differently to alternatively worded but objectively equivalent descriptions of the same item
- Reference-point bias: Tendency to overemphasize a predetermined benchmark for a variable when estimating the level of that variable
- Availability heuristic: Tendency to give more weights to events that can be recalled more easily
- Planning fallacy: Making judgments about a planned activity that are systematically over-optimistic, including underestimating project completion time, underestimating costs, or over-estimating benefits
- "Satisficing rule": Tendency to stop searching for a better decision once a decision that seems sufficiently good is identified
- Loss aversion: Tendency to value losses more highly than similar gains
- Reliance on limited information: Tendency to use a subset of information even when full set of information is available
- Limited reliance on systematic learning: Tendency to use information from past successful efforts rather than using information from both successful and failed efforts

For a general list of behavioral biases, see Arnott (2006) and Gino & Pisano (2008).

Managers of natural resources and the environment are likely to be just as susceptible to these biases as are other professionals who must make complex judgments, such as judges and financial regulators (Carlsson & Johansson-Stenman 2012). However, these issues have received little attention in the conservation literature. Our aim in this article is to draw from psychology, behavioral economics, and behavioral decision theory research literatures to identify key insights about biases that are relevant to conservation, and to understand their implications for managers responsible for management of environmental projects or programs.

In doing so, we focus to some extent on Adaptive Management (AM), since this is a process that has been promoted or used to manage complex and uncertain natural resource issues. AM is a process of "learning by doing" (Walters & Holling 1990) where learning from experience is combined with the need for immediate action (Westgate *et al.* 2013). Under AM, management policies are formulated as experiments that investigate ecosystems' responses to changes in people's behavior or management actions (Lee 1999). Conceptually, a set of potential models representing relationships between human actions and ecological outcomes are developed and tested. Viewing the learning process through a Bayesian lens, each model is assigned a probability of being the true model. In each time step, a management decision is made based on the current model probabilities, the current system state, and predicted future states. Model probabilities are updated after each time step based on each model's success in predicting outcomes (Conroy & Peterson 2012), and management may subsequently be modified.

Traditionally, AM has focused on learning from experimental trials or pilots of management approaches for biological and ecological systems (Wilhere 2002; McCarthy & Possingham 2007). It has been assumed that the decision makers will interpret the information collected and make their choices or decisions rationally and without bias. We will explore the extent to which research on human behavior and decision making casts doubt on this assumption. Broader implications for management of natural resources and the environment will also be discussed.

AM: Definition and Stages of Learning

AM has been defined by Williams *et al.* (2009) as "a systematic approach for improving resource management by learning from management outcomes" (p. 1). In active AM, the learning process is supported by purposefully collected information (Walters & Holling 1990), rather from observation of management actions chosen without regard to their ability to provide useful information for future decisions. In active AM, learning is often represented through single- and double-loop processes (Figure 1). Under a single-loop learning cycle, the key steps involved are: (1) define management goals with stakeholders involvement (step 1); (2) develop alternative management options, including an option to maintain the "status quo" (step 2); (3) develop models or statistical processes to trace system responses to management actions (step 2); and (4) implement management options (step 3; Westgate *et al.* 2013). Steps 4 and 5 involve monitoring and assessment of the outcomes, respectively. In a single-loop learning cycle, it is often assumed that project objectives, societal needs, and policy structures are fixed (Allen & Gunderson 2011).

In double-loop learning, on the other hand, it is assumed that policy objectives and structure could change. For example, in long-term projects, societal values and

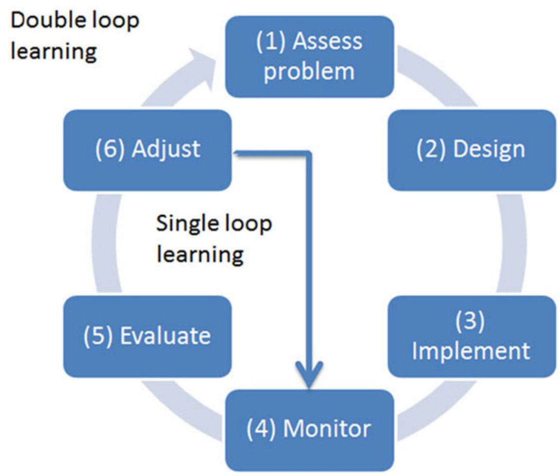

Figure 1 Different steps in active AM cycle with single- and double-loop learning (based on Williams & Brown 2014).

needs could change as time progresses and new management actions are introduced. The resource or the system under experimentation could also change to make the original project objectives unsuitable or unattainable. Therefore, the objectives, management options, or institutional arrangements might need to be changed. Under double-loop learning, original project objectives and management options are revisited after certain steps (step 6). New information from experimentation and model predictions are taken into account as well as changed policy and societal landscapes (Williams & Brown 2014).

In an AM regime, decision makers are responsible for defining management goals, identifying alternative management options, developing models, and implementing programs (Westgate *et al.* 2013). It is common to assume that in each step the resource managers would make "rational" decisions based on the information obtained from biological, physical, and social experiments. However, numerous studies inform us that people have cognitive limitation and bounded rationality, and are influenced by different types of biases. We expand on these issues in the following section.

Key Behavioral Biases

Both psychology and economics have rich literatures on the influences of different types of bias on behavior. Experimental economics serves three main purposes: testing theories, building new theories from observing experimental outcomes, and testing policy and management options. Behavioral economics also integrates insights from psychology to explain economic decision making. It studies the effect of psychological factors such as emotional, social, and cognitive factors on many decisions and economic processes (Camerer 1999). A related field is behavioral decision theory, which studies how people make decisions as well as how they should make decisions (Moore & Flynn 2008). The key biases identified in these research efforts that are relevant to AM are outlined below.

Action bias

"Action bias" occurs when the decision makers choose to take actions even when a "rational" decision maker would prefer to delay actions to allow further information collection, or to take no action. Possible reasons for action bias include that decision makers give higher weight to things that are readily observable and attributable (i.e., the management actions themselves), rather than to things that are delayed, indirect, or unobservable (i.e., potentially the outcomes from those actions; Patt & Zeckhauser 2000). For example, a study of elite soccer goalkeepers showed that they tend to jump to try to save goals even when the optimal strategy is to stay in place (Bar-Eli *et al.* 2007). In this case, taking action is valued in its own right, in addition to the value attributed to the outcome achieved. Similarly, environmental managers may feel that they will earn credit from their superiors, the general public, and the media if they take action even when it is not justified or should be of relatively low priority (Tasic 2011).

Action bias could be increased by uncertainty (Tan *et al.* 2012). In most environmental projects, knowledge of the effectiveness of interventions that will be taken on the ground is rather weak (Ferraro & Pattanayak 2006). As a result, taking action may be evaluated more positively than collecting additional information, partly because of a lack of evidence that actions would be ineffective.

The implication of "action bias" for AM is that it may be difficult to convince managers that an investment in information collection (i.e., AM) is worthwhile. They will tend to prefer to allocate the resources to additional on-ground management actions. Proponents of AM may enhance their persuasiveness by arguing that AM does not require actions to be delayed, and allows more effective or less costly actions to be taken in future. If AM is implemented, it should help to reduce action bias over time by providing additional information about whether the actions being undertaken are effective.

The planning fallacy

The "planning fallacy" is the tendency of project planners to be excessively optimistic about the performance of a project that they are developing (Kahneman & Tversky 1977; Kahneman & Lovallo 1993). For example, many investments in abatement of dryland salinity under Australia's National Action Plan for Salinity and Water Quality program were too small to make a notable difference to salinity outcomes (Auditor General 2008; Pannell & Roberts 2010). Apparently, managers choosing these investments greatly overestimated the effectiveness of the actions being funded, despite ample scientific evidence being available (Prosser *et al.* 2001; Dawes *et al.* 2002). The extent of bias due to the planning fallacy can be substantial. According to Griffin & Buehler (1999), only 1% of the U.S. military high-technology equipment purchases were delivered on time and on budget.

There are various factors that contribute to the planning fallacy. Buehler *et al.* (1994) observed that people estimate a project's expected completion time by constructing mental scenarios of how the project may develop. However, due to cognitive limitations, they generate a smaller range of scenarios than is realistically possible, overlooking many barriers and risks. The scenarios generated tend to reflect their hopes and preferences (Newby-Clark *et al.* 2000) and to neglect their own previous negative experiences with similar projects (Koole & van't Spijker 2000). To some extent, overoptimism is likely to reflect strategic biases adopted to increase the competitiveness of projects when funding is being allocated (Flyvbjerg 2007), but overoptimism is often present even when planners are attempting to be realistic (Kahneman 2012).

A strategy to reduce the planning fallacy is to ask managers to forecast the completion time, cost, or benefits for a range of comparable projects rather than a single project. This strategy, known as Reference Class Forecasting (Kahneman & Tversky 1977), has been effective in reducing time and cost overruns of large infrastructure projects (Buehler *et al.* 2010).

Where the planning fallacy is in evidence, AM may help to reduce its adverse consequences. AM, involving information collection and refinement of project design, helps in correcting decisions that were initially made on an excessively confident or optimistic basis. If necessary, targets can be modified or the project can be terminated following the collection of improved information (Dvir & Lechler 2004).

Reliance on limited information

Decision makers sometimes use only a subset of information even when the full-set information is available. In a series of experiments with common-pool resources, Apesteguia (2006) studied the impact of additional information on individual behavior and payoffs. The individual payoff depended on player's own investment as well as investments made by others. In one treatment, participants had complete information about the expected payoffs from their choices, while in another they had no relevant information. The experimenter observed that the aggregate outcomes (in terms of investment decisions and actual payoffs from the decisions made) were not significantly different between these two treatments (Apesteguia 2006). More-or-less similar observations have been made in other studies (Mookherjee & Sopher 1994; Oechssler & Schipper 2003; Van Huyck *et al.* 2007). One hypothesis to explain this phenomenon is that decision makers follow a "satisficing rule" to limit the cognitive costs of decision making (Hertwig & Pleskac 2010). Under such a rule, the decision maker stops searching for a better decision once he or she identifies a decision that seems sufficiently good.

Another version of this bias is "availability bias" in which people give more weights to certain types of events that can be recalled more easily (Tversky & Kahneman 1974). For example, a manager may assess the risk of bushfire higher than the risk of plant disease spread if bushfires have been more common or more salient in recent times. Underutilization of information is often observed in environmental planning. For example, it has been observed that many existing environmental planning systems fail to account for project costs (Mazor *et al.* 2013), for the effectiveness of management actions (Maron *et al.* 2013), or for behavior change (Pannell & Roberts 2010).

AM potentially provides a mechanism to counter this tendency of decision makers to ignore relevant information. It has been shown in many studies that use of systematic learning through use of data and models could outperform heuristic decision making and predictions by experts (Camerer 1981). It has also been shown that decision makers may employ information more comprehensively if they are asked to make a decision several times sequentially (with time delays) and to explain their decisions to third parties (Vul & Pashler 2008; Herzog & Hertwig 2014). By emphasizing the importance of using accurate information and encouraging use of a structured approach for doing so, AM may prompt a general strengthening of the evidence base for environmental decision making. There can also be a social aspect to AM, with different people contributing to decisions about how management should be adapted in response to new information. This socialization of the process may reduce the tendency of any individual to ignore information.

Limited reliance on systematic learning

Active AM involves systematic experimentation and learning from the outcomes. However, experimental studies on learning reveal that humans are not good at systematic learning. Instead, learning is often messy, noisy, and based on trial-and-error (Hertwig & Pleskac 2010). In practice, people hardly use systematic learning models where they compute and compare expected outcomes from every option before making a decision. Rather, they use heuristics and repeat their past successful choices without fully considering other potentially superior alternatives (Erev & Haruvy 2009).

One implication of limited reliance on systematic learning is that managers will try to learn only from their past "successful" project rather than learning from both "successful" and "failed" projects. In doing so, risk-averse managers are more likely to repeat their past successful choices instead of trying new management interventions (Denrell & March 2001). They are less likely (relative to risk-neutral managers) to invest resources to collect more information about the past unsuccessful strategy (Erev & Haruvy 2009). By contrast, a systematic AM approach would seek to learn from previous mistakes to avoid repeating them, and to enhance the resilience of the management system. AM encourages a systematic approach to learning, and to the use of new information for decision making. It makes explicit the importance of obtaining and using new information, at least partially countering tendencies not to do so.

An institutional barrier to systematic learning is staff turnover, which can be high in the environmental sector, sometimes due to the short duration of funding programs (Grafton 2005). Unless new staff commence before the departures of experienced staff, they must rely on written or verbal communication to learn about the existing or past project (Shogren & Taylor 2008). If the logic behind past decisions is not well-documented, new staff cannot integrate the successes or failures of past decision-making processes into their decision making. There are also differences in the way a new and an experienced manager would approach a problem. A new manager would use facts in a context-free manner whereas, for an experienced manager, problem recognition and action selection would be more intuitive (Hayes 2013).

One potential way to promote systematic learning is through the use of decision support systems (DSSs) that enable the storing of such information. There can be synergies between the use of DSSs and AM. Depending on the type of DSS, it may increase the transparency and evidence base of the initial decision to support a project. This transparent information can be updated as the AM process proceeds, allowing the DSS to inform decisions about modifications to the project (Dicks *et al.* 2014).

Framing effect and reference-point bias

The "framing effect" refers to a situation when people respond differently to statements that are worded differently but are objectively equivalent. Among the many ways of framing an environmental management issue, we mention three that are commonly discussed in the literature: (1) risky choice framing, where the expected outcomes of a risky option are described in different ways; (2) attribute framing, where some characteristics of an object or event are highlighted or focused on; and (3) goal framing, where different potential objectives of the program or activity are emphasized (Levin *et al.* 1998). In a risky choice, framing the outcomes from a lottery could be presented as a loss (say 50% chance of losing) or as a gain (50% chance of winning). In attribute framing, we might focus on only one or a few features of a project (say number of days required to complete a project) rather than all relevant features. For example, we could say that the project is successful if it is completed within a certain number of days (and ignore other features such as the achievement or nonachievement of environmental outcomes). In goal framing, we could focus on gain from undertaking a project (such as "Native animal population will increase if fox control bait is used") or loss from not undertaking the project (such as "Native animal population will continue to decline if fox control bait is not used"; Krishnamurthy *et al.* 2001).

Reference-point bias may cause managers to respond differently to a program or activity depending on the level of a predetermined reference point or benchmark. For example, the same level of environmental improvement could be seen as a success if it is well above a benchmark level of improvement or a failure if it is less than a benchmark, even if the benchmark is arbitrary (Kühberger 1998). It has been shown that people are more sensitive to losses relative to a benchmark than to gains (Camerer 1998). This may mean that managers are strongly motivated to prevent their program from being perceived to be a failure relative to the reference point, but less strongly motivated to seek to make a program perform above the reference point, even if a stronger performance would be feasible and worthwhile.

By regular monitoring and evaluation of project outcomes, AM may help to enhance flexibility in the setting of project goals and to reduce dependence on a fixed reference point. AM, in conjunction with a DSS could help in reducing the impacts of framing effect and reference-point bias by helping managers to assess potential strategies more comprehensively and objectively. Reasons why DSSs are not more commonly used by environmental managers include: lack of adequate training, no clear policy guideline to use the best possible information or DSS, and pressure to spend money within a deadline that is too short to allow time for using the DSS (Shtienberg 2013). To address the last of these issues, in particular, agencies should ideally plan and prepare for potential programs or the next phase of an existing program well before the existing program has concluded.

Discussion

Although many natural resource managers claim to use AM, rigorous and systematic applications are rare (McFadden *et al.* 2011; Westgate *et al.* 2013; Williams & Brown 2014). This is surprising given the theoretical attractiveness of AM in the face of risk and uncertainty (Stankey *et al.* 2005). There has been little research about the impact of psychological biases on decision making by managers of environmental or natural-resource programs (Westgate *et al.* 2013). Based on a survey of the economics and psychology literature, we have identified a set of biases that have implications for AM in particular and NRM in general. As a result of this review, there are grounds to expect that: (1) the managers are likely to take on-ground actions even when these are not worthwhile (Patt & Zeckhauser 2000); (2) they could suffer from the cognitive illusion of being more in control of the system than they actually are (Koole & van't Spijker 2000); (3) they could be overconfident about the expected outcome of their decisions (Flyvbjerg 2007); (4) they may be overly optimistic in terms of expected completion time of the project (Kahneman 2012); (5) they might rely on a partial set of information for decision making even when fuller information is available (Hertwig & Pleskac 2010); (6) they might rely on trial-and-error learning and repeat their past successful choices instead of collecting and comparing information about the full set of decision options (Erev & Haruvy 2009); and (7) managers could try to achieve predefined goals rather than the best possible outcomes from a project (Kühberger 1998; Table 1).

Different biases could influence various steps of the AM cycle differently. For example, action bias could influence the design phase of the AM cycle and lead the planners and managers to design projects with more emphasis on on-ground actions and less on the expected outcomes. Similarly, overconfidence and reliance on limited information would mean the managers would fail to consider all relevant information during the design and monitoring phases. Limited use of systematic learning process would mean failure to learn from previous mistakes during the evaluation phase. Lack of systematic learning would also make mangers susceptible to framing effect and reference-point bias (Klayman & Brown 1993). Agencies should be cautious about the impact of these biases and take remedial measures (Fischhoff 1982).

First, the agencies need to promote a culture of learning (e.g., García-Morales *et al.* 2012). It needs to be recognized that both successful and failed projects generate valuable information about the future state and expected impacts of the management interventions. This could be done by providing appropriate incentives (tangible and intangible) for the managers and decision makers to consider the full range of options before making any decision (Arnott 2006), requiring them to repeat the same decision several times before finalizing it (Vul & Pashler 2008; Herzog & Hertwig 2014), or asking mangers to justify their decisions to external parties (Gollwitzer & Sheeran 2006).

Second, adoption of a DSS could facilitate retention and storing of relevant information (e.g., Behrens & Ernst 2014). It may also make learning from past projects easier and help in systematic evidence-based decision making. Relevant staff should be adequately trained and properly incentivized to use DSSs (Dicks *et al.* 2014).

Third, conducting benefit-cost analyses of planned options would help to refine and prioritize the options during the design phase of the AM cycle (e.g., Pannell *et al.* 2012, 2013). Benefit-cost analysis provides a systematic and objective framework to include all relevant costs and benefits (both market and nonmarket goods and services) related to a project. In the process of identifying benefits and costs, it also helps in identifying if there is complementarity among them (to avoid double counting) and the time lag and uncertainty attached to realization of each benefits and costs. Thus, benefit-cost analysis could be used as a tool to comprehensively assess the expected benefit of a project (Sunstein 2000; Atkinson & Mourato 2008).

Fourth, involvement of external third-party reviewers may also help in designing more realistic and feasible projects (Chen & Volden 2013; Behrens & Ernst 2014). Finally, scenario analysis should be conducted as part of the assessment and design phase of AM cycle to anticipate the expected outcomes of different options (Lautenbach *et al.* 2009). The likely impact of different types of biases, their impact and the effectiveness of potential remedial measures should be systematically analyzed and studied before making any final recommendation for use in decision making for natural resources.

Table 1 Potential psychological biases, their impacts on different steps of the AM cycle, and potential remedial measures to overcome the impact of the biases

Biases	Potential impact on behavior	Potential impact on different steps of AM cycle	Potential remedial measures
Action bias	• Tendency to rely more on actions rather than on results	• During design phase (step 2) projects with visible actions will be prioritized which may lead to wastage of valuable resources (money and time)	• Emphasize the value of information and learning from the AM cycles during the evaluation (step 5), adjustment (step 6), and assessment (step 1) phases rather than on the actions undertaken on ground • Conduct a benefit-cost analysis during the design phase (step 2) of the cycle
Planning fallacy	• Overoptimistic or wrong judgments on the expected benefits, completion time, and costs of the project	• Failure to implement the project (step 3) in due time • During the monitoring phase (step 4), all relevant indicators may not be included, which lead to inadequate assessment during the evaluation phase (step 5)	• Conduct feasibility study as part of the assessment of the problem (step 1) and design of the options (step 2) • Involve external third parties during design phase (step 2) to review proposed actions and their underlying assumptions.
Reliance on limited information	• Make quick judgment • Lack of clearly specified project goals	• During assessment of the problem (step 1), full set of information will not be considered, which will lead to faulty prioritization of projects	• Develop DSSs which will automate incorporation of available information and facilitate consideration of full range of available information during assessment (step 1) and design (step 2) phases
Limited reliance on systematic learning	• Failure to consider the full range of the options • Repetition of the "safe" options • Failure to learn from previous mistakes	• Failure to consider learning from "failed" projects during the evaluation phase (step 5) may lead to missed opportunities to learn and realize the full potential of the situation	• During the evaluation (step 5) and adjustment (step 6) phases, consider learning from all projects (complete/incomplete, successful/failed, etc.) • Always conduct a scenario analysis with a range of options and expected future states during assessment (step 1) and design (step 2) phases
Framing effect and reference-point bias	• Failure to understand the real implications of an option • Success as well as failure is measured relative to a reference point • Follow a satisficing rule rather than a maximization rule while making decisions	• Use wrong measures to evaluate a project (step 5) • Managers may not give their full efforts if they think that they have performed better than others (or with respect to a predefined goal) already (step 3)	• Use DSSs and train managers on how best to use it • A scenario analysis could demonstrate the best possible outcomes from a given situation

Global fire emissions buffered by the production of pyrogenic carbon

Matthew W. Jones[1,4*], Cristina Santín[1,2], Guido R. van der Werf[3] and Stefan H. Doerr[1]

Landscape fires burn 3–5 million km^2 of the Earth's surface annually. They emit 2.2 Pg of carbon per year to the atmosphere, but also convert a significant fraction of the burned vegetation biomass into pyrogenic carbon. Pyrogenic carbon can be stored in terrestrial and marine pools for centuries to millennia and therefore its production can be considered a mechanism for long-term carbon sequestration. Pyrogenic carbon stocks and dynamics are not considered in global carbon cycle models, which leads to systematic errors in carbon accounting. Here we present a comprehensive dataset of pyrogenic carbon production factors from field and experimental fires and merge this with the Global Fire Emissions Database to quantify the global pyrogenic carbon production flux. We found that 256 (uncertainty range: 196–340) Tg of biomass carbon was converted annually into pyrogenic carbon between 1997 and 2016. Our central estimate equates to 12% of the annual carbon emitted globally by landscape fires, which indicates that their emissions are buffered by pyrogenic carbon production. We further estimate that cumulative pyrogenic carbon production is 60 Pg since 1750, or 33–40% of the global biomass carbon lost through land use change in this period. Our results demonstrate that pyrogenic carbon production by landscape fires could be a significant, but overlooked, sink for atmospheric CO_2.

Globally, landscape fires, which include wildfires, deforestation fires and agricultural burns, emit approximately 2.2 Pg C yr^{-1} to the atmosphere (1997–2016)[1]. The majority of this total emission flux is contributed by non-deforestation and non-peatland fire emissions, which are approximately balanced by vegetation regrowth and thus have no net influence on atmospheric stocks of carbon on decadal timescales[2,3]; however, around ~0.4 Pg C yr^{-1} are emitted during tropical deforestation and peatland fires, which contribute to the net global emissions of carbon due to land use change (~1.1–1.5 Pg C yr^{-1} (Fig. 1))[4–6]. These global carbon budget (GCB) estimates are generated by models that represent the temporally distinct processes of immediate carbon emission from burned areas and decadal-scale sequestration through vegetation (re)growth in a spatially explicit manner[1,7,8]. However, such models routinely overlook the coincident flux of biomass carbon to recalcitrant by-products of fire, which can be stored in terrestrial and marine pools for centuries to millennia, and thus provide a long-term buffer against fire emissions (Fig. 1)[9,10–13]. Consequently, the legacy effects of fire that operate on the longest timescales are systematically excluded from models of the carbon cycle and from GCBs[12,14].

These legacy effects are due to the incomplete combustion of vegetation during landscape fires, which transforms part of the remaining organic carbon in the biomass to a continuum of thermally altered products that are collectively termed pyrogenic carbon (PyC)[10,12,15]. The majority of the PyC produced during landscape fires remains initially on the ground in charcoal particles of varying size and is subsequently transferred to its major global stores in soils[16–18], sediments[19,20] and water bodies[21,22]. A smaller fraction of fire-affected vegetation carbon is emitted as PyC in smoke[23,24]. PyC includes labile products of depolymerization reactions as well as aromatic molecules that result from condensation reactions, the latter of which are depleted in functional groups and thus chemically and biologically recalcitrant[25–27]. The enhanced resistance of PyC to biotic and abiotic decomposition leads to its preferential storage in environmental pools[15,20] and a residence time that is typically 1–3 orders of magnitude greater than that of its unburnt precursors[12]. This makes PyC one of the largest groups of chemically discernible compounds in the soil with a contribution to the soil organic carbon stocks of 14% globally[16]. A fraction of the PyC is also conserved across the land-to-ocean aquatic continuum and thus accounts for approximately 10% of riverine dissolved organic carbon[28], 16% of riverine particulate organic carbon[29] and 10–30% of the organic carbon in ocean sediments[13,19,30,31].

A series of reviews and data syntheses have recognized the potential of PyC production to invoke a drawdown (sink) of photosynthetically sequestered CO_2 to pools that are stable on timescales relevant to anthropogenic climate change and its mitigation[9,10,12,13,32–37]. Owing to the relative recalcitrance of PyC, the conversion of biomass carbon to PyC represents an extraction of carbon from a pool cycling on decadal timescales to a pool cycling on centennial or millennial timescales[13,19,20,25,38]. This storage potential contrasts with that of dead vegetation, which degrades on timescales of months to decades or enters soil pools with a shorter residence time than that of PyC[7,11,25,39,40]. Consequently, postfire PyC pools emit carbon to the atmosphere over a significantly longer time period than would be the case in the absence of PyC production and also provide a buffer that moderates atmospheric CO_2 stocks (Fig. 1)[9,12,13]. At present, the fire-enabled vegetation models that are used to make GCB calculations account for short-term fire emissions but routinely exclude fluxes of carbon from biomass to PyC or the delayed emission of carbon from legacy PyC stocks to the atmosphere (Fig. 1)[7,8,14,41,42]. This introduces systematic errors to GCBs through misrepresentation of the effects of modern and historical fires on the exchange of carbon between the atmosphere and terrestrial–marine pools[12–14].

Although PyC has been recognized as a major component of the postfire ecosystem carbon stocks for a number of decades[10,35],

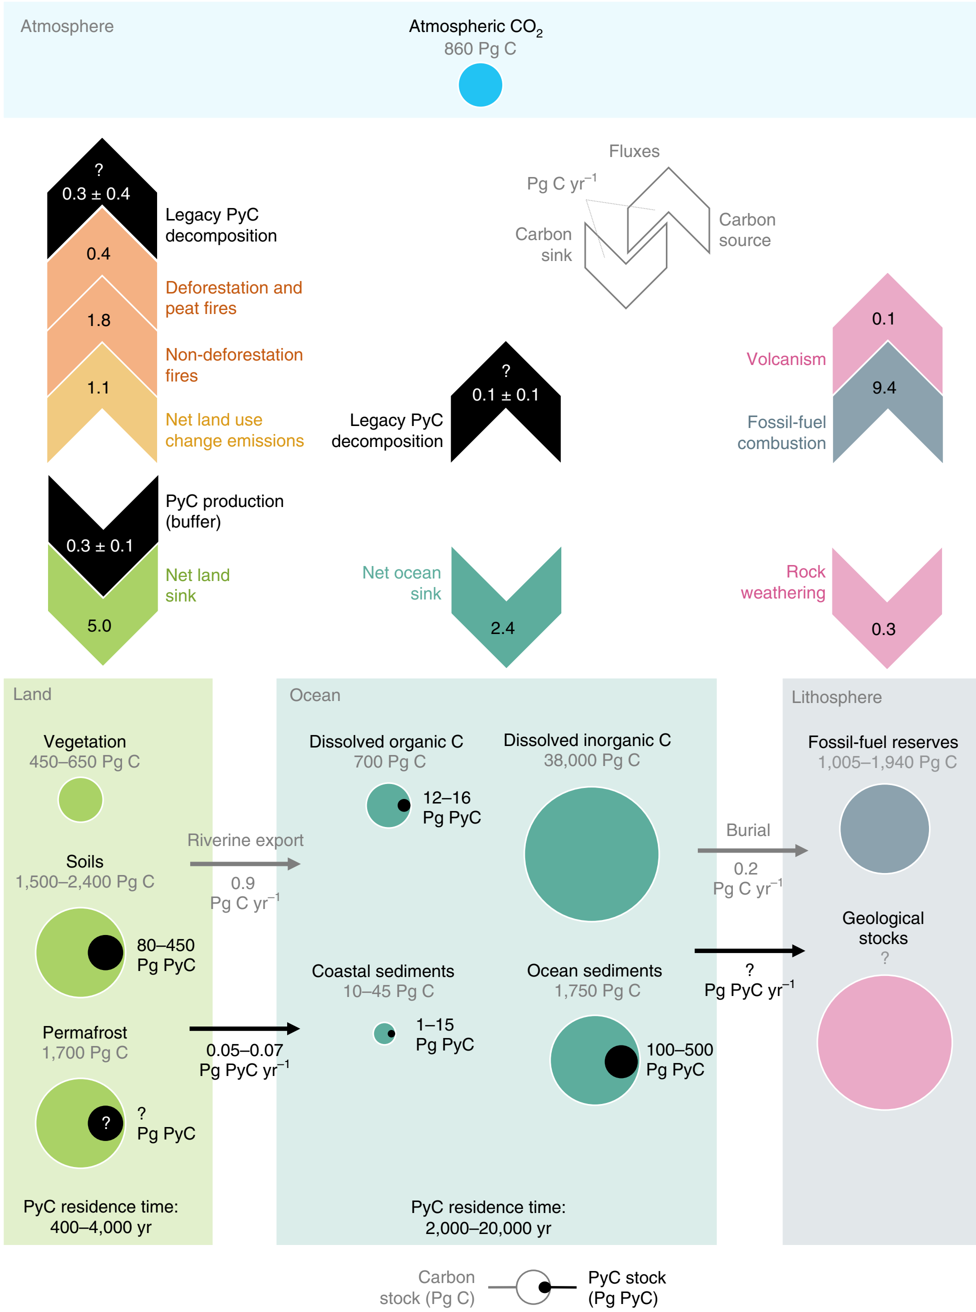

Fig. 1 | Schematic of the global carbon cycle including the buffer and legacy roles of PyC. Stocks (Pg C (1 Pg C = 1×10^{15} g of carbon)) and fluxes (Pg C yr^{-1}) of the global carbon cycle are represented by values from the GCB assessment of the decade 2008–2017[4] and the Intergovernmental Panel on Climate Change fifth assessment report of the decade 2000–2009[6]. Fluxes of carbon due to the net land sink are modified from the GCB to exclude non-deforestation fire emissions, whereas net land use change emissions are modified to exclude deforestation fire emissions. Carbon emissions from deforestation and peat fires and from non-deforestation fires were derived from GFED4s (ref. [1]) and relate to the period 1997–2016. PyC production fluxes due to deforestation and non-deforestation fires are based on estimates from GFED4s+PyC (this study). PyC stocks in soils, ocean dissolved organic carbon and ocean sediments are based on representative PyC/organic carbon ratios in the literature[13,16,68] applied to the estimates of organic carbon stocks and fluxes. PyC fluxes through rivers are the sum of global dissolved and particulate PyC export fluxes[28,29]. Residence times shown for soils derive from a meta-analysis of PyC decomposition in space-for-time substitution studies[69] and incubation experiment estimates extrapolated to field conditions[25]. Residence times for oceanic PyC pools are derived from the literature[19,70]. First-order estimates for legacy PyC decomposition fluxes and their uncertainties are calculated in quadrature for land and ocean pools as the product of the PyC stocks and the reciprocal of the residence times for PyC in these pools, assuming that the low- and high-end estimates for each term represent a consistent portion of normally distributed uncertainty.

quantification of its production rate at the global scale has been problematic and estimates vary by roughly an order of magnitude (50–379 Tg C yr^{-1}) (refs. [12,13,34,36]). A cause of the large range of production estimates is that calculations previously relied on incomplete information regarding the spatial distribution and type of fires, the allocation of carbon among the biomass fuel

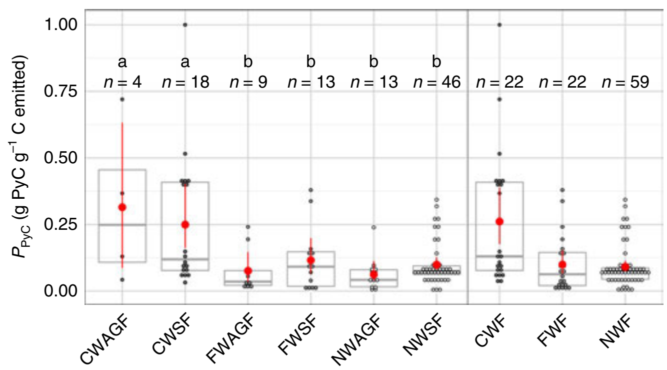

Fig. 2 | The box plots show the distributions of P_{PyC} values for each of the biomass component classes in the production factor dataset. Dots mark the distribution of P_{PyC} values across 1% intervals on the *y* axis. Red dots show the mean P_{PyC} values and red lines show the bootstrapped 95% confidence interval (Methods). Boxes illustrate the median and interquartile range of values. Letters a and b indicate biomass components with statistically similar P_{PyC} distributions at the 95% confidence level according to Tukey honest significant difference tests. The number of data entries (*n*) is also shown. CWF includes both CWSF and CWAGF. CWAGF, coarse woody aboveground fuels; CWSF, coarse woody surface fuels; FWAGF, fine woody aboveground fuels; FWSF, fine woody surface fuels; NWAGF, non-woody aboveground fuels; NWSF, non-woody surface fuels; FWF, fine woody fuels (includes both FWAGF and FWSF); NWF, non-woody fuels (includes both NWAGF and NWSF).

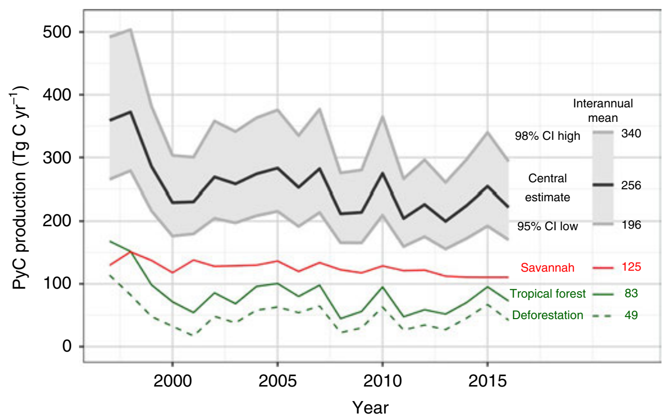

Fig. 3 | Annual global PyC production estimates from GFED4s+PyC for the period 1997–2016. The black line plots the modelled rate of production based on central P_{PyC} ratios (g PyC g^{-1} C emitted) from the global dataset. The shaded area indicates the uncertainty range of the modelled values based on the 95% confidence intervals (CIs) of P_{PyC} values (Fig. 2). The contributions of savannah burning (red line) and tropical forest burning (green solid line) to global PyC production totals are shown, the latter of which includes tropical deforestation fires (green dashed line).

components in burned areas and the specific PyC production factors for these distinct biomass fuel components. To alleviate these issues, we enhanced the Global Fire Emissions Database version 4 with small fires (GFED4s)[1], which is one of the principal process-based models used to make estimates of carbon emission from landscape fires[41,43,44]. Specifically, PyC production was incorporated by following a three-step approach that consisted of: (1) the assembly of the most comprehensive global database of PyC production factors (P_{PyC} (g PyC g^{-1} C emitted)) compiled to date, (2) the assignment of production factors for individual fuel classes stratified as coarse or fine and as woody or non-woody (Fig. 2) and (3) the application of P_{PyC} values to fuel-stratified carbon emissions (grams of C emitted) modelled by the native fuel consumption model in GFED4s. The output is the first global gridded dataset for monthly PyC production at a resolution of 0.25 × 0.25°, covering the years 1997–2016.

Global PyC production

Our central estimate for global PyC production in the period 1997–2016 was 256 Tg C yr^{-1} (Fig. 3), with an uncertainty range of 196–340 Tg C yr^{-1}, which includes variability in the measured P_{PyC} and interannual variability in global production, but excludes uncertainty in GFED4s emissions estimates (Methods). Interannual variability in global PyC production, expressed as the s.d. around the mean, was 47 Tg C yr^{-1} and was most strongly associated with variability in woody fuel combustion, which includes standing wood and coarse woody debris (CWD) (Supplementary Section 1 and Supplementary Fig. 1). Coarse woody fuels (CWF) produce PyC at a greater rate than finer fuels (Fig. 2) and consequently forest fires have disproportionate potential to influence global rates of PyC production (Supplementary Fig. 2).

The El Niño–Southern Oscillation (ENSO) is the primary driver of interannual variability in the burned area in the tropics[45] and previous analyses conducted with GFED showed that carbon emissions from tropical forest ecosystems more than doubled on average during the positive (El Niño) phases relative to the negative (La Niña) ENSO phases[46]. Correspondingly, we calculated that global rates of PyC production in tropical forests were 111% greater during the main fire season of the El Niño phases than during the La Niña phases (Supplementary Table 1). As rates of PyC production by non-forest fires were not sensitive to ENSO (Supplementary Table 1), the major driver of interannual variability in the total PyC production was variability in the tropical forest burned area (Fig. 3). The production of PyC was anomalously high in 1997–1998 (366 Tg C yr^{-1}), which aligns with a particularly strong positive El Niño phase that promoted extensive burning of (tropical) forests in South and Central America and in Southeast and Equatorial Asia[1,46].

Major production regions

The PyC production rates modelled by GFED4s+PyC conformed to a latitudinal pattern (Fig. 4) in which the tropical latitudes clearly dominated production at the global scale. Of the global production, 91% occurred in the tropics and subtropics (0–30° N and 0–30° S), whereas temperate (30–60° N and 30–60° S) and high-latitude (60–90° N) regions provided small contributions to the global total (8% and 1%, respectively).

The global distribution of PyC production also shows intricate regional patterns driven by variation in both the frequency at which fuel stocks were exposed to fire and the magnitude of the fuel stocks that were combusted during the fires that occurred (Supplementary Figs. 3 and 4). Fire frequency was ultimately the key determinant of PyC production rate, which explains why the tropics and subtropics were the dominant source regions. Although savannah fires affect low fuel stocks (Supplementary Section 2), these fires occur frequently and were spatially extensive (Supplementary Fig. 5 and Supplementary Table 2). They thus made the largest contribution to the global PyC production flux (125 Tg C yr^{-1}). Although tropical deforestation fires affected approximately 1% of the area of savannah fires, they affected large stocks of fuel (Supplementary Table 2) and were thus the second largest driver of global PyC production, at 49 Tg C yr^{-1}. The area affected by non-deforestation tropical forest fires was more than a factor of four larger than that of deforestation fires, but fuel consumption was relatively low (Supplementary Table 2). These fires provided the third major component of the global PyC production flux (34 Tg C yr^{-1}). Overall, 81% of the total global PyC production in the period 1997–2016 occurred in savannahs (49%) and tropical forests (32%).

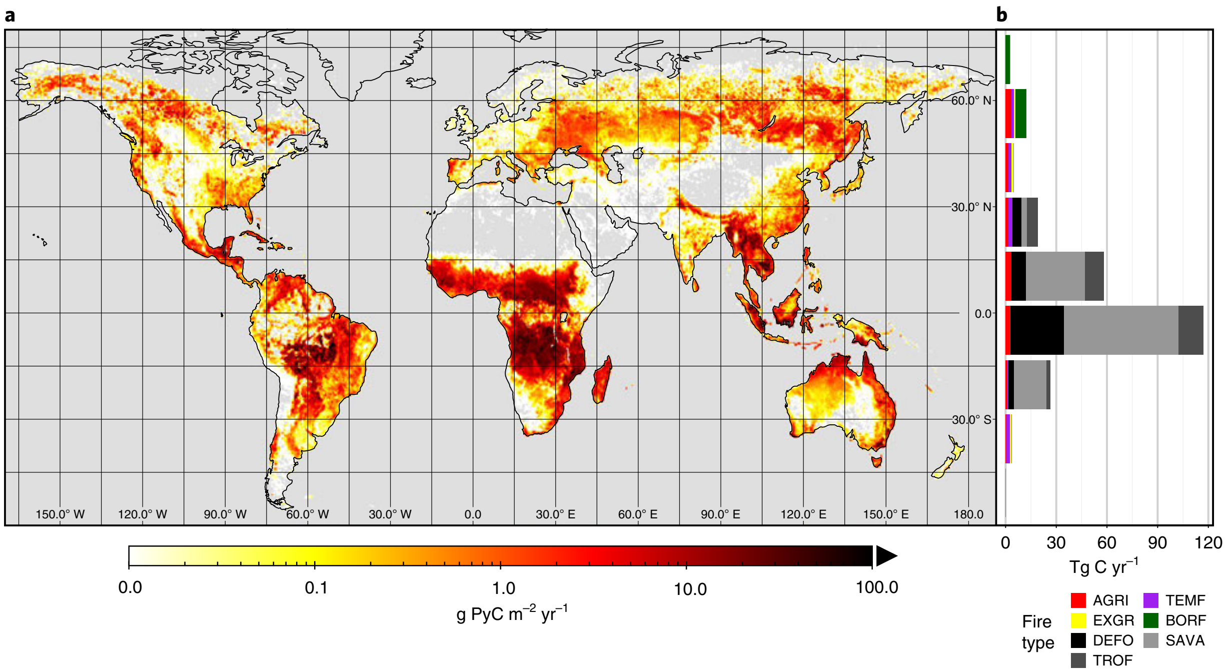

Fig. 4 | Annual average PyC production rates for the period 1997–2016 from GFED4s+PyC, based on central production factors (Fig. 2). a, The average global distribution of PyC production (g C m^{-2} yr^{-1}; note the log scale). **b**, The total production of PyC (Tg C yr^{-1}) in 15° latitudinal bands segregated according to the fire type, which includes savannah fires (SAVA), non-deforestation tropical forest fires (TROF), tropical deforestation fires (DEFO), agricultural fires (AGRI), temperate forest fires (TEMF), extratropical grassland fires (EXGR) and boreal forest fires (BORF).

Global carbon budget implications

Here we have quantified the global gross sink of atmospheric carbon caused by the transfer of photosynthetically sequestered biomass carbon to stocks of PyC during vegetation fires. Our central global PyC production flux estimate (256 Tg C yr^{-1}) is non-trivial within the context of the global carbon cycle (Fig. 1), as it equates to 12% of the global carbon emissions flux due to biomass burning and ~8% of the land sink for atmospheric CO_2 (~3.0–3.2 Pg C yr^{-1}) (refs. [4,6]). The global PyC production flux also equates to 75% of the carbon emitted from tropical deforestation and peat fires, which are the main categories of fire that cause a net loss of carbon to the atmosphere[1,9,47]. The PyC flux modelled here occurs in addition to the smaller global flux of 2 Tg C yr^{-1} caused by the emission of PyC in smoke from vegetation fires (according to equivalent estimates made using GFED4s in the years 1997–2016)[1].

The magnitude of our global estimate for PyC production indicates that the production of PyC during vegetation fires has the potential to significantly influence the atmospheric stock of carbon. A net sink of atmospheric carbon to stocks of PyC can be expected to develop if the flux associated with its production is unmatched by remineralization fluxes from legacy PyC stocks in terrestrial–marine pools (Fig. 1). Earth system models (ESMs) are the most sophisticated tools available to quantify the exchange of carbon between the atmosphere and these pools in time periods for which robust empirical data are sparse or unavailable. Despite previous attempts to highlight the importance of PyC production for carbon storage over timescales relevant to anthropogenic climate change and its mitigation[34,35,48], the absence of the PyC cycle from ESMs has restricted the scope to quantify its role in the carbon cycle[14]. The method introduced here allows for the routine integration of PyC production into fire-enabled vegetation models in a manner that systematically considers the spatial distribution of fire, the composition of the fuel stocks affected and the specific PyC production factors that apply to individual fuel components. This procedure is simple to implement in other fire-enabled vegetation models, which means that the major outstanding challenge to quantifying the net exchange of carbon between the atmosphere and PyC stocks with ESMs is to improve constraints over its storage and residence time in terrestrial and marine pools (Fig. 1)[13,14].

We also show that the PyC cycle must be integrated into ESMs if they are to represent accurately the role of fire in Earth's carbon cycle. The production flux of PyC represents the quantity of carbon that models would otherwise treat either as emitted or as unburned biomass with a residence time in terrestrial pools on the order of months to decades[7,11,25,39,40,49]. At present, the fate of 11% of the global biomass carbon stocks affected annually by fire is misrepresented in global models. As PyC dynamics are not represented in the ESMs used to make GCB calculations[4], this pool may represent a quantitatively significant missing sink or source of carbon to the atmosphere[14,50]. Recent estimates suggest that total carbon emissions from biomass burning in the period 1750–2015 amounted to ~500 Pg C (averaging 1.9 Pg C yr^{-1}) (ref. [41]). Under the assumption that the modern global PyC production flux maintained a constant ratio with the carbon emissions flux throughout this period, we estimate that since the beginning of the industrial revolution ~60 Pg C was transferred to the PyC stocks. This value is equivalent to 33–40% of the carbon lost from biomass pools due to land use change in the same time period (145–180 Pg C) (refs. [6,51]).

Our estimates for the modern and historical PyC production incorporate the best current understanding of PyC production through the combustion of vegetation biomass; however, the limitations of these estimates are worthy of mention. Notably, we do not include the production of PyC through the combustion of organic matter in soils, which may be an important process that drives the accumulation of PyC stocks in environments with deep organic layers, particularly peatlands[52]. We also do not account for the recombustion of PyC in locations that experience secondary burns, which can drive losses of the PyC that remains exposed at the surface[53]. PyC mass losses through recombustion have been reported as <8% in savannahs[54] and 17–84% in boreal forests[53,55]; however, the long fire return intervals in the latter biome typically allow sufficient time for PyC to be protected from recombustion through its burial in soils[17]. Our exclusion of recombustion is deliberate as we consider the process to be a component of the legacy PyC decomposition flux, which we do not quantify here (Fig. 1). Finally, our dataset of PyC production factors provides values for P_{PyC} that are modulated by fuel class (Fig. 2), but does not take into account fire characteristics (for example, temperature and duration) that are relevant to the formation of PyC[36,56,57]. The continued study of PyC production, with a particular focus on regions with high or rising fire incidence[58–60] and a range of fire intensities[61], will facilitate the application of more specific production factors in spatially explicit global models and thus result in reduced uncertainties in the global PyC production.

The production of PyC may become an increasingly important process for global carbon cycling in future centuries. Although the global burned area has declined in at least the past two decades, due predominantly to the conversion of savannah and grassland to agriculture[62,63], recent fire modelling studies generally agree that this decline is unlikely to continue past the year 2050[58–60]. It is also likely that a higher fraction of global burned area will be distributed in forests in which significant stocks of vegetation carbon are held[58,64,65]. As woody fuels generate more PyC per unit of biomass carbon than other fuels (Fig. 2), the spread of fire into forests can be expected to disproportionately enhance the global PyC production (Supplementary Fig. 2). Although it is less clear how fire prevalence will change in tropical and temperate forests owing to a stronger human control over burning in these regions[58,62], recent increases in fire extent caused by an increasing drought frequency in Amazonia already counteract reductions in the extent of deforestation fires[66]. Notwithstanding the significant uncertainty that exists in model predictions of future fire regimes, there are strong indications that PyC production rates will increase in some of the Earth's most carbon-dense regions in response to a changing climate[7,9,67]. This implies that the buffer for atmospheric CO_2 emissions that results from PyC production will grow in future centuries.

This work was funded by a Leverhulme Trust Research Project Grant awarded to S.H.D. (RPG-2014-095), a Swansea University College of Science Fund awarded to M.W.J., a Vici grant awarded to G.R.vdW. by the Netherlands Organisation for Scientific Research (NWO), and a European Union Horizon 2020 research and innovation grant awarded to C.S. (Marie Skłodowska-Curie grant 663830). We thank C. Aponte, C. Boot, G. Clay, G. Cook, F. Cotrufo, P. Fearnside, B. Goforth, R. Graham, M. Haddix, P. Homann, D. Hurst and M. Jenkins for their assistance during the collation of the global dataset of PyC production factors. We also thank B. de Groot for his part in securing funding of the Leverhulme Trust Grant.

Author contributions

M.W.J., C.S. and S.H.D. designed the study. S.H.D. led the Leverhulme Trust Research Project grant that funded the main body of the work. M.W.J. collated the PyC production factor dataset with support from C.S. C.S. and S.H.D. provided unpublished PyC production data. G.R.vdW. provided access to the GFED4s code. M.W.J. adapted the GFED4s code to include PyC production with the support of G.R.vdW. M.W.J. conducted the formal analysis of the production factor dataset and model outputs. All the authors contributed to the interpretation of the results. M.W.J. wrote the manuscript and produced all the figures. All the authors contributed to the refinement of the manuscript.

Methods

Global fuel consumption modelling in GFED4s. In GFED4s, carbon emissions to the atmosphere are quantified based on burned area and fuel consumption per unit of burned area. Burned area is derived from satellite data[71] and fires that are too small to be detected by regular burned area algorithms are derived statistically based on active fire detections and relations with, among others, vegetation indices[72]. Fuel consumption is modelled using a satellite-driven biogeochemical model[1] and tuned to match observations[73]. Most of the underlying satellite input datasets have a 500 × 500 m resolution but are aggregated to the model resolution of 0.25° × 0.25°. Total fuel consumption is based on the fuel consumption of several fuel components, which include leaves, grasses, litter, fine woody debris, CWD and standing wood. van der Werf et al.[1] give more information on the GFED4s modelling approach.

To calculate the PyC production within GFED4s we added the production factor P_{PyC}, which quantifies the production of PyC per unit carbon emitted. Until now, the principle obstacle to performing a global modelling exercise of this type was the lack of a sufficiently rich and standardized dataset with which to constrain representative values for P_{PyC}.

Our estimates of uncertainty in the annual PyC production relate only to variability in the PyC production factors and interannual variability in emissions and do not include uncertainties in carbon emission estimates propagate from GFED4s. Uncertainties in GFED4s emissions estimates are discussed at length in van der Werf et al.[1,74] and are predominantly the result of uncertainties in the satellite detection of small fires using thermal anomalies and burn scars. As carbon emissions and PyC production are codependent on the burned area, estimation errors that relate to fire detection introduce scalar uncertainties. Uncertainty in the fuel consumption is an additional component of the overall uncertainty in GFED4s emission estimates[1] and has been reduced from previous versions (for example, GFED3) through its incorporation of a global dataset of fuel consumption estimates[73]. As discussed in the primary literature that relates to the development of the GFED4s[1], a formal global-scale assessment of the uncertainties in fuel consumption cannot be completed due to a paucity of ground truth data for some input datasets. For the previous version of GFED (GFED3), Monte Carlo simulations that accounted for uncertainty in both burned area detection and fuel consumption were used to obtain first-order constraints on the uncertainty in carbon emissions, which were ±20–25% at global, annual scales as a 1 s.d. (1σ) value[74]. Developments of GFED4s included the incorporation of small-fire burned area detection, which led to important reductions in the negative bias in the emissions estimates[72]; however, small fires are also challenging to detect and a lack of validation data prevents the formal investigation of uncertainty in burned area for GFED4s[1,72]. Hence, the true uncertainty of GFED4s is not known precisely, but it is likely to be on the same order as that of GFED3 ($1\sigma = \pm 20$–25%). Nonetheless, uncertainty ranges are likely to be greater in regions where small fires are prevalent or where organic soils are affected (for example, Central America, Europe and Equatorial Asia)[1,72].

Regional-scale field studies of fire emissions have served to validate that the GFED modelling framework produces reliable estimates at large scales, for example, in Alaska[75] and the tropics[76]. Studies that involve atmospheric tracers have also provided vital diagnostics for the performance of GFED[1], and generally highlight its proficiency at large scales but reveal some weaknesses in specific regions or during isolated events[77–82]. Overall, GFED4s is highly suited to the investigation of the effects of fire in global-scale biogeochemical cycles and is thus regularly used in GCB assessments[4] and as a reference point for the fire modules of ESMs[7].

Collating a global dataset of PyC production factors. We compiled a new database of P_{PyC} factors (Supplementary Dataset) from a global collection of 22 published studies that reported on PyC production in 91 burn units, as well as two new datasets produced by the authors with 23 burn units reported for the first time here, and we standardized their reporting. All the studies used one of the following two broad approaches to quantify the impacts of fire on the biomass carbon stocks, either prefire and postfire stocks of biomass carbon and PyC are measured or space-for-time substitution is used to constrain burned and unburned stocks of biomass carbon and PyC, which are assumed to be equivalent to prefire and postfire stocks, respectively. Hereafter, the terms 'prefire' and 'postfire' are used to refer to both types of assessment. Here we focus only on PyC present in charcoal and ash[83] on the ground following fire and on charred vegetation. PyC emitted with smoke, transported in the atmosphere and deposited on a regional-scale area is not included as this process has been studied in separate dedicated studies conducted by atmospheric scientists[23] and represents a relatively small flux in comparison (see main text)[12,13].

The P_{PyC} values were calculated for each of the six classes of widely used biomass components: CWSF, which includes CWD or downed wood defined by typical diameter thresholds of >7.6 cm or >10 cm (refs. [84,85]); FWSF, which includes fine woody debris or any other woody debris with diameters below the thresholds for CWSF; CWAGF, which includes trees or branches with diameters greater than the thresholds for CWSF; FWAGF, which includes material described as shrubs, trees or branches with diameters below the thresholds for CWSF; NWSF, which includes litter, understory vegetation, grass, root mat and any other form of non-woody material directly in contact with the ground surface[85,86] and, finally, NWAGF, which includes foliage, leaves, needles, crown fuels and any other forms of non-woody material that attach to standing wood structures above the ground surface.

For each biomass component, P_{PyC} (PyC produced per C emitted) was calculated using the following equation:

$$P_{PyC} = \frac{C_{Py}}{C_{PRE} - C_{POST} - C_{Py}}$$

where C_{Py} is the mass of PyC created during the fire that was attributed to the component, C_{PRE} is the prefire stock of biomass carbon in the component and C_{POST} is the postfire stock of biomass carbon in the unburnt component. C_{Py}, C_{PRE} and C_{POST} are all expressed in the units g C km^{-2}.

Criteria were applied as filters to the dataset to ensure that P_{PyC} could be calculated in a consistent and representative manner. Specifically, P_{PyC} was calculated if the following conditions were met: first, both prefire and postfire biomass stocks were reported and the carbon content (%) was either measured or assumed based on representative values from the literature; second, postfire stocks of pyrogenic organic matter (charcoal, ash and the charred components of partially affected vegetation) were reported and their PyC content (%) was either measured or assumed based on representative values from the literature; third, the type of fire that occurred was representative of a widespread regional fire type (for example, wildfires, slash-and-burn deforestation and prescribed fire) and fourth, in experimental fires, the biomass carbon stock was designed to replicate the density and structure of biomass carbon stocks observed in the field and the burning efficiency was not optimized or adapted as a factor of the study design.

The set of criteria outlined above does not exclude studies that assess the PyC content of charcoal using one of the various chemical or thermochemical techniques available for the separation of PyC from bulk organic carbon[87,88]. Such techniques are frequently used for the detection of PyC in well-mixed soil, sediment and aquatic matrices. However, we note that none of the studies included in our dataset utilized a chemical or thermochemical approach to separate PyC from non-PyC; instead, these studies considered all the organic carbon in residual products of interest (charcoal, ash and the charred components of partially affected vegetation) to be PyC. Thus, we highlight that our estimates of P_{PyC} are free of the intermethod variability in PyC quantification that often confounds the comparison of PyC concentration in environmental matrices across studies and contributes to the notable uncertainty in the magnitude of Earth's major PyC stocks[12,13] (Fig. 1).

Like biomass carbon, total PyC stocks are distributed across several components, which include charcoal and ash on the ground, charcoal attached to CWD and charcoal attached to aboveground vegetation[12]. The majority of the studies included in the production factor dataset matched the studied PyC components to individual biomass carbon components from which they were known to derive. However, as some individual components of the PyC stocks can have a mixture of sources that are indistinguishable from their location or appearance alone, it was occasionally necessary to make assumptions about the biomass components that were sources of these components. This was done on a study-by-study basis. In cases where the source of each PyC component was not explicitly stated, the following procedural steps were adhered to. On a first basis, the PyC component was assigned to a biomass component according to the most probable source inferred, but not explicitly stated, in the primary literature. Second, where more than one biomass component was inferred to be a source of the PyC stock in the primary literature, the PyC stock was weighted proportionally to the prefire stock of carbon present in each of the implicated biomass components. Otherwise, if no sources of PyC were inferred in the primary literature it was necessary to make independent assumptions about the source of PyC in a manner that was consistent with the other studies included in the dataset and our collective experience of quantifying PyC production in the field.

Summary of the production factor values for use in GFED4s+PyC. Our global database suggested that CWSF and CWAGF produce significantly more PyC, relative to carbon emitted, than other fuel classes (their P_{PyC} averaged at 0.25 and 0.31 g PyC g^{-1} C emitted, respectively (Fig. 2)). In contrast, the mean P_{PyC} values for FWSF and FWAGF (0.12 and 0.076 g PyC g^{-1} C emitted, respectively) did not differ significantly from those of NWSF and NWAGF (0.099 and 0.062 g PyC g^{-1} C emitted, respectively). These results are consistent with previous studies, which suggest that large-diameter woody fuels burn less completely and produce PyC in greater proportions than finer fuels[34,35].

For each class, the mean PyC production factor was used as the central estimate for P_{PyC} and the confidence interval around the mean P_{PyC} was calculated through a bootstrapping procedure. Specifically, the available PyC production factors from the dataset were resampled 50,000 times, the mean P_{PyC} was calculated for each resample and the 95% confidence interval was calculated as the middle 95% of the observed 50,000 means (that is, those ranked 1,250th to 48,750th).

According to an analysis of variance with a Tukey honest significant difference post hoc test, no significant differences in mean P_{PyC} were observed between the distributions of P_{PyC} for coarse, fine and non-woody fuels positioned at the ground surface and those same fuels located above the ground surface. Therefore, the

P_{PyC} values applied in GFED4s+PyC are based on the distribution of values in three simplified fuel classes (Fig. 2): CWF (mean 0.26 g PyC g^{-1} C; 95% confidence interval, 0.18–0.39 g PyC g^{-1} C), FWF (mean 0.096 g PyC g^{-1} C; 95% confidence interval, 0.064–0.15 g PyC g^{-1} C) and NWF (mean 0.091 g PyC g^{-1} C; 95% confidence interval, 0.074–0.11 g PyC g^{-1} C).

Assigning PyC production factors in GFED4s+PyC. P_{PyC} values were assigned to each of the native fuel classes of GFED4s[1], which are leaves, grasses, surface fuels (which include litter and fine woody debris), CWD and standing wood (which includes trunks, stems and branches). Mean P_{PyC} values and bootstrapped confidence interval values for CWF, FWF and NWF from the global dataset were used to define representative P_{PyC} values for each of the GFED4s fuel classes (Fig. 2). Full details as to the assignment of P_{PyC} values to each GFED4s fuel class are provided in Supplementary Section 3 and Supplementary Table 3). Briefly, leaf, litter and grass were assigned the relevant P_{PyC} values of NWF, fine woody debris and CWD were assigned the values of FWF and CWF, respectively, and P_{PyC} values for standing wood were applied in a spatially explicit manner as weighted combinations of the P_{PyC} values for CWF (carbon in trunks) and FWF (carbon in branches). The weighted CWF:FWF ratio was assigned according to empirical relationships that defined biomass carbon apportionment to branches and trunks in the various forest types of the GFED4s land cover scheme (Supplementary Section 3 and Supplementary Table 4)[89].

Quantifying ENSO impacts on PyC production. To investigate the influence of pantropical climatic variability driven by the ENSO on the production of PyC, we replicated the analysis presented by Chen et al.[46] with a focus on PyC production rather than on carbon emissions. The pantropics were defined as consisting of Central America, Northern Hemisphere South America, Southern Hemisphere South America, Northern Hemisphere Africa, Southern Hemisphere Africa, Southeast Asia, Equatorial Asia and Australia (Supplementary Fig. 6). The PyC production in El Niño and La Niña phases was compared for the major fire season periods defined in each tropical region by Chen et al.[46]; their study gives a thorough explanation of the rationale for selecting these comparison periods. We summed PyC production in the major fire season period of each region and disaggregated this total to forest and non-forest fires according to the dominant land cover type in the GFED4s land cover scheme (based on the MODIS Land Cover Type Climate Modelling Grid product MCD12C1)[90].

Apportioning sources of PyC. After the GFED4s+PyC model runs, PyC production was assigned to specific sources following a method developed previously for use in GFED4s model runs[1,74]. Specifically, PyC production that occurs as a result of non-deforestation fires was disaggregated in each cell to tropical forest, savannah/grassland, boreal forest, temperate forest and agricultural fires using an existing algorithm that utilizes fractional tree cover, climate and fire-persistence variables. van der Werf et al.[74] give a full discussion of this algorithm. We added an additional latitudinal constraint (30° N to 30° S) to further disaggregate the savannah compartment, which thus separates tropical savannahs and grasslands from extratropical grasslands.

Data availability

The global dataset of the PyC production factors is available as a supplementary data file (GlobalPyC_supplementarydataset.xlsx). This dataset will also be uploaded to the GFED website (http://www.globalfiredata.org) and updated with new data as it becomes available. Supplementary Section 4 contains full references to the studies included in the production factor dataset. Burned area and fire emissions data are publicly available at the GFED website. Additional ancillary data are available from the corresponding author on request.

Livestock Impacts on Riparian Ecosystems and Streamside Management Implications... A Review

J. BOONE KAUFFMAN AND W.C. KRUEGER

Historically, riparian vegetation has been defined as vegetation rooted at the water's edge (Campbell and Franklin 1979). Quite often, however, the stream influences vegetation in many ways and well beyond the water line. In lotic systems, the stream is not only responsible for increased water availability, but also for the soil deposition, unique microclimate, increased productivity, and the many consequential, self-perpetuating biotic factors associated with riparian zones. These factors all contribute in the formation of a unique assemblage of plant communities quite distinct from upland communities surrounding the riparian zone. Therefore, along streambanks, other lotic systems, and even ephemeral drainages, riparian ecosystems could best be defined as those assemblages of plant, animal, and aquatic communities whose presence can be either directly or indirectly attributed to factors that are stream-induced or related (Kauffman 1982).

Riparian zones can vary considerably in size and vegetation complexity because of the many combinations that can be created between water sources and physical characteristics of a site (Odum 1971, Platts 1979, Swanson et al. 1982). Such characteristics, include gradient, aspect, topography, soil type of streambottom, water quality, elevation, and plant community (Odum 1971). However, riparian zones, particularly those bordering streams or rivers, have several characteristics in common. They are ecotonal, with high edge to area ratios (Odum 1978). As functional ecosystems they are very open with large energy, nutrient, and biotic interchanges with aquatic systems on the inner margin (Cummins 1974, Odum 1978, Sedel et al. 1974) and upland terrestrial ecosystems on the other margin (Odum 1978).

Thomas et al. (1979) stated that all riparian zones within managed rangelands of the western United States have the following in common: (1) they create well-defined habitat zones within the much drier surrounding areas; (2) they make up a minor proportion of the overall area; (3) they are generally more productive in terms of biomass—plant and animal—than the remainder of the area; and (4) they are a critical source of diversity within rangelands. Both density and diversity of species tends to be higher at the land/water ecotones than in adjacent upland, especially where regional climates are characterized by dry periods (Odum 1978). Ganskopp (1978) described 44 vegetation communities in a 49-hectare riparian zone in the Blue Mountains of northeastern Oregon. Kauffman et al. (1984) stated that the several biotic, environmental and other abiotic factors interacting in a riparian zone in Oregon created a disproportionately greater number of niches compared to surrounding upland ecosystems. Two-hundred and fifty-eight stands of vegetation representing 60 discrete plant communities were identified within this study area. The higher diversity, productivity, and other unique factors associated with the riparian zone when compared to the surrounding uplands are the primary factors that create the importance of these areas as focal points for the management of the livestock, fishery, and wildlife resources.

Authors are former graduate research assistant and professor, Department of Rangeland Resources, Oregon State University, Corvallis, respectively.

Importance of Riparian/Stream Ecosystems

Importance to Instream Ecosystems

Vegetation along small streams is an important component of the riparian/stream ecosystem (Campbell and Franklin 1979, Jahn 1978). Riparian vegetation produces the bulk of the detritus that provides up to 90% of the organic matter necessary to support headwater stream communities (Cummins and Spengler 1978). In these tributaries of forest ecosystems 99% of the stream energy input may be imported from bordering riparian vegetation (i.e., it is heterotrophic) and only 1% derived from stream photosynthesis by attached algae (periphyten) and mosses (Cummins 1974). Berner (in Kennedy 1977) found that even in large streams such as the Missouri River, 54% of the organic matter ingested by fish is of terrestrial origin. The riparian zone vegetation functions both in light attenuation and as the source of allochthonous inputs, including long-term structural and annual energy supplies (Cummins 1974).

Vegetation along streams exercises important controls over physical conditions in the stream environment. It acts as a roughness element that reduces the velocity and erosive energy of overbank flow during floods (Li and Shen 1973). The result is a higher flood peak than a channel without riparian vegetation but lower erosional factors acting on the floodplain and bank (Schumm and Meyer 1979). Healthy riparian vegetation tends to stabilize streambanks, determines bank morphology and may help reduce streambank damage from ice, log debris, and animal trampling (Platts 1979, Swanson et al. 1982).

Channel and floodplain obstructions such as branches, logs, and rocks enhance detention and concentration of organic matter, thereby facilitating its use locally rather than washing downstream (Everest and Meehan 1981, Jahn 1978, Swanson et al. 1982). In addition, wood debris in channel bottoms appears to play an important role in the dynamics of stream morphology. Large pieces of woody debris in streams dissipate stream energy, control routing of sediment and water through channel systems, and serve as substrates for biological activity by microbial and invertebrate organisms (DeBano 1977, Swanson et al. 1982).

Streamside vegetation strongly influences the quality of habitat for anadromous and resident coldwater fishes (Duff 1979, Everest and Meehan 1981, Marcuson 1977, Meehan et al. 1977). Riparian vegetation provides shade, preventing adverse water temperature fluctuations (Meehan et al. 1977). The roots of trees, shrubs, and herbaceous vegetation stabilize streambanks, providing cover in the form of overhanging banks (Marcuson 1977, Meehan et al. 1977). Streamside vegetation acts as a "filter" to prevent sediment and debris from man's activities from entering the stream (Meehan et al. 1977). Riparian vegetation also directly controls the food chain of the ecosystem by shading the stream and providing organic detritus and insects for the stream organisms (Cummins 1974, Meehan et al. 1977).

Importance to Wildlife

It is believed that, on land, the riparian/stream ecosystem is the single most productive type of wildlife habitat, benefiting the greatest number of species (Ames 1977, Hubbard 1977, Miller 1951, Patton 1977). The riparian zone provides an almost classic example of the ecological principles of edge effect (Odum 1978). Riparian habitat provides living conditions for a greater variety of wildlife than any other types of habitat found in California (Sands and Howe 1977), the Great Basin of southeast Oregon (Thomas et al. 1979), the Southwest (Hubbard 1977), the Great Plains (Tubbs 1980), and perhaps the entire North American continent (Johnson et al. 1977).

Examples of the wildlife values of riparian habitat are numerous (Carothers et al. 1974, Carothers and Johnson 1975, Henke and Stone 1978, Hubbard 1977, Thomas et al. 1979). Hubbard (1977) reported that 16–17% of the entire breeding avifauna of temperate North America occurs in 2 New Mexico river valleys over the course of a "few score" miles. Johnson et al. (1977) reported that 77% of the 166 nesting species of birds in the Southwest are in some manner dependent on water related (riparian) habitat and 50% are completely dependent on riparian habitats. In western Montana, 59% of the land bird species use riparian habitats for breeding purposes and 36% of those breed only in riparian areas (Mosconi and Hutto 1982). Thomas et al. (1979) stated that of the 363 terrestrial species known to occur in the Great Basin of southeastern Oregon, 299 are either directly dependent on riparian zones or utilize them more than any other habitats.

When riparian vegetation is eliminated, several wildlife species dependent on riparian ecosystems may be either severely reduced or may disappear altogether. Henke and Stone (1978) found 93% fewer bird numbers and 72% fewer avian species on 2 riprapped plots from which riparian vegetation had been removed, and 95% fewer birds and 32% fewer species on cultivated lands previously occupied by riparian forests.

The influence of riparian ecosystems on wildlife is not limited to those animal species that are restricted in distribution to the streamside vegetation. Population densities of birds in habitats adjacent to the riparian type are influenced by the presence of a riparian area (Carothers 1977). When a riparian habitat is removed or extensively manipulated, not only are the riparian species of the area adversely influenced, but wildlife productivity in the adjacent habitat is also depressed (Carothers 1977).

Riparian ecosystems are valuable to wildlife as a source of water, food, and cover (Stevens et al. 1977, Thomas et al. 1979). They also provide nesting and brooding habitat for avian species (Carothers et al. 1974, Johnson et al. 1977, Tubbs 1980). By furnishing abundant thermal cover and favorable micro-climates, especially when surrounded by nonforested ecosystems, they facilitate the maintenance of of homeostatis, particularly for big game (Thomas et al. 1979). Riparian ecosystems also serve as big game migration routes between summer and winter range (Thomas et al. 1979), and provide routes and nesting cover for migrating avian species (Stevens et al. 1977, Wauer 1977).

Importance to Livestock

Livestock grazing on rangelands is the most extensive form of land use in the interior Pacific Northwest (Skovlin et al. 1977). Cattle tend to congregate on meadows and utilize the vegetation much more intensively than the vegetation of adjacent ranges (Reid and Pickford 1946).

In northeast Oregon, Reid and Pickford (1946) stated that moist meadow soils in riparian ecosystems are generally so highly productive than an acre of mountain meadow has a potential grazing capacity equal to 10–15 acres of forested range. Although riparian meadows cover only about 1–2% of the summer range area of the Pacific Northwest, potentially they can produce 20% of the summer range forage (Reid and Pickford 1946, Roath and Krueger 1982). However, Roath and Krueger (1982) found that because of livestock concentrations, limits on livestock movements imposed by steep slopes, and erratic distribution of watering areas away from the creek, the riparian zone (covering about 2% of a Blue Mountain grazing allotment) accounted for 81% of the total herbaeous vegetation removed by cattle.

Cattle exhibit a strong preference for riparian zones for a number of the same reasons other animals prefer and use these areas. The main attributes believed to attract and hold cattle to riparian areas are the availability of water, shade, and thermal cover, and the quality and variety of forage (Ames 1977, Severson and Boldt 1978). In addition, sedges (Carex spp.) tend to retain relatively constant crude protein levels until the first killing frost. Several sedges common to riparian zones of the Pacific Northwest outrank key upland forage species in sustained protein and energy content (McLean et al. 1963, Paulsen 1969, Skovlin 1967).

Livestock Riparian Relationships

The impact of livestock on riparian zones in public grazing lands of the western states has received much attention recently. Several studies are presently underway examining the impact of livestock grazing on stream ecology, water quality, channel stabilization , salmonid fish habitat and physiology, terrestrial riparian wildlife populations, and riparian vegetation.

It is often difficult for one to interpret science from opinion in the literature. Many of the studies reported in this paper have not necessarily followed the generally accepted "scientific method" for research today. However, it is not the purpose of this paper to determine, even if possible, which published reports represent quality scientific results and which are little more than a forum to express one's opinion. Rather the purpose of this paper is to familiarize the reader with the accepted facts and management theories available today concerning livestock interactions in riparian zones with the other valid resources also dependent or utilizing this resource. Where possible, in this paper, results of properly conducted research are reported using terms such as "significant", referring to a statistically significant result and those of reports relying on observational data or "hearsay" will be reported as suggestions or observations.

General Considerations for Livestock-Riparian Management

The quality of the riparian habitat and its associated aquatic environment, both formed over geologic time, are fragile ecosystems which currently serve as focal points for management of livestock, recreation, and fisheries and timber resources. It has been reported that inappropriate livestock management results in overuse and subsequent degradation of the riparian/stream ecosystem (Behnke and Raleigh 1978, Oregon-Washington Interagency Wildlife Council 1978, Platts 1979). Davis (1982) suggested that one of the most destructive forces in riparian ecosystems is the long-term impact of overgrazing by cattle. Livestock grazing can affect 4 general components of an aquatic system-streamside vegetation, stream channel morphology, shape and quality of the water column and the structure of the soil portion of the streambank (Behnke and Raleigh 1978, Marcuson 1977, Platts 1979, Platts 1981). Improper livestock use of riparian ecosystems can affect the streamside environment by changing, reducing, or eliminating vegetation bordering the stream (Ames 1977, Behnke and Raleigh 1978, Platts 1979). The channel morphology can be changed by widening and shallowing of the streambed, gradual stream channel trenching, or braiding, depending on soils and substrate composition (Behnke and Raleigh 1978, Gunderson 1968, Marcuson 1977, Platts 1979). The water column can be altered by increasing water temperatures, nutrients, suspended sediments, bacterial counts and by altering the timing and volume of water flow (Behnke and Raleigh 1978, Johnsen et al. 1978, Rauzi and Hanson 1966, Platts 1979). Overgrazing can cause bank sloughoff creating false setback banks, accelerated sedimentation, and subsequent silt degradation of spawning and food producing areas (Behnke and Raleigh 1978, Everest and Meehan 1981, Platts 1979, Platts 1981). These impacts on the water column due to abusive livestock practices result in decreased fish biomass and in percent of salmonid fishes in the total fish composition (Behnke and Raleigh 1978, Bowers et al. 1979, Duff 1979, Gunderson 1968, Marcuson 1977).

Livestock abuse of riparian areas can severely impact terrestrial wildlife habitat causing a subsequent decrease in wildlife species and numbers (Ames 1977, Townsend and Smith 1977, Tubbs 1980, Wiens and Dyer 1975).

Improper grazing can have a considerable effect on vegetation, resulting in decreased vigor, biomass and an alteration of species composition and diversity (Ames 1977, Bryant et al. 1972, Evans and Krebs 1977, Knoph and Cannon 1982, Pond 1961).

While various other land management activities have caused serious losses or reductions in wildlife habitat productivity, livestock grazing has been suggested as the major factor identified in numerous studies throughout the 11 western states (Oregon-Washington Interagency Wildlife Council 1978). Conversely, Busby (1979) suggested that it was not reasonable to conclude that livestock grazing is the only, nor necessarily the major cause of impacts to riparian ecosystems.

Impacts of Livestock on the Instream Ecology

A healthy instream environment is vital for the aquatic life forms inhabiting the stream, as well as for various human needs that directly depend on water quality. High concentrations of suspended solids or other sediment loads, and fecal coliforms or fecal streptococci are usually associated with the degree of impact of man's activities, and can have a major impact in altering an existing stream ecosystem or even creating an entirely new ecosystem (Johnson et al. 1977, Johnson et al. 1978, McKee and Wolf 1963).

During the grazing season, Johnson et al. (1978) could not find any significant differences in physical and chemical properties of streamwater (suspended solids, total dissolved solids, and orthophosphates) between an area grazed at 1.2 ha/AUM and an ungrazed area. After the grazing season, however, there was a significant increase in total dissolved solids which indicated that some livestock waste products may have eventually reached and enriched the stream, probably from the action of rain showers. The presence of cattle significantly elevated the fecal coliform and fecal streptococci for about 9 days after cattle were removed.

Winegar (1977) found sediment loads were reduced 48–79% while flowing through 3.5 miles of a stream protected from grazing.

Rauzi and Hanson (1966) found a nearly linear relation between runoff and infiltration to the degree of grazing intensity. They found that runoff from a heavily grazed watershed (1.35 acre/AUM) was 1.4 times greater than from a moderately grazed watershed (2.42 acre/AUM) and 9 times greater than from a lightly grazed watershed (3.25 acre/AUM).

Changes in water temperature have been shown to have drastic effects on fisheries and aquatic insect populations (Johnson et al. 1977). Changes in average temperature or daily fluctuations can in effect create an entirely new aquatic ecosystem (Johnson et al. 1977).

Van Velson (1979) found average water temperatures dropped from 24°C to 22°C after 1 year of livestock exclusion on a creek in Nebraska. Claire and Storch (unpublished) compared stream temperatures between an area that had been grazed season long (June 1–October 15) and an area that had been rested for 4 years and, thereafter, grazed only after August 1. The maximum water temperatures outside and downstream from the exclosure averaged 7°C higher than those sampled within the exclosure. Daily fluctuations of water temperatures averaged 15°C outside the exclosure as compared to 7°C inside the exclosures. Winegar (pers. comm. 1982) observed similar results in an exclosure along Beaver Creek in central Oregon.

The effects of livestock grazing have been shown to vary greatly depending upon several factors, in particular, the nature of the stream studied. Duff (1979) stated that introduction of livestock for 6 weeks into a riparian area rested for 4 years resulted in elimination of overhanging banks and a fracturing of the streambank, causing it to erode into the stream. In contrast, after 6 weeks of mid-summer grazing by cattle, Roath (1980) gave a visual estimate of 90% bank stability with little indication that trampling was contributing to or causing erosion. He attributed nearly all erosion present to geologic erosion caused by the actions of streamflow.

Buckhouse et al. (1981) could find no particular relationship between streambank erosion and various grazing treatments (including nonuse) in northeastern Oregon. There appeared to be no significant patterns of accelerated streambank deterioration due to moderate livestock grazing (3.2 ha/AUM and 60–65% utilization of the riparian vegetation). Most bankcutting losses in this system were associated with over-winter periods where ice floes, high water, and channel physiognomy were critical factors involved in the erosional process.

Hayes (1978) found that stream channel movement did not occur more frequently in grazed riaprian meadows under a rest-rotation grazing scheme compared to ungrazed meadows after 1 year of study. Rather, streambank degradation appeared to occur more often and to a greater magnitude along ungrazed streams. However, Hayes stated that sloughoff increased as forage removal was above 60%. High forage removal, high amount of foraging time along banks, and high percentages of palatable sedges along the bank were shown to significantly increase the probability of sloughoff occuring during the grazing season.

Kauffman et al. (1983b) measured significantly greater streambank losses in grazed areas (1.3–1.7 ha/AUM) compared to ungrazed areas in northeastern Oregon. The grazed pastures had utilization levels greater than 35% and less than 85% on the different vegetation stands while utilization by native animals was less than 20% on every stand. During 2 late season grazing periods (late August–mid-September), a mean of 13.5 cm of streambank was lost in grazed areas and 3.0 cm was lost in ungrazed areas. Total annual streambank losses were 30 cm in grazed areas and 9 cm in ungrazed areas.

Marcuson (1977) found the average channel width to be 53 meters in an area grazed season long at 0.11 ha/AUM and an average channel width of only 18.6 meters in areas that were ungrazed. Marcuson (1977) also recorded 224 meters of undercut bank/km in the grazed area and 686 meters of undercut bank/km in the ungrazed area. Heavy grazing and trampling by cattle were suggested to cause the excessive erosion.

Duff (1979) found the stream channel width in a grazed area was 173% greater than the stream channel not grazed for 8 years inside an exclosure. Similar results have been reported (Behnke and Zarn 1976, Dahlem 1979, Gunderson 1968, Heede 1977) where overgrazing and excessive trampling caused a decrease in bank undercuts, increases in channel widths, and a general degradation of fish habitat.

Claire and Storch (unpublished) stated that the production of game fish in headwater streams can be used as a biological indicator of the quality of land management that is occurring within the watershed and/or streamside. Overgrazing, causing a reduction in vegetative cover and the caving in of overhanging banks, has been suggested as one of the principal factors contributing to the decline of native trout in the West (Behnke and Zarn 1976).

Bowers et al. (1979) reported an average increase in fish production of 184% for 5 independent studies where livestock use was light or eliminated by fencing. They concluded with a prediction that trout production in streams currently being heavily grazed could be increased about 200% if management decisions were made to optimize habitat conditions for trout.

Van Velson (1979) found rough fish made up 88% of a fish population before relief from grazing and only 1% of the population after 8 years' rest. Rainbow trout *(Salmo gairdneri)* made up 1% of the fish population before cessation of grazing and 97% of the population after relief from grazing. Marcuson (1977) found that an overgrazed section (.11 ha/AUM) of Rock Creek, Montana, supported only 71 kg of brown trout *(Salmo trutta)* per hectare; whereas an ungrazed section produced 238.8 kg of brown trout per hectare. Claire and Storch (unpublished) found in the Blue Mountains of Oregon that game fish were 24% of the total population in area grazed season long, contrasted to a 77% game fish composition within a livestock exclosure.

Chapman and Knudsen (1980) found 8 sections of streamside vegetation in western Washington, judged to be moderately to heavily affected by livestock, had significant reductions in total biomass for Coho salmon *(Oncorhychus kisutch)*, Cutthroat trout *(Salmo clarki)*, and all salmonids compared to those areas that had not been grazed. Similar relationships between livestock grazing and salmonid fish populations have been reported by Dahlem (1979), Duff (unpublished), Gunderson (1968), Keller et al. (1979), and Lorz (1974).

Impacts of Livestock on Terrestrial Wildlife

Riparian zones are the most critical wildlife habitats for many species in managed rangelands (Thomas et al. 1979). It is readily apparent that riparian ecosystems are of paramount importance in producing and maintaining a large degree of biotic diversity in North America (Hubbard 1977, Johnson et al. 1977).

Changes in plant vigor, growth form and species composition due to grazing have frequently been related to the increase or decline of various species of birds (Townsend and Smith 1977). Several studies have shown a negative impact on certain avian populations due to grazing (Dambach and Good 1940, Overmire 1963, Owens and Meyers 1973, Reynolds and Trost 1980, Smith 1940). The tendency for livestock to congregate and linger around ponds and streambanks may result in the elimination of food and cover plants and reduces nest sites and habitat diversity (Buttery and Shields 1975, Behnke and Raleigh 1978, Crouch 1978, Evans and Krebs 1977). However, grazing may improve habitat for some avian species (Burgess et al. 1965, Crouch 1982, Kirch and Higgins 1976). In areas of higher precipitation (or productivity), grazing may be highly desirable to open up "roughs" and provide more diversity and patchiness (Ryder 1980). Grazing effects on breeding avifaunas are not uniform nor easily defined, primarily because grazing varies so much in its local intensity and because of the general difficulties in unraveling cause-effect relationships in rangeland faunas (Wiens and Dyer 1975).

Several studies have shown wildlife numbers increased when a riparian area that was abused by improper grazing practices was fenced and allowed to recover (Crouch 1978, 1982, Duff 1979, Van Felson 1979, Winegar 1977). Duff (1979) reported a 350% increase in small mammal songbird and raptor use after 8 years' rest from grazing. Van Velson (1979) reported increased pheasant *(Phasianius colchicus)* production, increased deer populations, and that watefowl production occurred for the first time in the rested area. Crouch (1982) found more ducks (primarily mallards) *(Anas platyrhynchos)*, more upland game animals, and twice as many terrestrial birds in an ungrazed bottomland rested for 7 years compared to adjacent grazed bottomlands on the South Platte River in northeastern Colorado. The grazed areas, utilized at "varying intensities, provided habitat for significantly more aquatic species of birds.

Mosconi and Hutto (1982) found no significant differences in total bird densities between heavily grazed riparian communities (2.5 cow-calf units/ha) and lightly grazed riparian communities (0.3 cow-calf units/ha). However, significant differences were recorded in bird species composition and foraging guilds. The majority of the bird species significantly affected were of the flycatcher, ground-foraging thrust, or foliage-gleaning insectivore guilds.

Similar results were reported by Kauffman (1982) and Kauffman et al. (1982). No significant differences in total avian densities were noted between riparian communities grazed under a late-season grazing scheme (2.0–2.5 ha/AUM) and those totally excluded from grazing. However, forage removal causing a change in habitat physiognomy did appear to cause some differential use in species and foraging guilds. These differences were particularly evident immediately after forage removal and negligible during seasons when cover and plant growth were similar between treatments. The grazed riparian communities were preferred by birds of insect foraging guilds; ungrazed riparian communities were preferred by birds of herbivorous/granivorous foraging guilds.

Livestock grazing and the subsequent removal of forage in the riparian zone has been shown to cause significant short-term decreases in small mammal composition and densities (Kauffman et al. 1982). When mammal densities before and after the grazing season in 1979 (stocking rate of 2.0–2.5 ha/AUM) were compared, small mammal communities decreased from 800 to 83 mammals/ha in Douglas hawthorn *(Crataegus douglasii)*-dominated communities; from 450 to 60 mammals/ha in riparian meadow communities; and from 129 to 42 mammals/ha in black cottonwood *(Populus trichocarpa)*-mixed conifer communities. By late summer the following year (10 months after grazing) and just prior to the grazing season, small mammal densities were not significantly different between grazed and ungrazed areas.

When properly managed, the grazing of domestic livestock is generally compatible with wildlife, and may even increase the numbers of some species (Tubbs 1980). Nongame wildlife which depend on riparian ecosystems have intangible values which are very hard to evaluate (Peterson 1980). It has been demonstrated that livestock can graze streamsides without causing serious damage, and the capability to achieve positive on-site livestock control appears to be the limiting factor (Claire and Storch unpublished).

Impacts of Livestock on Riparian Vegetation

Recently there has been much published research and opinion on the effects of livestock in riparian ecosystems. Specifically, these reports have dealt with soil compaction and its relationship to root growth; plant succession and productivity; and species diversity and vegetation structural diversity. Opinions on the subject have varied from there being no evidence of heavy, season-long cattle grazing affecting the productivity of a riparian zone, or causing bank deteriorations by trampling (Roath 1980) to grazing only a few days seriously impairing a riparian zone's reproductive capability.

Impacts to riparian vegetation induced by livestock can basically be separated into: (a) compaction of soil, which increases runoff and decreased water availability to plants; (b) herbage removal, which allows soil temperatures to rise and increases evaporation to the soil surface; and (c) physical damage to vegetation by rubbing, trampling, and browsing (Severson and Boldt 1978).

Impacts of Trampling

The impact of livestock trampling on soil compaction bulk density and subsequent effects on forage growth have been documented. Alderfer and Robinson (1949), Bryant et al. (1972), Orr (1960), and Rauzi and Hanson (1966) all found soil compaction increased linearly with increases in grazing intensity.

Alderfer and Robinson (1949) found grazing and trampling Kentucky bluegrass *(Poa pratensis)* upland pastures to a 1-inch (2.5 cm) stubble height reduced vegetation cover, lowered yields, decreased noncapillary porosity, and increased the volume weight of the 0-1 inch (0-2.5 cm) layer of soil.

Rauzi and Hanson (1966) found water intake rates on silty clay and silty clay loam soils to be 2.5 times greater in an area grazed at 1.35 acres/AUM compared to an area grazed at 3.25 acres/AUM. After 22 years of grazing at this intensity, not only had species composition been altered but soil properties had been changed as well.

In a riparian zone continuously grazed season long, Orr (1960) found bulk density and macropore space to be significantly greater in grazed areas over exclosures. Differences in total pore space (both macro- and micro-pores) between grazed and exclosed areas were small because of a transformation of macropore spaces to micropore spaces by trampling. Macropore space is a more sensitive indicator of compaction or recovery from compaction than either micro or total pore space (Orr 1960).

Bryant et al. (1972) found increasing trampling pressure had an adverse effect on Kentucky bluegrass swards, particularly during the months of June and September. After one overwinter period, there was a significant difference in soil compaction between an area trampled by 120 cow trips over bluegrass plots and an area that was untrampled.

Impacts of Herbage Removal

Impacts of herbage removal can be divided into 2 categories according to vegetation structure: (1) utilization of herbaceous vegetation and subsequent impacts on species composition, species diversity, and biomass produced and (2) utilization of woody vegetation and subsequent impacts on foliage cover, structural height diversity and stand reproduction.

A major vegetation change that has taken place in mountain riparian systems of the Pacific Northwest is replacement of native bunchgrass with Kentucky bluegrass. It has successfully established itself as a dominant species in native bunchgrass meadows as a result of overgrazing by herbivores and subsequent site deterioration (Volland 1978).

Pond (1961), in Wyoming, found clipping native bunchgrass meadows every 2 weeks for 4 years caused a marked reduction in native sedges (*Carex* spp.), tufted hairgrass *(Deschampsia caespitosa)* and fostered the appearance of Kentucky bluegrass where it was not present before. Kauffman et al. (1983a) found that when grazing was halted in moist meadows, succession towards a more mesic/hydric plant community occurred. Exotic grasses such as meadow timothy *(Phleum pratense)* and forbs more attuned to drier environments were decreasing and were being replaced by native sedges and mesic forbs.

In central Oregon, Evenden and Kauffman (unpublished) compared plant communities on each side of a fence that was heavily grazed on one side and protected from grazing on the other. The grazed site was dominated by Kentucky bluegrass and Baltic rush *(Juncus balticus)*, while the ungrazed site was dominated by panicled bullrush *(Scirpus microcarpus)*. Twenty herbaceous species were recorded in the grazed area with 12 herbaceous species recorded in the ungrazed area. Dobson (1973) also found an increase in species numbers due to grazing in a riparian zone in New Zealand. He concluded the effect of grazing had been to open up the vegetation, creating more niches in which weeds could establish themselves. Hayes (1978) in central Idaho also observed that the abundance of forb species appeared to be higher in grazed areas than in pristine areas.

The impact of cattle on herbaceous productivity in riparian zones has been examined along several streamsides in the western United States. Duff (1979), Gunderson (1968), Kauffman et al. (1983a), Marcuson (1977), McLean et al. (1963), and Pond (1961) found either decreases in biomass due to herbage removal or increases in biomass due to cessation of grazing in riparian ecosystems.

Kauffman et al. (1983a) compared grazed and ungrazed responses on 10 riparian plant communities in northeastern Oregon from 1978 to 1980. Three of 10 communities displayed significant standing biomass differences. Production in ungrazed moist meadows dominated by Kentucky biomass, meadow timothy, and sedges was significantly less after 2 years of rest compared to grazed meadows but was not significantly different after 3 years of rest. Standing biomass in a Douglas hawthorn-dominated community and in a Kentucky bluegrass-dominated community was significantly greater in ungrazed stands compared to grazed stands after 3 years. Conversely, Volland (1978) could find no significant differences in biomass between a Kentucky bluegrass meadow grazed annually and one that had been rested for 11 years.

Effect of herbivory on shrub and tree production is a critical impact in riparian ecosystems, because of the importance of the woody vegetation to wildlife habitat and its dominant influence in altering the riparian microclimate. While mature vegetation approaches senescence, excessive grazing pressures have prevented the establishment of seedlings, thus producing an even-aged nonreproducing vegetative community (Carothers 1977, Glinski 1977).

The effects of excessive herbivore use on woody vegetation bordering streamsides can generally be termed as negative. Knopf and Cannon (1982) found that cattle significantly altered the size, shape, volume, and quantities of live and dead stems of willows. Cattle grazing was also found to influence the spacing of plants and the width of the riparian zone. Marcuson (1977) found shrub production to be 13 times greater in an ungrazed area than in a severely overgrazed area. Cover was 82% greater in the natural area. On a stream rested from continuous grazing for 10 years, Claire and Storch (unpublished) found alders (*Alnus* sp.) and willows (*Salix* spp.) provided 75% shade cover over areas that had been devoid of shrub canopy cover before exclosure. Similar herbivore-woody vegetation relations have been reported by Crouch (1978), Davis (1982), Duff (1979), Evenden and Kauffman (1980), Gunderson (1968), and Kauffman (1982).

Management of Riparian Ecosystems

Recognizing and understanding the impacts on the streamsides which resulted from all previous land use practices is a prerequisite to streamside planning (Claire and Storch unpublished). Because of their small extent, riparian zones in the past were considered "sacrifice areas" (Oregon-Washington Interagency Wildlife Council 1978, Skovlin et al. 1977). Riparian vegetation has been intensively used by livestock over several decades causing a reduction in the productivity of fish and wildlife habitats and degrading water quality as well as promoting increases in flow fluctuations (Oregon-Washington Interagency Council 1978).

Platts (1979) indicated that riparian ecosystems are the most critical zones for multiple-use planning and offer the most challenge for proper management; therefore, stream habitats should be identified as separate management units from the surrounding upland ecosystems. Even among riparian zones the need to identify and classify them adequately is important for proper stewardship of these systems (Claire and Storch unpublished, Platts 1978, 1979).

However, there have been few attempts to come up with a viable classification scheme of riparian vegetation that is feasible for land management activities (Cowarden 1978, Norton et al. 1981, Padgett 1982, Pase and Layser 1977, Tuhy and Jenson 1982). The major problem has been the lack of successional knowledge to formulate classification schemes based upon potential climax communities. Other problems have been the lack of continuity of terminology. For example, terms such as riparian dominance type (Padgett 1982), community type (Tuhy and Jenson 1982), and riparian type (USFS-R-4 file data) have all been used to define the basic unit of land which supports a riparian community.

Land management agencies responsible for managing livestock grazing have not adequately considered the influence of grazing on the other uses and users of riparian ecosystems (Platts 1979). Often what is good range or timber management (in short-term economic terms) is not good riparian or stream management (Platts 1979). On the other hand, it has been suggested that proper stream management practices that protect stream banks from damage also improve the potential for riparian zones to enhance fisheries, wildlife, and livestock uses (Gunderson 1968, Marcuson 1977).

Methods discussed for riparian zone rehabilitation include exclusion of livestock grazing, alternative grazing schemes, changes in the kind or class of animals, managing riparian zones as "special use pastures," in-stream structures and several basic range management practices (eg. salting, alternative water sources, fencing, range riders, etc.).

The use of instream structures as a method of riparian rehabilitation has met with some success where instream structures are combined with rest from livestock grazing (Duff unpublished, Heede 1977). Bowers et al. (1979) indicated that some instream structures (e.g., trash catchers, gabions, small rock dams, individual boulder placement, rock jetties, and silt log drops) could serve the dual purpose of increasing the water table in areas of former wet meadows as well as improving salmonid habitat.

Heede (1977), combining rest from grazing with construction of check dams, obtained vegetation cover improvements, a change from an ephemeral stream flow to a perennial flow and a stabilization of gully erosion.

After losing 23 out of 26 instream structures in a grazed area in Utah, Duff (unpublished) suggested that stream improvement structures cannot work effectively to restore pool quality and streambank stability as long as livestock grazing continued. Keller et al. (1979) in Idaho found that rest from grazing negated the need for artificial instream structures intended to enhance trout production for stream ecosystems. Kimball and Savage (in Swan 1979) found aquatic ecosystems can be restored through intensive livestock management at a lower cost than through installation of instream improvement structures.

Grazing systems have achieved some success in riparian rehabilitation and much success in riparian ecosystem maintenance. The damage caused by heavy season or yearlong grazing is well documented (Evans and Krebs 1977, Gunderson 1968, Marcuson 1977, Severson and Boldt 1978). It appears that rest-rotation grazing schemes and/or specialized grazing schemes in which riparian zones are treated as special use pastures have been the most successful.

Hayes (1978), in Idaho, stated that species composition appeared to be improved under a rest-rotation grazing system and bank sloughoff occurrences were not increased if utilization was under 60%. In other Idaho mountain grazing studies, Platts (1982) stated that when rest-rotation strategies call for livestock to utilize riparian vegetation at a rate of 65% or more, some riparian habitat alteration occurs. He also indicated that riparian alteration may be insigificant when utilization is equal to 25% or less.

Claire and Storch (unpublished) found a rest-rotation system to be favorable for achieving desired streamside management objectives if 1 year's rest out of 3 is included in the scheme.

Davis (1982), in Arizona, found that a four-pasture rest-rotation system was a cost-effective and successful method for rehabilitation of the riparian resource when each pasture received spring-summer rest for 2 years out of 3. On 2 grazing allotments, cottonwood and willows had a mean increase from 78 plants/ha to 2,616 plants/ha, 2 years after implementation of the system. A rest-rotation system also obtained a very favorable response for vegetation surrounding a livestock pond in South Dakota (Evans and Krebs 1977).

Criticism of rest-rotation systems includes reports that objectives for herbaceous vegetation were not being achieved within desired time limits (Storch 1979), and that rest-rotation systems may increase trailing and trampling damage, causing streambank erosion and instability (Meehan and Platts 1978).

Fencing and managing riparian zones separately from terrestrial upland sites as special use pastures has been shown to be an adequate multiple use system of riparian zone management (Kauffman 1982, Winegar 1977). Simulated grazing of a fenced riparian zone annually after August 1 had no measurable effect on production or species composition in riparian meadows, contrasted to decreased production and composition in a simulated season-long scheme in northcentral Wyoming (Pond 1961).

Kauffman (1982) suggested that positive characteristics of a late season grazing scheme on a riparian zone in Oregon included increased livestock production, good plant vigor and productivity, minimal soil disturbance, and minimal short-term disturbance to wildlife populations dependent on riparian ecosystems.

Another grazing system for fenced riparian zones includes winter grazing, where possible, to minimize damage (Severson and Boldt 1978). For riparian meadows dominated by Kentucky bluegrass, Volland (1978) recommended an initial year's rest, then late spring grazing alternated with late fall grazing to discourage flowering, increase tiller development, maintain plant vigor, and maximize productivity.

Changes in the kind or class of animal as well as selective culling and breeding may be another positive tool for riparian rehabilitation or maintenance. Roath (1980) found that cattle exhibited distinctive home range patterns in which certain groups of cattle preferred upland sites and groups preferred riparian sites. As forage became limiting on stream bottoms, some cattle actually decreased intake rather than move away from the riparian zone. Selective culling of these cattle and replacing them with those that prefer uplands may be beneficial for the livestock operator as well as for the riparian zone.

Platts (1982) stated that because sheep grazing on public lands is usually controlled by the use of herders, it may be possible to graze a watershed without exerting direct significant influence on riparian habitats. May and Davis (1982) suggested that sheep have been shown to exert a lesser influence on certain riparian and aquatic ecosystems and converions back to a sheep operation may be necessary to improve some riparian areas.

The most successful riparian management alternative on public lands to date has been intensive livestock management by permit holders (Storch 1979). Herding livestock on a somewhat daily basis has been successful in limiting the number of livestock that visit streambottoms and improving utilization of upland areas. Proper stewardship of riparian ecosystems is, in effect, money in the bank for the floodplain rancher (Marcuson 1977). Proper management of riparian zones means decreased streambank erosion and floodplain losses (Duff 1979, Gunderson 1968, Marcuson 1977), increased forage production (Evans and Krebs 1977, Pond 1961, Volland 1978), and an increased wildlife and fisheries resource (Buttery and Shields 1975, Duff 1979, Tubbs 1980, Van Velson 1979).

In conclusion, public grazing lands must be managed on a true multiple use basis that recognizes and evaluates the biological potential of each ecological zone in relation to the present and future needs of our society as a whole (Behnke et al. unpublished). Management strategies that recognize all resource values must be designed to maintain or restore the integrity of riparian communities (Behnke et al. unpublished).

The Status of Our Scientific Understanding of Lodgepole Pine and Mountain Pine Beetles – A Focus on Forest Ecology and Fire Behavior

A synthesis of our current knowledge about the effects of the mountain pine beetle epidemic on lodgepole pine forests and fire behavior, with a geographic focus on Colorado and southern Wyoming.

The status of our scientific understanding of lodgepole pine and mountain pine beetles – a focus on forest ecology and fire behavior. The Nature Conservancy, Arlington, VA. GFI technical report 2008-2.]

Introduction

Major lodgepole pine forest changes and how they affect us. Mountain pine beetle populations have reached outbreak levels in lodgepole pine forests throughout North America. The geographic focus of this report centers on the southern Rocky Mountains of Colorado and southern Wyoming. The epidemic extends much more widely, however, from the southern Rocky Mountains in Colorado in the United States to the northern Rocky Mountains in British Columbia and Alberta, Canada.

Worries about large-scale tree mortality in lodgepole pine forests have created public concerns across the West. The appearance of red trees during the last decade, a clear sign of recent beetle attack, has been followed by bare dead tree skeletons throughout this large area. Unquestionably, millions of dead trees foretell large forest changes in the near future, and more might be anticipated in areas where the mountain pine beetle has not yet reached epidemic levels.

People are concerned for many reasons. At a minimum, the loss of mature lodgepole pine trees will significantly change the present and future appearance of affected forests for half a century or more. Extensive areas of dead trees and snags are not as aesthetically appealing as live forests. Perhaps more seriously, dying and dead trees raise fears of increased fire danger. Some people worry that the dead needles and wood generated by the mountain pine beetle epidemic will lead, perhaps quickly, to severe wildfires that threaten lives, property, wildlife, and watersheds. Many are concerned that trees not yet attacked will succumb to the epidemic. Some people worry that the forest in and around our communities and recreation areas will become sparse or disappear forever, and that these forest changes will affect timber commodities, game habitat, and recreation resources.

Some contend that the current epidemic with synchronous outbreaks at many locations is unprecedented and a clear warning of global climate change impacts on ecosystems around the world. Scientists and others point to other changes occurring in our region – *Ips* beetle-caused mortality of piñon pine in the Southern Rocky Mountains, aspen decline, and large fires in Front Range ponderosa pine forests and elsewhere. It is difficult to prove cause and effect, but all of these changes began during the last 10-15 years, coinciding with recent warm climatic conditions, increasing numbers of large trees, and advancing age of many forests. Whether or not the current epidemic is unprecedented is a question to which there is currently no clear answer because of the lack of precise information on extent and severity of beetle outbreaks prior to the early 1900s. Nevertheless, many in the scientific community believe the probability of a similar event historically over at least the past few 100 years is low.

There are many insights and opinions about lodgepole pine being discussed by stakeholders of all kinds -- forest managers, agency administrators, researchers, policy-makers, politicians, the news media, industries, and the general public. Some concerns and fears are supported by scientific evidence. Others are probably justified given the current status of our scientific knowledge, but lack clear scientific support. Still others are myths with little or no basis in science. A further complication is that some of the information emerging from the science community has appeared on the surface to be somewhat contradictory.

The reason for this report. This document is written to report our current scientific understanding of the ecology and fire behavior of lodgepole pine, with a focus on the direct and indirect effects of the current mountain pine beetle epidemic that is so dominant in our minds. We recognize that important socio-economic implications stemming from the mountain pine beetle epidemic exist, and we hope that examining the status of science will aid in addressing these issues. While this document focuses on lodgepole pine and mountain pine beetles, there are also many other forest types and non-forested systems subject to extreme or at least unexpected impacts of climate, other insect and pathogen species, and other disturbances including fire and wind.

This report results from a meeting in January 2008 convened in Colorado by The Nature Conservancy, bringing together expertise of scientists who study lodgepole pine throughout its geographic range. We hope to provide as much scientific help to stakeholders as possible by sorting out what is known with a high degree of certainty, what we are confident about but with less certainty, and what is truly not understood and in need of more research. While our primary geographic focus during the workshop was Colorado and southern Wyoming, some of the findings may be appropriate for lodgepole pine throughout much of its natural range of distribution. *We urge caution, however, in applying our findings beyond our initial area of focus or to other forest types in the region.*

During the workshop and through subsequent email dialogue, the lodgepole pine team reached consensus on nine key points. As always, science is a work in progress, and uncertainties surfaced during discussion of some key points. For some points we provide what is known with adequate confidence rather than waiting for more definitive information, when this information is useful to interested stakeholders. This report provides the nine key points along with explanatory material intended to help the reader understand the degree of confidence we have from scientific study for these key points. To help the reader, we provide a list of suggested reading at the end of this report for more detailed information on many of the topics discussed. We begin with the obvious.

A. Lodgepole pine forests are being heavily impacted by the ongoing mountain pine beetle epidemic.

From British Columbia to Colorado, forests are experiencing high mortality of lodgepole pine trees from attack by mountain pine beetles. An insect epidemic with multiple outbreaks at this scale has not been observed during the last century of scientific study, though small outbreaks have occurred. This mortality is changing forest structure and composition, and modifying fuels in ways that will affect fire behavior for decades.

Many believe the mountain pine beetle epidemic, now nearly a decade in duration, might be unprecedented at least in recent centuries, stemming from a unique alignment of factors. These factors include extensive forests of trees at the right age, size, and density to support large numbers of mountain pine beetles, and a climate warm enough over the last decade to favor beetle reproduction and survival. But records are short. Modern records cover little more than a century, and for this period there is no account of a similar severe mountain pine beetle epidemic in lodgepole pine over such a large area.

For earlier periods, however, little scientific evidence exists to suggest that severe mountain pine beetle outbreaks either did or did not occur. Forest fires, another important natural disturbance, often scar living trees, which provides physical evidence indicating dates, locations, and severity of fires back through much of the last millennium. Fire-scarred wood is often resistant to rot and may persist for centuries, preserving a record of fire. But mountain pine beetle attacks that might have occurred more than a century ago leave little or no physical evidence helpful for determining dates or severity of such attacks. Wood from trees killed by beetles rots quickly, especially where wood moisture is high (e.g. fallen trees). Both stand-replacing fires and beetle epidemics that kill large numbers of trees allow stands of trees of the same age to establish in the wake of the disturbance. The ages of these trees can be used to estimate the time of the last stand-replacing disturbance, but it is often not possible to tell what kind of disturbance initiated the stand, and disturbances such as beetles, fire, and wind may act synergistically. Thus we cannot exclude the possibility that factors aligning so perfectly to result in the current epidemic could not have aligned equally in past centuries or millennia.

Regardless of whether or not the current mountain pine beetle epidemic and lodgepole pine mortality are within the historical range of variability at some time scale, the epidemic and associated tree mortality are large and are having immediate effects on forest structure and function over a vast area.

B. Not all lodgepole pine forests are the same.

Some forests are composed of nearly pure lodgepole pine established following large fires decades or centuries ago. Others are mixtures of lodgepole pine with subalpine species such as Engelmann spruce, subalpine fir, and aspen at higher elevations, or with mixed conifer species such as ponderosa pine, Douglas-fir, and aspen at lower elevations. Each type of forest has unique features of ecology and fire behavior. And lodgepole pine trees in all three types are vulnerable to attack by mountain pine beetles.

Lodgepole Pine Ecology 101. Lodgepole pine is found over a large area in western North America, from northwestern Canada in the northern Rocky Mountains; Washington, Oregon, and California in the Cascades and Sierra Nevada; Idaho, Montana, and Wyoming in the central Rockies; down to Colorado and even northern New Mexico in the southern Rockies. It comes as no surprise that across this large area and also locally, lodgepole pine trees are found in diverse forest conditions. In Colorado and southern Wyoming, pure stands of lodgepole pine occur. Even where pure stands occur, lodgepole pine forests may range from extremely dense to open and savanna-like. Elsewhere, lodgepole pine is mixed with other species. These differences in species composition of forests influence the way forests are affected by mountain pine beetles and fire, and how forests may change in the future.

Two key features of lodgepole pine are especially important in the way the species interacts with the environment and with other trees. Lodgepole trees are relatively intolerant of shade, and they are adapted to reproduce prolifically after fire. Unshaded lodgepole trees survive and grow more readily than trees overtopped either by larger lodgepole pines or by other species. Fire adaptation in trees occurs in two primary forms: the capacity to survive fire, or the ability to reproduce after fire even if killed. While species like ponderosa pine are adapted to survive fire, lodgepole pine is adapted to reproduce readily after fire.

Many lodgepole pine trees have serotinous cones that remain closed and store viable seeds in the crowns of trees for years, actually requiring the heat of a fire for seed release and dispersal. When crown fires kill trees, the resin sealing the cones melts, allowing the cones to open shortly after the fire. Huge numbers of seeds are released at once to the forest floor, falling on exposed soil that is an excellent seedbed for germination and seedling establishment. It is not uncommon to find 50,000 or more seedlings per acre several years after a stand-replacing fire. Competition then thins out trees naturally as these young forests grow to maturity. After a mountain pine beetle epidemic, lodgepole pine stands also generally regenerate, because serotinous cones on branches that have fallen near the ground heat adequately to release seeds, and seeds previously released from non-serotinous cones may exist in the forest litter. However, the role of serotinous and non-serotinous cones as seed sources, and the effect of cone serotiny on subsequent stand density, are not well understood.

The three most common natural agents influencing lodgepole pine in Colorado and southern Wyoming other than fire are mountain pine beetles, dwarf mistletoe, and wind. Of these, mountain pine beetles have the capacity like fire to change forests at large scales. Beetle populations can occasionally reach epidemic densities over large areas, though not usually as large as the current epidemic. The spatial extent of the current epidemic is probably related to large numbers of suitable host trees existing over much of the range of lodgepole pine in the West. Mountain pine beetles are a native insect that has evolved with lodgepole pine. They normally exist in endemic populations that kill a few trees but are regulated by weather. Endemic populations of beetles typically infest diseased or stressed trees. Because temperature regulates beetle development, prolonged warm periods may help trigger outbreaks. Natural enemies also help regulate endemic bark beetle populations but their role under epidemic populations is not as effective.

Dwarf mistletoe typically occurs in localized patches. While mistletoe slowly spreads, it often remains only locally significant, and trees may live for decades with mistletoe. This native parasite, which also evolved closely with lodgepole pine, is periodically reduced by fires that kill the infected trees. Major wind events may topple trees and create small to large openings. In many places lodgepole pines are shallowly rooted in rocky soils or on steep slopes. Typically even the largest blowdowns affect forests only locally, and while they contribute to the landscape mosaic of forest age and composition, they are unlikely to affect forests regionally unless they become centers of another disturbance agent (e.g. spruce beetle).

Three kinds of lodgepole pine forest. Lodgepole pine forests occur along gradients of elevation and latitude that control the length of growing season, available moisture, and frequency of natural disturbances. Fire and mountain pine beetles affect forest structure and composition differently in each ecosystem, just as environmental conditions regulate the occurrence and intensity of the disturbances. To understand this, it is useful to identify three specific types of forest in which lodgepole pine occurs. In Colorado and southern Wyoming, these are pure lodgepole pine, subalpine forest, and mixed conifer forest.

Pure lodgepole pine forests may occur where environmental conditions are poorly suited for other tree species, or where human impacts such as logging followed by burning eliminate other species. Lodgepole pines are tolerant of cold, dry conditions and poor, rocky soils. Individuals rarely live more than 400 years. Typically, pure lodgepole pine stands result after stand-replacing fires have killed all or most trees, leaving behind lodgepole seeds stored in serotinous cones as the only significant seed source. Alternatively, fire-killed stands without serotinous cones may still reproduce if lodgepole pine seeds are blown in from unburned trees nearby. Stand-replacing fires may occur in healthy, green forests under extreme weather conditions. Similar fires might occur under more moderate conditions when mountain pine beetle mortality or mistletoe infestation in stands creates additional dry fuels, though there is no firm evidence thus far confirming this. Pure lodgepole pine stands are often established within a few years after the fire and have one dominant age class or cohort for the life of the new stand, although some stands may develop continuously over longer periods of time and have multiple age classes. However, if aspen is present even in small amounts before large fires, its sprouting capability may lead to aspen patches which often give way over time to slower-growing lodgepole pine.

The spatial extent of pure lodgepole pine forests typically reflects the size of the fires that established them. As a general rule, pure lodgepole pine forests occur more commonly at upper elevations in the mixed conifer (upper montane) zone and the lower portion of the subalpine forest zone, between 9,000 and 10,000 feet elevation in Colorado and southern Wyoming. Less commonly, pure stands exist because sites are unsuitable for other tree species. Historically, past fires may have been tens to hundreds of thousands of acres in size, resulting in large lodgepole pine stands that dominate the landscape for several hundred years. However, even large intense fires do not burn uniformly, and within a fire perimeter, some patches of trees or individuals may survive intact. The 1988 Yellowstone fires are a good example of this. Alternatively, smaller crown fires may have created patches of pure lodgepole pine as small as an acre or less.

If not renewed by fire every few centuries, pure lodgepole pine stands often but not always experience ingrowth by other tree species, especially those tolerant of moderate shade. Ingrowth of other species depends strongly on site suitability for the other species, and availability of seeds. Eventually these species may replace lodgepole pine as the dominant trees in the stand. Lodgepole pine may persist in these mixed stands even if only a limited number of seedlings become established periodically, usually as a consequence of minor local disturbances such as very small fires, wind, insects, or disease.

Subalpine forests at higher elevations (usually above 10,000 feet elevation but as low as 9,000 feet) often include lodgepole pine as a component along with Engelmann spruce, subalpine fir, and aspen. Stand-replacing fires may occur in subalpine forests, but intervals between fires are usually several to many centuries (compared to one to several centuries for pure lodgepole pine forests). After stand-replacing fire, lodgepole pine seedlings grow faster than spruce or fir seedlings and may dominate stands during early developmental stages, even when spruce and fir seeds are available nearby. When aspen is present, however, creation of openings by fire or other disturbances may shift species dominance to aspen because of its sprouting ability.

Mixed conifer forests at lower elevations (usually between 7500 and 9000 feet elevation) often include lodgepole pine along with ponderosa pine, Douglas-fir, aspen, and perhaps small amounts of subalpine fir, Engelmann spruce, and limber pine. Large stand-replacing fires can occur in mixed conifer forests and may lead to pure lodgepole pine stands. More typically, however, mixed-severity fires create smaller openings providing opportunities for patches of lodgepole pine establishment and persistence within the complex landscape mosaic of mixed conifer. Once again, aspen may become temporarily dominant if it existed prior to the fire.

C. Forests are living systems subject to constant change.

It is normal and expected that many natural agents, including mountain pine beetles, fire, and wind, change forests over time. Some changes are so gradual that we barely notice them, while others are relatively sudden and extensive. The forests that are presently losing many trees to insect attack will not look the same in our lifetimes, but healthy and vigorous forests will eventually return in most locations.

We tend to think of forests as static over time because their change is slow relative to human time scales. Yet forests are non-equilibrium systems, and we should expect them to change. Our adult human experience is measured in years or decades at most, and we often fail to notice all but the more dramatic changes that occur in forests. Thus we may believe that the structure and composition of forests typically do not (and even should not) change, and, when they do, it means something alarming has happened. However, lodgepole pine and other tree species live several centuries or more and during their life cycles a number of very natural, and ecologically predictable, forest-changing events or processes often occur. The 1988 Yellowstone fires are often cited as an example of natural change in lodgepole pine ecosystems.

Taking this more comprehensive view, it is clear that combinations of fire and other natural disturbance agents, along with differences in ecological characteristics of the various tree species suited for the landscape, result in frequent changes in forest landscapes over time. The overall forest mosaic is in fact not static, but rather experiences significant shifts and adjustments, all a part of the natural ecology of forests. Thus at any location in a given landscape, the species composition, distributions of tree sizes and ages, and stand density all are subject to change, even if in our memory they do not appear to.

Understanding and predicting the consequences of natural disturbance effects on landscapes is difficult. All of the natural disturbance factors – fire, insects, pathogens, wind, drought, etc. – are capable of affecting forest landscapes at various scales and may act individually or in combination. In the current mountain pine beetle epidemic, interactions between fire and beetle effects are certain, because the insects are changing fuel characteristics of forests significantly.

D. Lodgepole pine will not disappear from the southern Rocky Mountains.

The make-up of our forests is already changing where mountain pine beetles cause high mortality of lodgepole pine. However, this event will not cause the extinction or disappearance of lodgepole pine, and forests dominated by or including lodgepole pine will persist in the southern Rockies, though they may look different from those of the past due to changing climate. Future forests will continue to provide valuable ecological services and aesthetic and recreational benefits.

When viewed from a distance, it may appear that many pure lodgepole pine forests in Colorado and southern Wyoming are being completely killed. It even appears that in some places all the lodgepole pine trees in subalpine or mixed conifer forests are being killed. Yet there is wide variability in the amount of tree mortality, and even where all the mature trees have died, understory saplings may be released and new lodgepole pine seedlings are likely to emerge. Thus it is untrue that lodgepole pine will disappear from our forests.

Scientific knowledge is not complete, however, and there is considerable uncertainty about the composition of future forests after the epidemic. Clearly, major changes in these forests are occurring, but multiple factors will affect what kind of new forest will result. A high proportion of larger lodgepole pine trees (diameters greater than six inches) are dying, and in many places many smaller trees are being killed as well. Mortality may approach 100% in pure lodgepole pine stands having few small trees.

Recovery of lodgepole pine forests following previous beetle outbreaks suggests, however, that in many places significant numbers of lodgepole seedlings and small saplings will survive. These may produce new pure stands of lodgepole pine if no other species are present, or help sustain a lodgepole component in stands of mixed species. Height growth of Engelmann spruce or subalpine fir seedlings is slow compared with that of lodgepole seedlings. Where small seedlings of spruce or fir existed beneath a pure lodgepole pine overstory, lodgepole pine may still predominate after the first decade because of their more rapid growth. However, if saplings of spruce and fir trees are left under the dead pines, they may grow quickly into the canopy and dominate the site. If aspen is present, sprouting and rapid early growth may result in an aspen forest, perhaps with the shade tolerant conifer species in the understory. However, aspen sprouting after mountain pine beetle mortality is not as well understood as it is for disturbances that more directly affect aspen trees or roots.

In pure lodgepole pine forests with few or no surviving trees, it is reasonable to expect a new lodgepole forest to regenerate on suitable sites, but difficult to predict with certainty. The existing seed bank (seeds stored in cones of dead trees and in the litter) or seeds produced by non-serotinous trees near the time of tree death may produce enough new seedlings to regenerate a new lodgepole pine forest. It is also possible that other species will colonize the sites, including other wind-dispersed trees such as spruce and fir, ponderosa pine and Douglas-fir, or bird-dispersed trees such as limber pine. Grasses, forbs, and shrubs may flourish in the new openings for periods of time, and tree establishment may be limited or slowed. Under such conditions, the landscape is likely to become more diverse than it was in the previously pure, single-aged lodgepole forests. This in itself may be beneficial for reducing the risk of a future large-scale mountain pine beetle epidemic or other monolithic disturbance.

E. Active vegetation management is unlikely to stop the spread of the current mountain pine beetle outbreak.

Mountain pine beetles are so numerous and spreading so rapidly into new areas that they will simply overwhelm any of our efforts where trees have not yet been attacked, and no management can mitigate the mortality already occurring. However, judicious vegetation management between outbreak cycles may help mitigate future bark beetle-caused tree mortality in local areas.

In the current epidemic, it is impractical to expect that silvicultural treatment of lodgepole pine forests will prevent or even impede the advance of the epidemic in Colorado and southern Wyoming. There are simply too many suitable host trees over too large an area, and unusually high insect populations. Unless climatic conditions become less favorable for beetle reproduction and spread, the most likely scenario is that the epidemic will be sustained until host trees are depleted.

Preventive spraying of high-value trees with insecticides is effective in protecting trees from bark beetle attack. Direct control measures such as removing infested trees may provide some mitigation on a small local scale but are not be effective at a landscape scale.

The current epidemic is so extensive and severe in part because large areas of lodgepole pine forest are suitable hosts for mountain pine beetles. As noted earlier, it is unclear if epidemics occurred at such a large scale historically, though smaller-scale or less severe epidemics most likely did occur and are expected in the future. Active vegetation management *between* periods when lodgepole pine forests are vulnerable to a mountain pine beetle epidemic may reduce the magnitude of future landscape-scale outbreaks, if that is chosen as a management objective. Creating diverse patch ages and sizes (including young patches) and perhaps more mixed-species forests across the landscape may or may not reduce the spread of future mountain pine beetle outbreaks, but it likely would reduce the amount of forest susceptible through time to a monolithic disturbance, including mountain pine beetle attack or fire. Thus while unproven, this increased landscape heterogeneity may be effective for limiting the scale and severity of future mountain pine beetle impacts. The effectiveness of such measures cannot be assured, nor are all the ecological consequences known, though even in the current epidemic, stands and patches of younger lodgepole pine trees appear to have survived the epidemic with no or only limited mortality.

F. Large intense fires with extreme fire behavior are characteristic of lodgepole pine forests, though they are infrequent.

Very dry and windy conditions can lead to large intense fires in lodgepole pine forests. Such fires are a natural way for lodgepole pine to be renewed and are largely responsible for extensive pure lodgepole pine forests.

Fire history studies based on fire scars and stand structure evidence extending over at least the past 500 years show that large, severe fires (often involving multiple ignitions) occurred in subalpine lodgepole pine forests of Colorado and southern Wyoming during periods of exceptionally warm and dry weather. These studies also show that long intervals (e.g. of 80 to 100 years) during which large fires were absent from study areas extending over 10,000 or more acres were common during the past five centuries in subalpine lodgepole pine forests. Climatic variation at annual and multi-decadal time-scales has been the major driver of fire occurrence in these forests and is the key explanation for the non-equilibrium behavior of these ecosystems. Large fires shaped the amounts and locations of extensive lodgepole pine forests on the landscape and this process is relatively well understood, but additional research would be helpful to characterize stand history in local areas, especially in relation to past climate.

Fire is complex, and its behavior varies with variations in weather, ignitions, fuel amounts and arrangement, and fuel moisture. Historically, most ignitions in lodgepole pine forests were caused by lightning. The role of Native American ignitions is unknown, but given that extensive fire occurs in these forests only under dry and windy conditions, their contribution was probably small. Young and mature stands of pure lodgepole pine are relatively unlikely to burn except under the most extreme weather conditions. Unless residual fuels remain from the effects of previous fire or insect epidemic, fuels commonly are sparse in the understory, and closed canopies help keep the forest floor cool and somewhat moist. The snow-free period above 9000 feet elevation is relatively short, leaving little time for fuels to dry. The term “asbestos forest” has been applied to these forests, attesting to their low probability of an intense crown fire except under extreme weather conditions.

As lodgepole pine forests mature they become increasingly vulnerable to natural disturbances such as mountain pine beetles and wind. Even with only partial overstory mortality, openings created in the forest canopy allow more air circulation beneath the canopy, and drying of surface fuels. In addition, fuel amounts may be increased by the localized tree mortality, including fuel ladders provided by fallen trees, young understory trees, and shrubs that may help fire reach the overstory. Such changes may increase the probability of fuel ignition from lightning and may alter fire behavior in several ways. Fire behavior in maturing stands is not fully understood, however, and more research would be beneficial.

These remarks about fire behavior apply especially to pure lodgepole pine forests. In subalpine mixed forests, the likelihood of dry fuels is even less as the snow-free period is shorter. In mixed conifer forests below 9000 feet, the complexity of the landscape, greater productivity and longer and more frequent fire season encourages mixed-severity fires which have both surface and stand-replacing components. Even in the mixed conifer forests, however, fire extent is highly variable due to climatic variation, and fire-scar studies show that years of widespread fires during past centuries were dependent on exceptional drought. Typically, lodgepole pine occurrence can be suppressed with shortened fire intervals because its long-term presence depends on seed germination after fire and trees growing to reproductive maturity before the next fire. In general, fire history and potential fire behavior are less well understood in mixed conifer forests than in pure lodgepole pine forests.

G. In forests killed by mountain pine beetles, future fires could be more likely than fires before the outbreak.

Large intense fires with extreme fire behavior are again possible.

There is considerable uncertainty about fire behavior following a mountain pine beetle epidemic on this scale. In pure lodgepole pine forests, crown fires are possible both before an epidemic and after while needles are still on trees. Intense surface fires are possible after most dead trees have fallen to the ground. The probabilities of such fires are uncertain, and more research is needed to learn in what ways and how long the fuels and fire environment are altered by the beetles. Nevertheless, protection of communities and other values at risk continues to be imperative.

More research is required to fully understand fire behavior over time following a mountain pine beetle attack. Nonetheless, the extensive epidemic now occurring is precipitating enormous changes in fuel structure over large areas in Colorado and southern Wyoming, through changes in the condition and arrangement of the forest biomass (which is fuel for forest fires). The mature lodgepole pine trees that provided abundant but moist living fuels are now dead, dry, and falling, and have the potential to contribute to extreme fire behavior in post-beetle forests similar to historical fires in lodgepole pine forests. However, the realization of that potentially extreme fire behavior will depend on a number of contingencies, particularly future climatic conditions.

Empirical data are very limited. One study of fire extent and severity of wildfires that burned in subalpine forests in Colorado in the extreme drought of 2002 did not find that fire extent or severity were greater in stands recently killed by mountain pine beetle. The authors cautioned, however, that the conclusions regarding the influence of the recent beetle outbreak on fire extent and severity are limited by spatial and temporal limitations associated with aerial detection of the outbreak. More importantly, any broader applications of this case study would need to be tested by additional studies considering different initial forest (fuel) conditions and especially weather conditions that drive fire behavior. Even though only limited scientific information is available to predict likely fire behavior during and in the decades following a mountain pine beetle epidemic and under varying climate conditions, we believe that both field observations of fire behavior and modeling provide some insights into what could be expected. We offer these insights as preliminary guidance for those concerned with management of beetle-killed forests, even as new research is being conducted to clarify our scientific understanding.

Pure lodgepole pine. In the initial phases of the epidemic when trees are being killed, needles die, turn red and dry out but persist on trees for two or three years. During this phase, needles and small branches provide dry fine fuel that could burn in a crown fire. The amount of fuel is relatively unchanged compared with the pre-epidemic forest. However, fuel moisture is lower, and some think it likely that a crown fire could ignite and spread under somewhat less extreme fire weather conditions than were required for initiating a crown fire in an equivalent forest of live trees.

The fuel structure of dead lodgepole pine stands changes significantly when needles fall to the ground. During this phase, little fine fuel remains in the forest canopy to support an active crown fire that spreads from tree to tree. Furthermore, the fallen needles lie close to the ground surface and, in the absence of other fuels near the ground, provide a relatively poor fuel bed for generating significant flame heights. Increased growth of grasses, low shrubs and forbs may create a moist fuel bed during the growing season but provide dry fine fuels near the end of the growing season. However, large amounts of biomass in the boles and branches of standing trees remain well above typical flame heights, and without needles these canopy fuels are relatively unlikely to burn. Thus surface fires in years following needle fall may not be intense and crown fires may be nearly impossible (assuming the forest is relatively pure lodgepole pine and most or all large trees are dead). In some areas, rapid development of a tall shrub community (which may precede tree regeneration) may provide shade and protection from drying of fuels on or near the ground. However, this is unlikely in most lodgepole pine forests in Colorado and southern Wyoming (the focus area of this report), because few tall shrub species occur in these relatively dry forests. Instead, low shrubs such as huckleberry and buffaloberry are more common.

Trees killed by mountain pine beetle may remain standing for a number of years, but as they progressively decay and fall to the ground (often aided by wind), the fuel structure changes once again. In this phase (typically 10-20 years or more after death), a large amount of biomass becomes available as fuel within flame heights that can be generated by the fine surface fuels. Some of the biomass is elevated above the ground where it dries out more easily and becomes available to support intense fire with a large release of heat. Such a fire is relatively hard to control and nearby structures may be hard to protect. Furthermore, fire intensities under these conditions could cause high mortality of young trees that survived or regenerated after the mountain pine beetle attack. If widespread fire mortality occurs before trees have matured to cone production age, rapid re-establishment of lodgepole pine on this site is less likely.

At the scale of a stand, none of the changes in fire behavior that we have described would be outside the historical range of variability for this ecosystem. Even in stands with tremendous wood accumulation on the ground, fire behavior may differ little from historical fires within blow-downs or areas recently burned by stand-replacing fires. However, we are uncertain about fire behavior at landscape or regional scales because we have not seen systems with such heavy fuel loads over such extensive areas; and we know little about the ecological consequences of such fires at these scales.

Lodgepole pine with other species. Similar transitions in fuel structure also will occur in the lodgepole pine-dominated component of subalpine and mixed conifer stands. But the mixture of dead lodgepole pine with live trees of other species creates a more complex fuel structure. An important effect of lodgepole pine mortality in mixed stands is a change in the environmental conditions and thus the fuel moisture near the forest floor. Prior to beetle mortality of the overstory, solar radiation is largely intercepted by the forest canopy, and air movement beneath the forest canopy is moderated by the overstory. The understory beneath the canopy remains relatively cool and moist.

When lodgepole pine trees die and needles fall from dead trees, radiation reaching the forest floor and air movement beneath the residual live tree canopy are increased, and both contribute to fuel drying. More open canopies also contribute to greater understory vegetation growth. The consequences of these changes on fire behavior are not fully understood, but such conditions may favor ignition and spread of fire more readily than in forests having few canopy gaps or fuels created by mountain pine beetle mortality, particularly later in the growing season when fuels near the ground become drier. Because several associated species, firs and spruces, typically have low crown bases due to poor self-pruning, higher surface fire intensity from added lodgepole pine fine fuels coupled with drier, warmer, windier surface conditions, could lead to an increase in potential for passive crown fire (torching). Furthermore, increased human activity in today's forests has increased fire ignitions compared with the historical period.

H. Mountain pine beetle outbreaks are not likely to cause increased erosion.

Soils are not disturbed and protective ground cover is not reduced when mountain pine beetles kill lodgepole pine trees. If anything, understory plants may grow more vigorously in the increased light and with the higher available soil moisture and nutrients. Where tree mortality is high, annual streamflow may increase and the timing of water delivery may be changed, because of reduced canopy interception of precipitation and reduced water uptake by the trees.

Interactions between forest structure and hydrology have been studied extensively, and there is little question that major changes in the structure of Colorado and southern Wyoming forests alter several key hydrologic characteristics of these forests. Forests are widely viewed as important for protecting sloping terrain in watersheds from extreme runoff and erosion. Wildfire severe enough to kill forests is viewed as a major threat to watersheds, because protective vegetation, litter, and duff are often consumed. In many cases, fire exposes soils directly to precipitation, and runoff during heavy precipitation events (often exacerbated when fire makes soils temporarily hydrophobic) can result in extreme erosion for several months following a fire.

Soil type, steepness of slope, precipitation intensity and duration, and timing of understory vegetation recovery all affect the severity of erosion after fire.

Death of forest trees during a mountain pine beetle epidemic affects the forest floor and soil much differently than fire. Tree mortality caused by beetles leaves behind protective layers of litter and duff, and often quickly results in more productive understory vegetation. Thus severe erosion events are not expected as a result of the mountain pine beetle epidemic. In fact, mulching and seeding after fire often are used in attempts to mimic the stabilizing effects of litter, duff, and understory vegetation found after overstory mortality by beetles.

The potential for erosion from wildfire still exists, however, if extensive fire occurs in the decades following the epidemic, when large amounts of fuel are on the ground. Thus while the mortality of trees does not increase erosion significantly, erosion remains a possibility if a post-beetle fire occurs with heavy fuel loading on the ground. We note, however, that erosion is a natural process, and concerns about extreme erosion may be more a human issue than an ecological one.

There may be other hydrologic effects of mountain pine beetle mortality. Paired watershed studies around the world support the conclusion that substantially decreasing forest density results in increased runoff, though many factors affect the degree to which this occurs. Subalpine forest studies in Colorado and elsewhere are among the best examples supporting these findings. While no empirical studies of runoff in relation to the current mountain pine beetle epidemic have been completed in Colorado and southern Wyoming, it is reasonable to expect that the total annual runoff will increase where pure stands of lodgepole pine are killed by mountain pine beetles. More research is needed to determine how the hydrologic features of watersheds change during and after such epidemic changes in forest structure.

I. Climate changes will most likely contribute to substantial forest changes in the decades ahead.

Given the climate changes in the last several decades and projected changes for coming decades, large fires and other natural disturbances and shifts in vegetation composition and distribution are anticipated in many ecosystems of Colorado and southern Wyoming. These large disturbances and other changes in growing conditions will likely contribute to restructuring many forest landscapes.

Many uncertainties about climate and vegetation exist for the years, decades, and centuries ahead. As noted in our introduction, we have seen a number of significant ecological events in the last decade, including the mountain pine beetle epidemic in lodgepole pine. All of them coincide with warmer climatic conditions than were typical for the past century or more for which we have records. Warming temperatures (especially winter minimum temperatures), longer growing seasons, and growing season drought may be playing major roles in the widespread bark beetle outbreaks in Colorado and southern Wyoming and elsewhere. Fuel quantity and arrangement and fire behavior may be influenced directly or indirectly by the same variables. Germination and establishment success of new seedlings may be affected. However, it is difficult to prove whether climate changes, consequences of past forest management practices on forest conditions, or both are the primary causes of these ecological changes.

Implications for future forests. Models for predicting future climates have progressed dramatically in recent years, but their accuracy is questionable for planning purposes, particularly at local levels. Nonetheless, model predictions suggest significant alterations in climate from past observed patterns. These predictions are supported by recent climate events that themselves had largely been predicted several years ago. Therefore, the potential for future changes justifies thinking about future ecosystem dynamics that are very different from what we have seen in the last few centuries, including vegetation responses involving natural disturbance agents, species distribution, habitat suitability, and conservation of biodiversity. Areas at the elevational and latitudinal edges (ecotones) of lodgepole pine distribution may be the most likely to experience notable changes following the beetle epidemic.

Our understanding of natural disturbance phenomena such as fire, drought, and insect epidemics under new climatic scenarios is inadequate for us to judge the likely consequences of future climatic conditions. We all observe and acknowledge that natural disturbances can be major change agents regardless of their cause. Climate warming may be contributing to substantial forest changes now, but there may be more subtle changes in the future as well. Through time forest species (including insect associates and other animal species, shrubs, grasses, and forbs as well as trees) may shift to other elevations and latitudes where habitats have become more suitable for them. Some species with rapid generation times, such as mountain pine beetle, may adapt to the changing climate. Alternatively, without adaptation local extinction in bark beetle populations could occur with increased warming due to a disruption of their tightly coupled developmental timing with local weather. Groups of species may migrate together or separately, perhaps leading to unanticipated new forest communities. We cannot make firm predictions about the makeup of future forests or the biodiversity associated with these forests. Regeneration and plant community restructuring in the landscape may follow novel pathways. Information is lacking, however, and extensive research (including use of monitoring data and reconstructions of past changes) is needed to relate potential future climate and the requirements and environmental amplitudes of species and communities.

Is re-establishment of lodgepole pine assured after the mountain pine beetle epidemic? Undoubtedly, but subtle or even large shifts in its location and plant associations are not out of the question. Nonetheless, most of the area experiencing a mountain pine beetle epidemic will likely remain forest. Even if future forests differ from those of today, such forests are likely to provide valuable (if different) benefits and opportunities, both ecologically and socially. Monitoring of changes in forests as they occur is important for enabling research on such changes, and to allow managers to adapt practices to achieve desired effects as conditions change and consequences of past actions are better understood.

J. Summary

The current mountain pine beetle epidemic affecting lodgepole pine forests is an important ecological event with significant socio-economic implications. What will be the consequences for the affected ecosystems? How do we protect our communities and other human values at risk in ways that are socially and economically (as well as ecologically) feasible? These are difficult questions. This report has focused specifically on the ecology and fire behavior issues associated with lodgepole pine and the mountain pine beetle epidemic. We recognize that the socio-economic aspects are as important as the ecological issues, but they are beyond the scope of this report.

Ecologically, much is known about lodgepole pine and mountain pine beetles. Even though the scale of the current epidemic is unprecedented over the past approximately 100 years of reliable observations, beetle-caused tree mortality at some scale has long been part of the dynamics of the lodgepole pine ecosystems. Similarly, fire behavior and its role in ecological processes and fuel management practices are relatively well understood. While we are confident about our general understanding, we have identified at least some scientific uncertainties about lodgepole pine, mountain pine beetle effects, and fire behavior that should be acknowledged and further researched.

We are most concerned about several wildcard issues that create some uncertainty in applying what we know from science. The scale of this epidemic is larger than any mountain pine beetle epidemic studied thus far. We do not fully understand if or how the magnitude of this ecological event will affect future forests in terms of regeneration of the present species or transitions to different vegetation types. Furthermore, there is the question – both tantalizing and troubling – about possible climate change (including its rate, direction and magnitude) and the degree to which scientific findings need to be qualified as they are applied.

If humans were not a part of the equation, forests would simply mature, die, and regenerate or be replaced by other vegetation types, following ecological trajectories over time driven by climate, environment, and species capabilities.

Because humans cause changes in forests by choosing to live there and deriving economic services from them, our communities are impacted by forest changes, whether they are natural or not. Thus both the scale of the mountain pine beetle epidemic and the uncertainties about future forests leave us with questions that are important to us but may not be answerable with the knowledge we have now.

Knowledge from scientific research about lodgepole pine and mountain pine beetles is valuable in two ways. It offers answers to some of the questions we have about forest ecology and provides valuable insight for management of these forests for ecological and community protection purposes. It also clarifies what we do not know. This is valuable not just to direct new research, but also to inform stakeholders of the degree of confidence they should have as land and natural resource management practices are considered.

As noted in the introduction, science is a work in progress. Many of the scientific uncertainties discussed in this report already are receiving attention in the research community. Even as research continues, however, the scientific knowledge already available is usable by a wide variety of stakeholders and in the collaborative and adaptive management process. Adaptive management is perhaps best described as managing while learning on the fly. In this report, the scientific community provides information to managers and other stakeholders, but the scientific community also will help advance the knowledge base through lessons learned as management practices are planned, implemented, monitored, and evaluated. We humans must decide how to manage forests based upon their intrinsic value and natural processes as well as some desired future condition contingent on human wants and needs. We must be realistic about the degree to which we as observers, managers and stewards of the forest can affect what is happening now and what will happen in the future. Whatever we do from here should be done together.

c0015
Using Bird Ecology to Learn About the Benefits of Severe Fire

Richard L. Hutto, Monica Bond and Dominick DellaSala Au1

s0010
3.1 INTRODUCTION

p0010 In this chapter we do not provide an encyclopedic review of the more than 450 published papers that describe some kind of effect of fire on birds. In other words, we are not systematically proceeding through a litany of fire effects on birds of southeast pine forests, California chaparral, Australian eucalypt forests, South African fynbos, and so forth. Instead, we have chosen to highlight underappreciated principles or lessons that emerge from selected studies of birds in ecosystems born of, and maintained by, mixed- to high-severity fire. Those lessons show how important and misunderstood basic fire ecology is when it comes to managing fire-dependent forest lands and shrublands, and the lessons apply to all fire-dependent ecosystems that have historically experienced severe fire—fires that are severe enough to stimulate an ecological succession of plant communities (as described in Chapter 1). We also focus our attention primarily on conifer forest ecosystems of the western United States because they undergo an amazing transformation following severe fire and because studies of these systems clearly reveal how birds evolved with, and now require, severe fire. Insight that emerges from the study of bird populations is overlooked in management circles worldwide. This is unfortunate because the insight one can gain by studying the ecology of individual bird species argues strongly that severe fire needs to be maintained in the landscape if we hope to maintain the integrity of most fire-dependent ecological systems.

p0015 Most studies of fire effects on birds are disappointingly "empty" because they are merely lists of birds that benefit from or are hurt by fire; they are not placed in the broader context of what a self-sustaining fire-dependent system looks like. To understand whether a particular change in abundance is "good" or "bad" requires insight into what ought to be, which requires an understanding of the patterns that occur under conditions that are as natural as possible for any given vegetation system. That, in turn, requires replicated study of what we can expect to find after "natural" fire in any given system.

B978-0-12-802749-3.00003-7, 00003

Thus, a study of the effects of, say, prescribed understory fire on birds is meaningless without knowing what a "natural" fire in that system would ordinarily produce. Many studies might show that bird species A increases after a prescribed fire, but is that a good thing? If bird species B increases after postfire salvage logging, is that a good thing? If bird diversity is higher in one fire treatment versus another, is that a good thing? For studies of fire effects to be useful, we need to address questions that inform management by tapping into a solid understanding of what constitutes a "natural" response to fire, and that requires knowing something about the fire regime under which a given system evolved. Only through distribution patterns and adaptations of individual species (not through effects on bird guilds or on diversity and similar composite metrics) can we begin to understand which kind of fire regime necessarily gave rise to specific patterns of habitat use and to adaptations that have evolved over millennia. Birds are excellent messengers; they carry all the information we need to reconstruct the historical conditions under which they evolved. All we have to do is listen.

s0015 3.2 INSIGHTS FROM BIRD STUDIES

s0020 Lesson 1: The Effects of Fire Are Context Dependent; Species Respond Differently to Different Fire Severities and Other Postfire Vegetation Conditions

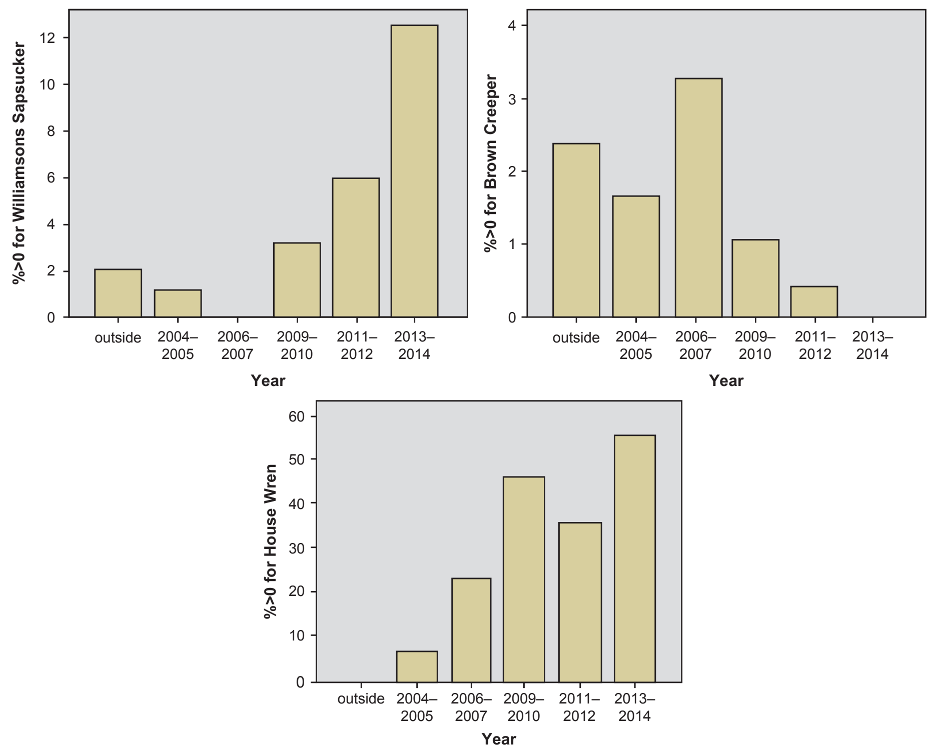
p0020 One extremely important lesson that has emerged from studies of the fire effects on birds is that a given effect depends entirely on the vegetation type, the kind of fire, and the time since the fire (Recher and Christensen, 1981; Woinarski and Recher, 1997). For years, individual bird species have been labeled as "positive responders" or "negative responders" or "mixed responders" when, in fact, any species can be all of the above. The actual response of a bird species (or of any species) to fire, then, is dependent on context. The earliest papers on fire effects rarely provided details about the nature of the fire being studied, so the first attempt to conduct a meta-analysis based on a compilation of published results of fire effects (Kotliar et al., 2002) necessarily generated a lot of "mixed" responses by birds because some papers said a species was positively affected and others said the same species was negatively affected by fire. The seeming disagreement among studies was, in most cases, a simple result of researchers looking at different postfire vegetation conditions and times since fire. It was not until Smucker et al. (2005) separated their data into categories of fire severity and time since the fire that responses began to look much more consistent among studies that share a particular vegetation type, fire type, and time since the fire. As soon as one accounts for these factors, it becomes clear that the responses of most bird species are quite consistent and that most bird species benefit from severe fire (as we discuss below).

s0025 ## *Time Since Fire*

p0025 Species that benefit from severe fire are not only those that flourish during the first year or two following the disturbance event. The same can be said for species that are restricted to years 2-4, years 5-10, or even years 50-100 following severe fire. In fact, *most* plant and animal species are present only during a limited time period following a disturbance. Therefore, *most* plant and animal species in disturbance-based systems depend on disturbance to periodically create the conditions they need. Many bird species that thrive after fire have been mislabeled as species hurt by fire because studies of bird response to fire typically involve only a brief period of time soon after the fire. For example, although Williamson's sapsucker (*Sphyrapicus thyroideus*) was labeled a "mixed responder" and brown creeper (*Certhia americana*) a "negative responder" in the meta-analysis by Kotliar et al. (2002), and the change in house wren (*Troglodytes aedon*) abundance was labeled "insignificant" in a recently published study by Seavy and Alexander (2014), each of these species typically reaches its peak abundance several years after a fire, as revealed in an 11-year postfire study conducted after the Black Mountain fire, which burned near Missoula, Montana, in 2003 (Figure 3.1). Thus, each species clearly benefits from severe fire when viewed in the proper (and perhaps very restricted) time frame after fire.

p0030 By extending the duration of a postfire study beyond the first few years after a fire, most bird species reveal a unimodal response to time since fire, and most benefit from fire; they reveal a greater probability of detection in the burned forest at some point during that postfire period than in the same forest before fire or in the surrounding unburned forest (Taylor and Barmore, 1980; Reilly, 1991a, 2000; Taylor et al., 1997; Hannon and Drapeau, 2005; Saab et al., 2007; Chalmandrier et al., 2013; Hutto, 2015). These results force one to appreciate that if for a period of time after a fire conditions remain better than they are in very old plant communities near the end of the late seral stage of succession, then disturbance is periodically necessary to create the conditions needed by that species. Thus a species being "hurt" in the short term by fire is not evidence that fire is somehow "bad" for that species and that it would have been better off without fire. In fact, once a system is beyond the ideal postdisturbance time period for a species, the only way to periodically "restore" conditions needed by that species is to disturb the system with another severe fire and then wait for the appropriate time period following disturbance again. The lesson is this: one cannot assess the effects of fire on any plant or animal species without examining whether the species is restricted to a period of time preceding the oldest possible vegetation condition.

p0035 A necessary consequence of different species occurring at different points in time following fire (in association with changes in vegetation type and structure) is that we must embrace natural severe disturbance processes because they create starting points for the development of the full range of vegetation-age



f0010 **FIGURE 3.1** The probabilities of occurrence of Williamson's sapsucker ~~(Sphyrapicus thyroideus)~~, brown creeper ~~(Certhia americana)~~, and house wren ~~(Troglodytes aedon)~~ were significantly greater several years after the 2003 Black Mountain fire than they were either before the fire (as determined from survey data "outside" the burn perimeter in unburned, mixed-conifer forest of the same type) or during the first 2 years following the fire (R.L. Hutto, unpublished data; sample sizes exceed 150 point counts for each time period; $P < 0.05$, log linear analyses). Therefore, the benefit of severe fire for some species cannot be detected without restricting data collection to within a specific time period after the fire event.

categories, which, in turn, are needed for the maintenance of biological diversity (in particular beta diversity, the turnover in species number across gradients). Moreover, mixed-severity fires (which can result only from high-severity fire events) help provide a variety of kinds of starting points, which, in turn, also help maintain biological diversity (Smucker et al., 2005; Haney et al., 2008; Rush et al., 2012; Sitters et al., 2014; see also Chapters 4-6).

s0030 Old Growth

p0040 As already emphasized, most bird species clearly depend on severe fire to reset the clock, which stimulates development of the particular postdisturbance "age" to which they are best adapted. Still, many bird species are restricted in their habitat distribution to an end-of-the-line successional stage—they are dependent on old growth. There are also ecosystems (e.g., eucalyptus forests, chaparral) where severe fire is natural but where there are few, if any, early

f0015 **FIGURE 3.2** Resprouting eucalyptus trees following a severe fire that burned through the area only months earlier. *(Photograph by Richard Hutto, taken in November 1999 near −34.284030°S, 150.725373°E in the tablelands above Wollongong, New South Wales, Australia.)*

fire-dependent bird species because many of the dominant plant species resprout, yielding a plant community structure and composition that "recovers" rapidly after fire (Figure 3.2). In these instances most bird species are associated with "mature" forms of those plant communities and would appear to do well if there were no fire at all (e.g., Taylor et al., 2012).

p0045 In all vegetation types that undergo plant succession following mixed- to high-severity fire, there will always be some bird species that depend on long-unburned vegetation. Therefore, discovering that those species are absent in the short term or "hurt" by fire is not unexpected, nor is it a necessarily a problem that needs to be addressed. The fact that fire temporarily removes large parts of a landscape from the pool of suitable conditions for those species is not a problem because the loss of suitable conditions is temporary, and there are usually nearby "refuges" of suitable conditions in places that have not burned for a long time (Bain et al., 2008; Leonard et al., 2014; Robinson et al., 2014; Winchell and Doherty, 2014). Natural systems exist as an ever-changing mosaic of different postfire ages—all vegetation ages are present at some point in space all the time. A significant problem emerges only when humans remove or degrade so much of the older vegetation through timber harvesting or land conversion that there is now a perceived risk of fire to those species that depend on older vegetation stands that are too few and far between. Understand clearly, however, that the absence of late-succession forest refuges is a problem that stems from excessive logging or development, not from the presence of fire per se.

p0050 Now that we are down to the last remaining old-growth forest remnants in California and Oregon ~~landscapes that have been subjected to excessive logging~~, some feel that we should thin the forests around those remnants to protect them from fire. The effect of altering mature forest surrounding the last remaining old-growth remnants on the remnants themselves is, however, unknown.

B978-0-12-802749-3.00003-7, 00003

Moreover, as has been discussed in reference to eucalyptus forest systems, many old-growth forest patches are old precisely because they are situated in places that are relatively immune to severe fire (Bowman, 2000); the same is undoubtedly true of many old-growth mixed-conifer forest patches. Unburned forest patches surrounding unburned, old-growth forest patches also have been suggested to be important as dispersal corridors across which old-growth species may recolonize recently burned areas as succession proceeds toward later stages (Pyke et al., 1995; Robinson et al., 2014; Seidl et al., 2014). Therefore, proposals to thin the forest around remaining old-growth stands may be well intentioned but reflect a lack of appreciation for the resilience associated with plant communities born of, and maintained by, natural disturbance processes (a case in point is the spotted owl [*Strix occidentalis*]; see Box 3.1).

s0035 *Postfire Vegetation Conditions*

p0070 One must account not only for time since fire but also for fire severity and other forest conditions (e.g., vegetation composition and tree density) to adequately assess fire effects on animal species. Smucker et al. (2005) accounted for both time since fire and fire severity in an analysis of bird occurrence patterns following the Bitterroot fires of 2000 in Montana, and the results were profound.

b0010 BOX 3.1 Old-Growth Species and Severe Disturbance Events

p0055 There are a number of old-growth-dependent species in North American conifer forests, but severe fire may not pose anywhere near the threat to those species that one might suppose. Consider the spotted owl ~~(*Strix occidentalis*)~~, one of the most iconic old-growth-dependent bird species in the Pacific Northwest, California, and Southwest (extending into northern Mexico). This federally listed threatened raptor typically nests, roosts, and forages in dense conifer and mixed-conifer-oak forests dominated by large (>50-cm diameter at breast height), older trees and peppered with big decadent snags and fallen logs. High levels of canopy cover (generally >60%) from overhead foliage is an important component of nesting and roosting stands; thus, spotted owls were long presumed to be seriously harmed where severe fire burned the forest canopy. Indeed, over the past several decades, most forest management efforts in the range of the spotted owl (a Forest Service management indicator species) has been driven by logging to prevent or reduce fire to "save" the owl, including the latest U.S. Fish & Wildlife Service recovery plans for the northern and Mexican spotted owls. Yet, the forests where the owl dwells have experienced mixed- and high-severity fire for millennia. So how do these birds actually respond when severe fire affects habitat within their home ranges?

p0060 Several studies have demonstrated that all three subspecies of spotted owl can survive and thrive (i.e., successfully reproduce) within territories that have experienced moderate- and high-severity fire (Bond et al., 2002; Jenness et al., 2004;

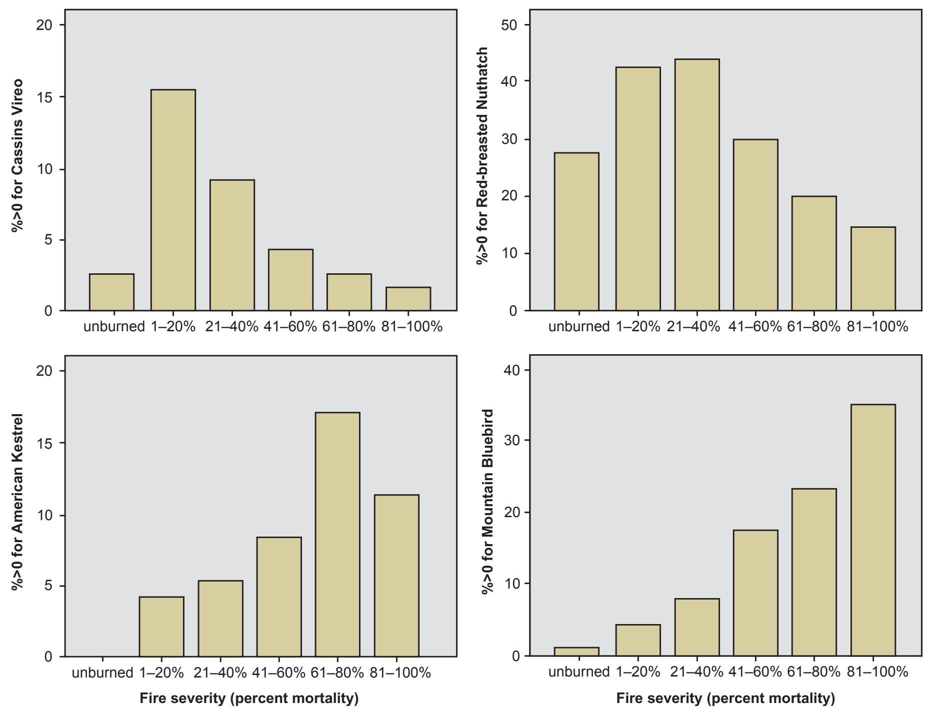
Continued

b0010

BOX 3.1 Old-Growth Species and Severe Disturbance Events—Cont'd

Roberts et al., 2011; Lee et al., 2012, 2013). Exceptionally high levels of severe fire in a nest stand can cause spotted owls to abandon that territory (Lee et al., 2013), but only a small fraction of sites ever exceed that threshold in any given fire. Moreover, a higher probability of abandonment after fire was documented only in a geographical region where prefire forest patches were limited or isolated; this did not occur in areas where prefire forest cover was more abundant (Lee et al., 2012, 2013) or in areas that were ~~salvage~~ logged after fire (Lee et al., 2013; Clark et al., 2013). For example, the year after the 2013 Rim Fire—one of the largest fires to occur in California within the past century—at least six pairs of California spotted owls were detected in sites where >70% of the "suitable habitat" around their nest stands burned at high severity. (At one occupied site severe fire burned 96% of the habitat!) Why do they stick around in burned territory? One study found California spotted owls selectively hunted (mostly for woodrats and gophers) in stands recently burned by severe fire when those burned forests were available to them and relatively near the nest or roost stand (Bond et al., 2009, 2013). Another study showed that during winter, Mexican spotted owls moved up to 14 km into burned forests where prey biomass was 2-6 times greater than in their breeding-season nesting areas (Ganey et al., 2014). Spotted owls are perch-and-pounce predators, so it is not surprising that they avoided foraging in areas that were logged after fire, as there were no longer any perch trees (Bond et al., 2009), nor is it surprising that postfire logging reduced site occupancy and survival rates (Clark et al., 2013; Lee et al., 2013). In these studies, spotted owls still preferred to nest and roost in green forests, underscoring the importance of unburned/low-severity refuges within the larger landscape mosaic of mixed-severity fire. Still, the point is that where severe fire is natural, even old-growth species can partake of its bounty. The spotted owl, too, is sending a message here: A natural fire regime provides a bedroom, nursery, and kitchen for even old-growth-dependent species, as long as the burned forest is left standing.

p0065 Despite this evidence, the U.S. Fish & Wildlife Service is now calling for aggressive, large-scale thinning in northern spotted owl habitat in dry forests as a means of reducing fire intensity (U.S. Fish and Wildlife Service, 2011). This "recovery" objective for the owl was developed over objections raised by scientists (Hanson et al., 2009, 2010) and professional societies such as The Wildlife Society and Society for Conservation Biology. Notably, Odion et al. (2014b) simulated changes in owl habitat over a four-decade period following fire and the kind of thinning proposed by federal land managers. The simulation study showed that thinning over large landscapes would remove 3.4-6.0 times more of their dense, late-successional habitat in the Klamath and dry Cascades, respectively, than forest fires would, even given a future increase in the amount of high-severity fire. Further, Baker (2015) documented that before extensive Euro-American settlement, mixed- and high-severity fires shaped dry forests in the Eastern Cascades of Oregon and provided important habitat for northern spotted owls there. These studies challenge the paradigm that severe fire is a serious threat to spotted owls, which evolved in landscapes shaped by such fire, and that extensive logging is needed to ameliorate this widely believed but overstated threat.



f0020 **FIGURE 3.3** Example plots of the percentage occurrence of four mixed-conifer bird species in relation to fire severity in the first few years after fire. Data were drawn from 7043 survey points distributed across 110 different fires that burned since 1988 in western Montana. Sample sizes exceed 700 point counts per severity category. All patterns are significant ($P < 0.05$, log linear analyses). Note that each species [illegible] abundant in burned than in unburned forest, and each is relatively abundant at a level o[illegible]everity (percentage of tree mortality) that differs from that occupied by the other species.

Once they accounted for fire severity alone, it became abundantly clear that many of the same bird species that had been labeled as "mixed responders" to fire by others (e.g., Kotliar et al., 2002) were not at all mixed in their response to fire. The importance of fire severity is strikingly apparent in even the simplest graphs of percentage occurrence across severity categories (Figure 3.3).

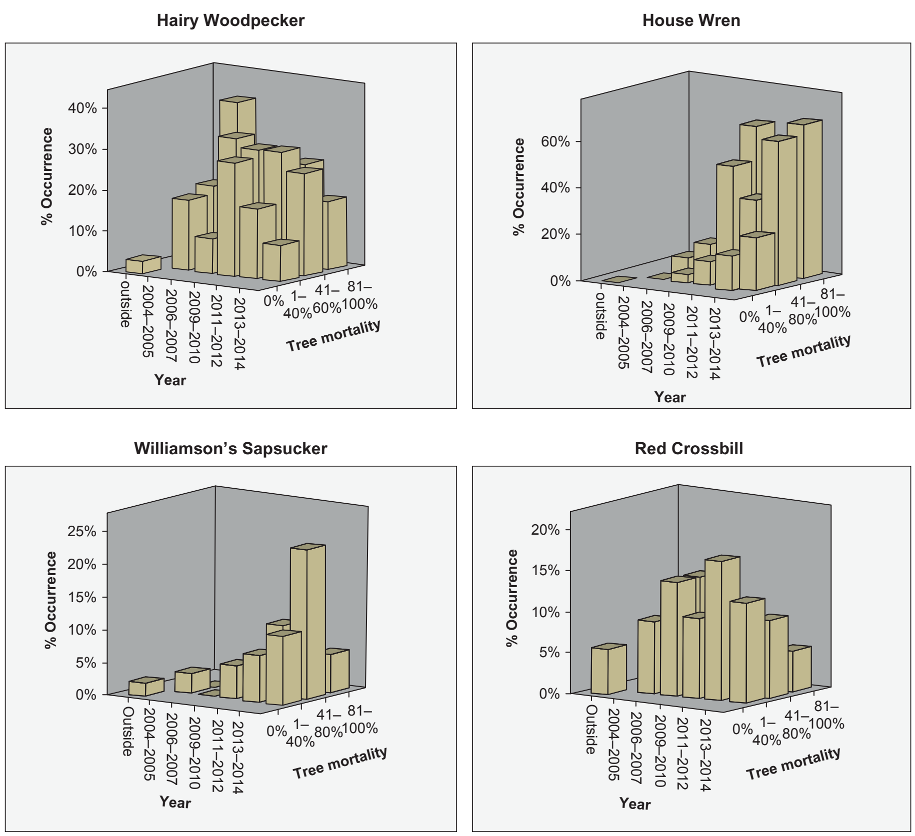
s0040 Lesson 2: Given the Appropriate Temporal and Vegetation Conditions, Most Bird Species Apparently Benefit from Severe Fire

p0075 After we combine information on the time since fire, fire severity, and perhaps one or two additional vegetation variables, most bird species apparently benefit from severe fire. For each species there is a particular combination of burned forest variables that creates ideal conditions for that species, as evidenced by an abundance that exceeds that in a long-unburned patch of the same vegetation type. Indeed, when Hutto and Patterson (2015) considered just two fire-context variables (time since fire and fire severity), they found 46 of 50 species to be

B978-0-12-802749-3.00003-7, 00003

more abundant in some combination of those two variables than in long-unburned stands (Figure 3.4). Thus, not only are most species relatively abundant in one burned forest condition or another, but the average point in space and time occupied by each species is also species specific (Figure 3.5).

p0080 As an introduction to some of the fascinating biology surrounding severely burned forests, consider the following bird species. The black-backed woodpecker (*Picoides arcticus*), American three-toed woodpecker (*Picoides dorsalis*), hairy woodpecker (*Picoides villosus*), northern flicker (*Colaptes auratus*), and Lewis's woodpecker are all more abundant in severely burned than unburned mixed-conifer forest (see patterns of habitat occurrence for four of the five species in Figures 3.11 and 3.12) because of an abundance of food (beetle larvae and ants) and potential nest sites associated with standing dead trees.



f0025 **FIGURE 3.4** Example plots of percentage occurrence for various mixed-conifer bird species in relation to both time since fire and fire severity after the 2003 Black Mountain fire near Missoula, Montana (R.L. Hutto, unpublished; sample sizes exceed 35 point counts for each time-by-severity category; all patterns are significantly nonrandom as determined by log linear analyses [$P < 0.05$]). The examples were selected to illustrate that each species is more abundant in burned than in unburned forest (the occurrence rate in unburned forest shown in the first time period), and each is most abundant in a different combination of time since fire and burn severity (percentage of tree mortality).

f0030 **FIGURE 3.5** In combination, the mean time since fire and mean fire severity at points of occurrence for each of 46 (mnemonically coded) species differs from that of every other species. Mean values were calculated from the kind of data presented in Figure 3.4.

The Williamson's sapsucker and olive-sided flycatcher (*Contopus cooperi*) find the abrupt edges between severely burned and unburned forest to be ideal nest locations (Figure 3.6). A host of secondary cavity-nesting and snag-nesting species (e.g., northern hawk owl [*Surnia ulula*], great gray owl [*Strix nebulosa*], mountain bluebird [*Sialia currucoides*], western bluebird [*Sialia mexicana*], house wren, and tree swallow [*Tachycineta bicolor*]) benefit from new forest openings, where they find a mature-forest legacy of already existing broken-top snags (Figure 3.7), where a disproportionately large number of nest sites are located (Hutto, 1995). These species depend on the kinds of snags that become common only after a forest reaches the mature- to old-growth stage and then burns in a severe fire. A variety of species (e.g., flammulated owl [*Psiloscops flammeolus*], mountain bluebird, Townsend's solitaire [*Myadestes townsendi*], and dark-eyed junco [*Junco hyemalis*]) make use of the cavities created by burned-out root wads or uprooted trees that happen to blow down in the first few years after severe fire (Figure 3.8). Many species (e.g., Clark's nutcracker [*Nucifraga columbiana*], Cassin's finch [*Haemorhous cassinii*], red crossbill (*Loxia curvirostra*], and pine siskin [*Spinus pinus*]) take advantage of seeds that are released or made available in cones that open after severe fire

Comp. by: Gunalan Stage: Revises1 Chapter No.: 3 Title Name: Dellasala

f0035 **FIGURE 3.6** Williamson's sapsucker ~~(*Sphyrapicus thyroideus*~~; left) and olive-sided flycatcher (~~*Contopus cooperi*;~~ right) are known to nest disproportionately often near the abrupt edges between severely burned and unburned forest. *(Photographs by Richard Hutto (left) and Bruce Robertson (right).)*

f0040 **FIGURE 3.7** Compared with burned trees with intact tops, broken-top snags that were already snags before the fire burned are used disproportionately more often as nest sites by cavity-nesting bird species. The black-backed woodpecker also roosts almost entirely in burned-out hollows, forked trunks, or other relatively unusual structures that create crevices in "deformed" snags that existed before the forest burned (Siegel et al., 2014). Pictured (left to right) are a young hairy woodpecker ~~(*Picoides villosus*)~~ in its nest cavity, an American robin (*Turdus migratorius*) nest, and a northern flicker ~~(*Colaptes auratus*)~~ nest. The implications are profound—old-growth elements (snags) are really important to birds that depend on burned forest conditions, so burned, old-growth forests are as valuable to wildlife as unburned old-growth forests. *(Photographs by Richard Hutto.)*

f0045 **FIGURE 3.8** The architecture of a burned forest becomes modified after trees begin to blow down in the first few years after a fire, and a number of bird species make use of the root wads as nest sites. A Townsend's solitaire ~~(*Myadestes townsendi*~~) nest is highlighted here. *(Photograph by Richard Hutto.)*

f0050 **FIGURE 3.9** Few people seem to realize how important Clark's nutcrackers ~~(*Nucifraga columbiana*~~) are as seed dispersers after severe fire in ponderosa pine forests. Pictured here are examples of a nutcracker extracting seeds from a ponderosa pine cone that opened after fire (left) and a nutcracker with a throat pouch full of seeds in the scorched ground beneath a ponderosa pine canopy. *(Photographs by Richard Hutto.)*

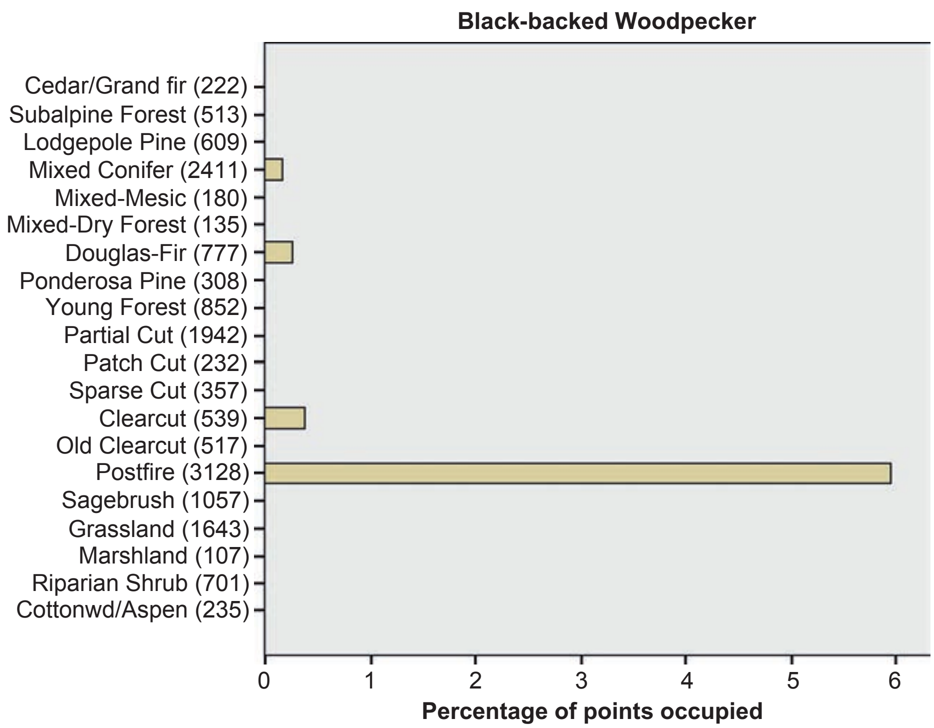
(Figure 3.9). Still more bird species (e.g., calliope hummingbird [*Selasphorus calliope*], lazuli bunting [*Passerina amoena*], and MacGillivray's warbler [*Geothlypis tolmiei*]) use the shrub-dominated early seral stage for feeding and nesting and as display sites (Hutto, 2014).

s0045 Lesson 3: Not only Do Most Bird Species Benefit from Severe Fire, but Some also Appear to *Require* Severe Fire to Persist

p0085 The black-backed woodpecker has become an iconic indicator of severely burned forests because its distribution is nearly restricted to such conditions. Bent (1939) provided the first description of the unusual association between this woodpecker species and burned forests when he noted that Manly Hardy wrote to Major Bendire in 1895 about finding the woodpecker to be "... so abundant in fire-killed timber areas that I once shot the heads off six in a few minutes when short of material for a stew." This anecdote, reflecting the importance of severe fire, went largely unnoticed until the 1970s, when Dale Taylor undertook a study of birds in relation to time since fire in the Yellowstone and Grand Teton National Parks. His more systematic study uncovered the same remarkable pattern. Taylor was the first person to evaluate data drawn from a series of burned conifer forest stands of differing ages, and he found the appearance of the black-backed woodpecker to be restricted to the first few years after fire (Taylor and Barmore, 1980). A subsequent before-and-after fire study by Apfelbaum and Haney (1981) and studies of burned versus adjacent unburned forest by Niemi (1978), Pfister (1980), and Harris (1982) provided additional evidence that this bird species is strongly associated with burned forest conditions. Following the Rocky Mountain fires of 1988, Hutto (1995) conducted a more comprehensive study of the distribution of black-backed woodpeckers across a broad range of vegetation types. That study served to reinforce the notion that this species is an ideal indicator of severely burned mixed-conifer forest. More specifically, Hutto provided a meta-analysis of his own and already published bird survey data collected from burned forests and from more than a dozen unburned vegetation types; those data showed the black-backed woodpecker to be relatively restricted to burned forests. To address the potential problem of putting too much faith in distribution patterns derived from bird occurrence rates that were based on a variety of study durations and methods, Hutto subsequently coordinated the collection of standardized bird survey data from more than 18,000 points distributed across every major vegetation type in the U.S. Forest Service Northern Region. The results (Hutto, 2008) were strikingly similar to what earlier studies showed: one is hard pressed to find a black-backed woodpecker anywhere but in a recently burned forest (Figure 3.10).

p0090 Numerous studies (most published just in the past decade) provide additional detail that can help us better understand this remarkable association between the black-backed woodpecker and severely burned forests. Here we list some of the insights we have gained:

o0010 **1.** The magical appearance of woodpeckers within weeks of a fire (Blackford, 1955; Uxley, 2014) suggests that either smoke, or perhaps the fire or burned landscape itself, provides a stimulus for birds to colonize newly burned forests.



f0055 **FIGURE 3.10** Histogram bars indicate the percentage of points (sample sizes in parentheses) at which the black-backed woodpecker was detected in each of 21 distinct vegetation types within northern Idaho and western Montana. The distribution is nonrandom ($X^2 = 559.43$; $df = 19$; $P < 0.0001$) and reveals that the black-backed woodpecker is highly specialized in its use of burned conifer forest. *(Data from Hutto (2008).)*

o0015 **2.** Breeding and nest densities increase more rapidly than expected on the basis of recruitment alone (Yunick, 1985; Youngman and Gayk, 2011), which suggests that the process of immigration after fire is significant.

o0020 **3.** Woodpecker diet, which is based mainly on wood-boring beetle larvae that feed almost exclusively on recently burned and killed trees (Murphy and Lehnhausen, 1998; Powell et al., 2002; Fayt et al., 2005), reflects the broad postfire change in animal community composition that accompanies severe fire.

o0025 **4.** The woodpecker's nonrandom use of forest patches containing dense, larger-diameter trees (Saab and Dudley, 1998; Saab et al., 2002, 2009; Nappi and Drapeau, 2011; Dudley et al., 2012; Seavy et al., 2012) that have burned at high rather than low severity (Schmiegelow et al., 2006; Koivula and Schmiegelow, 2007; Hanson and North, 2008; Hutto, 2008; Nappi and Drapeau, 2011; Youngman and Gayk, 2011; Siegel et al., 2013) is striking and consistent among studies.

o0030 **5.** The window of opportunity for occupancy by this species is not only soon after fire, but generally lasts only about a half-dozen years before the birds (and the abundant native beetle populations) disappear (Taylor and Barmore, 1980; Apfelbaum and Haney, 1981; Murphy and Lehnhausen, 1998; Hoyt and Hannon, 2002; Saab et al., 2007; Nappi and Drapeau, 2009; Saracco et al., 2011).

o0035 **6.** The size of the home ranges of black-backed woodpeckers within burned forests are significantly smaller (indicating better quality habitat) than those outside burned forests (Rota et al., 2014b; Tingley et al., 2014). Even more telling is that nest success is significantly higher inside than outside burned forests (Nappi and Drapeau, 2009; Rota et al., 2014a).

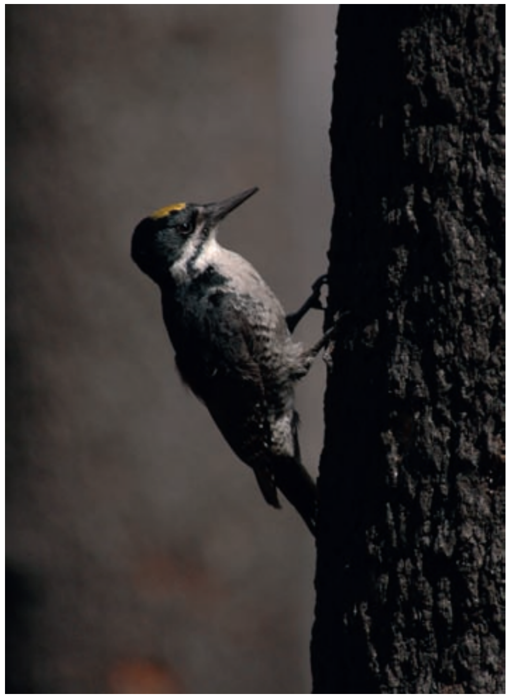
o0040 **7.** Estimated population growth rates are insufficient to maintain a growing population outside burned forests (Rota et al., 2014a). Thus, although one could argue that low woodpecker densities in green-tree forests multiplied by a much larger unburned forest area might yield even more woodpeckers in green forests (Fogg et al., 2014), a sink area alone (no matter how large) can never yield a viable population of woodpeckers (Odion and Hanson, 2013).

o0045 **8.** The importance of severely burned forests as foraging locations for wintering black-backed woodpeckers is virtually unknown; the only detailed work so far (Kreisel and Stein, 1999) revealed densities that were an order of magnitude greater in burned than in unburned forests.

p0135 The biology surrounding this single bird species clearly reflects not only the ecological importance but also the necessity of severely burned forests, but major environmental organizations have yet to focus conservation efforts on burned forests (Schmiegelow et al., 2006), and management guidelines developed by state agencies to designate important wildlife habitats (e.g., https://www.dfg.ca.gov/biogeodata/cwhr/) do not even have burned conifer forests on their radar.

p0140 The distributional stronghold of the black-backed woodpecker might be considered to lie within the boreal forests of Canada, which nobody doubts are among the most severe-fire-dependent ecosystems in the world, but the bird's distribution south into the California Sierras and Rocky Mountains of the Intermountain West confirms that severe fires in those areas have been historically important as well. A North American forest bird species that is more narrowly restricted to a single forest condition does not exist; the black-backed woodpecker is the definition of a specialist. Everything about this bird species, including its distribution, territory size, breeding success, and even coloration pattern (which matches blackened trees), all indicate that this species needs expansive patches of severely burned forest to persist (Figure 3.11).

p0145 We have taken the liberty to provide extensive detail on this particular species because its ecological story carries significant management implications. Because public land managers have a responsibility to manage for the maintenance of all vertebrate species, finding even a single species that depends on severe fire should be enough to raise their awareness that severely burned



f0060 **FIGURE 3.11** Black-backed woodpecker—a species that is relatively restricted in its distribution to severely burned forests. *(Photograph by Richard Hutto.)*

mixed-conifer forests provide necessary habitat as well. Thus the black-backed woodpecker is an ideal focal species for bringing attention to the fact that burned forest conditions are important to maintain in the landscape (DellaSala et al., 2014). The evolutionary history that has led to a strong association between burned forests and the woodpecker also raises questions about whether (as many assume) severe fires in mixed-conifer forests are really beyond the historical natural range of variation, whether we need to be thinning forests outside the wildland-urban interface to reduce fire severity, whether we need to be suppressing fire outside the wildland-urban interface, and whether we should "salvage" logging trees (including important legacy trees; see Chapter 11) after fire. Yes, the story surrounding this focal species is important.

s0050 *Bird Species in Other Regions That Seem to Require Severe Fire*

p0150 Do any other bird species seem not only to benefit from but also to require severe fire to persist? The presence of a species in a specific environment and its absence elsewhere would be a clear indication that it depends on that particular environment. For species that occur across a range of environmental conditions, the places where they are relatively abundant are also likely to represent places that are required for population persistence because they persist in source areas and they are generally less abundant in, and their abundance is

B978-0-12-802749-3.00003-7, 00003

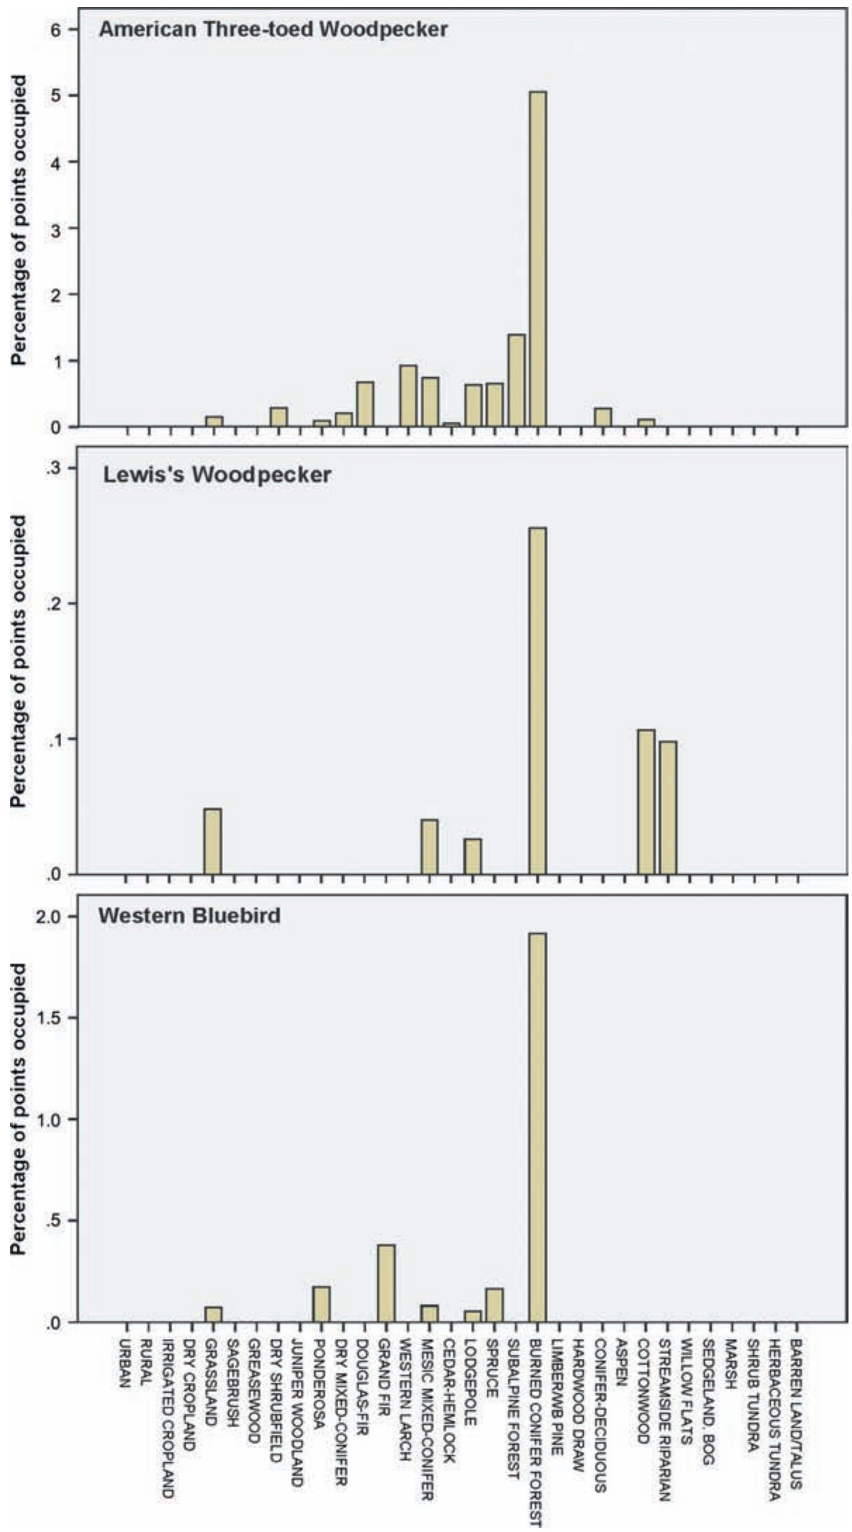
more variable through time in, more marginal areas (Pulliam, 1988; Sergio and Newton, 2003). Although the same level of biological detail that has been amassed for the black-backed woodpecker has not been collected for most other fire-associated bird species, the habitat distribution patterns of numerous bird species reveal that they are nowhere more abundant than in recently burned forests. For example, Hutto (1995) listed 15 species that were more abundant in recently burned forests than in any of 14 other vegetation types. Graphs generated from surveys conducted across an even broader range of vegetation types show just how striking these habitat distribution patterns can be: numerous species are nowhere more abundant than they are in severely burned forests (Hutto and Young, 1999) (Figure 3.12).

p0155 Many mixed-conifer bird species (e.g., black-backed woodpecker, American three-toed woodpecker, hairy woodpecker, northern flicker, olive-sided flycatcher, western wood-pewee [*Contopus sordidulus*], dusky flycatcher [*Empidonax oberholseri*], mountain bluebird, Townsend's solitaire, house wren, tree swallow, lazuli bunting, Clark's nutcracker, red crossbill) fall consistently into a short-term "benefit" category, as revealed either by some measure of abundance or nest success in studies of burned versus unburned or before versus after fire (Bock and Lynch, 1970; Bock et al., 1978; Taylor and Barmore, 1980; Apfelbaum and Haney, 1981; Raphael et al., 1987; Hutto, 1995; Kotliar et al., 2002; Hannah and Hoyt, 2004; Smucker et al., 2005; Mendelsohn et al., 2008; Seavy and Alexander, 2014). Even severely burned patches within conifer forests that we have come to associate with low-severity fire can provide critically important habitat for species like the buff-breasted flycatcher (Kirkpatrick et al., 2006; Conway and Kirkpatrick, 2007; Hutto et al., 2008).

p0160 One of the most celebrated examples of a fire specialist involves the federally endangered Kirtland's warbler (*Setophaga kirtlandii*). It occurs almost exclusively in young (5- to 23-year-old) jack pine (*Pinus banksiana*) forest historically created by severe fire (Walkinshaw, 1983). In addition, pairing success is significantly higher in burned than in unburned forests (98% vs. 58% success; Probst and Hayes, 1987). The need for severe fire is obvious not only because, historically, it must have taken severe fires to stimulate forest succession but also because of how its critically endangered population increased dramatically after a fire accidentally escaped within its breeding range (James and McCulloch, 1995). Managers have had difficulty trying to recreate conditions that mimic natural postfire conditions through the use of logging techniques (Probst and Donnerwright, 2003; Spaulding and Rothstein, 2009), and efforts to use these artificial means to maintain warbler populations miss the point. Conservation efforts should be directed toward maintaining severely burned forests, not toward finding a way around the natural fire disturbance process.

p0165 In Australia, where few species are thought to be restricted to recently burned shrubland or forest conditions, early colonists are viewed as generalists, and management concerns are focused on postfire decreases in late-succession specialists (Serong and Lill, 2012). Nevertheless, recent data from Lindenmayer

Comp. by: Gunalan Stage: Revises1 Chapter No.: 3 Title Name: Dellasala
Date:28/4/15 Time:12:06:28 Page Number: 71



f0065 **FIGURE 3.12** Several graphs depicting species that seem to be more abundant in burned forests than in any other vegetation type in the northern Rocky Mountains. Data were drawn from a subset of the Northern Region Landbird Monitoring Program database consisting of 20,000 survey points distributed across northern Idaho and western Montana.

et al. (2014) show that a number of bird species decline in abundance 1-2 years after moderate to severe fire but then return to levels comparable to, or *higher* than, those in unburned forests within 3 years following fire. Indeed, upon further inspection, we found that the superb fairywren (*Malurus cyaneus*), gray fantail (*Rhipidura albiscapa*), yellow-faced honeyeater (*Lichenostomus chrysops*), white-fronted honeyeater (*Purnella albifrons*), dusky robin (*Melanodryas vittata*), flame robin (*Petroica phoenicea*), willie wagtail (*Rhipidura leucophrys*), gray shrike-thrush (*Colluricincla harmonica*), varied sittella (*Daphoenositta chrysoptera*), apostlebird (*Struthidea cinerea*), white-browed scrubwren (*Sericornis frontalis*), brown thornbill (*Acanthiza pusilla*), spotted pardalote (*Pardalotus punctatus*), welcome swallow (*Hirundo neoxena*), dusky woodswallow (*Artamus cyanopterus*), black-faced woodswallow (*Artamus cinereus*), and silver-eye (*Zosterops lateralis*) each have been shown by one or more authors to be more abundant in severely burned than in long unburned, dry sclerophyll forests (Christensen and Kimber, 1975; McFarland, 1988; Reilly, 1991a,b, 2000; Turner, 1992; Taylor et al., 1997; Fisher, 2001; Leavesley et al., 2010; Recher and Davis, 2013; Lindenmayer et al., 2014). Thus many eucalyptus forest species also seem to require severe fire to create the early successional forest conditions within which they are most abundant, but most of those species are not restricted to conditions that occur during the first year or two after fire. In comparison with the dramatic change in bird species composition following severe fire in mixed-conifer forests, there is, in fact, a notable lack of turnover in bird species composition following severe fire in eucalyptus forests (compare before-and-after fire data from Australia and the western United States in Figure 3.13). This difference in response to fire is presumably because eucalyptus trees resprout rapidly from epicormic shoots (Figure 3.2). Lindenmayer et al. (2014) also note that in montane ash forests, "... very rapid vegetation regeneration and canopy closure on severely burned sites ... may limit the influx of open-country birds and preclude the evolutionary development of early successional species" (p. 474). Nevertheless, the bird species listed above suggest that many may depend on slightly later stages of succession before the development of a fully mature forest and that a slightly different perspective might be needed to expose the ecological importance of severe fire to birds of Australian eucalypt forests.

p0170 Taken together, we hope we have provided enough ecological information derived from birds to solidify the notion that severe fire in most severe-fire-dependent shrublands and forests is both natural and necessary for maintenance of the ecological integrity of such systems.

s0055 Postfire Management Implications

p0175 Severe fire is natural and necessary in most—not relatively few—conifer forest types and in many other vegetation types worldwide as well (see Chapters 1 and 2). Current management practices designed to prevent fire,

Australian eucalyptus forest			Western North American mixed-conifer forest

f0070 **FIGURE 3.13** Probabilities of the occurrence of bird species in burned and unburned Australian eucalypt forests in the tablelands above Wollongong, New South Wales, and in burned and unburned mixed-conifer forests in western Montana (R.L. Hutto, unpublished data). Numbers of survey points are given in parentheses. Birds are ordered by the unburned-to-burned ratio of abundance, and species that are completely absent from or are significantly (Mann-Whitney *U* tests) less abundant in the opposite condition are highlighted in yellow. In both locations are bird species restricted to either early or later successional stages, but the amount of species turnover (degree of replacement of late with early succession specialists) is less pronounced after severe fire in Australia than after severe fire in the western United States.

suppress fire, mitigate fire severity, "restore" or "rehabilitate" burned forests after fire, and mimic the effects of severe fire are incompatible with the maintenance of ecosystem integrity (Chapter 13). Below we use results from bird research as evidence to support this statement, and we offer positive suggestions about what land managers could be doing differently.

s0060 *Fire Prevention Should Be Focused on Human Population Centers*

p0180 The dependence of so many bird (and many other plant and animal) species on conditions created by severe fire is clear. It necessarily follows that we cannot prevent fire and still retain anything close to a natural world. The obvious

B978-0-12-802749-3.00003-7, 00003

alternative is to focus prevention efforts toward population centers that are most at risk from severe fire so that fire can be left to periodically restore forest conditions elsewhere. Smokey Bear needs to refine his message so that it reflects a desire to save human lives and property, *not* a desire to save trees from fire in our wildlands (see Chapter 13).

s0065 *Fire Suppression Should Be Focused on the Wildland-Urban Interface (or Fireshed)*

p0185 Because many species depend on severe fire, it also necessarily follows that we should focus suppression efforts on areas immediately adjacent to human settlements (see Chapter 13). Wildland firefighters should serve primarily as support for firefighters who defend homes and human lives. Efforts to suppress fire beyond settled areas should be viewed as little more than efforts to save the forest from itself—forests need fire in the same way that they need sunlight and rain.

s0070 *High-Severity Fires Beget Mixed-Severity Results*

p0190 In contrast with high-severity fire, low-severity understory fires cannot create as broad a range of postfire conditions as severe fires can, nor can they stimulate the postfire process of ecological succession like a severe fire can. Therefore, managing for the maintenance of biodiversity requires more conscientious management for the maintenance of severe fires and the mixed-severity landscape effects that result from such fires (Nappi et al., 2010; Taylor et al., 2012).

s0075 *Mitigate Fire Severity Through Thinning only Where such Fuel Reduction Is Appropriate*

p0195 Because many species depend on severe fire, it necessarily follows that we should focus forest-thinning efforts in the wildland-urban interface and perhaps beyond that in what are basically artificial tree plantations that have resulted from past timber harvesting (see Odion et al., 2014a for review of this topic). The distributions of black-backed woodpeckers and many other fire-dependent plant and animal species make it abundantly clear that a reduction in fire severity is ecologically justified in only a very small proportion of vegetation types (Odion et al., 2014a; Sherriff et al., 2014). The presence of numerous fire-dependent species in most conifer forests throughout the American West (as illustrated by the abundance of bird research results considered in this chapter) is the strongest possible indication that the same forests have burned severely for millennia and are well within the historical range of natural variation.

p0200 The distribution of birds like the black-backed woodpecker and other fire-dependent plant and animal species, which blanket most of the forested land in the American West, are clearly at odds with claims (e.g., Haugo et al., 2015) that as much as 40% of public forested lands in parts of the United States are in need of restoration to prevent or mitigate the effects of severe fire. Lower-severity fires do not produce the mixed- and high-severity conditions needed by the most

Comp. by: Gunalan Stage: Revises1 Chapter No.: 3 Title Name: Dellasala
Date:28/4/15 Time:12:06:29 Page Number: 75

fire-dependent bird species, so efforts to mitigate fire severity in most places is incompatible with maintenance of the ecological integrity of most conifer forest systems (Odion et al., 2014a). So, what should we be doing differently? We could realize that modeled estimates indicating that our forests are in conditions that lie beyond the historical natural range of variation are just that—modeled estimates that rest strongly on many untested assumptions. We should always compare modeled results with insight gained by ecologists who can also draw strong inferences about historical conditions and, more specifically, about the kind of environments that necessarily led to adaptations of plants and animals—adaptations that reflect the distant past much more accurately than other methods commonly used to reconstruct natural fire regimes.

s0080 *Postfire "Salvage" Logging in the Name of Restoration or Rehabilitation Is Always Inappropriate*

p0205 Postfire "salvage" logging, seeding, planting, and shrub removal have overwhelmingly negative effects on natural systems (Lindenmayer et al., 2004; Lindenmayer and Noss, 2006; McIver and Starr, 2006; Swanson et al., 2011; DellaSala et al., 2014; Hanson, 2014), and birds have been instrumental in uncovering that fact. There is nothing as obvious to a birdwatcher as the negative effect of postfire salvage logging on the most fire-dependent birds (Uxley, 2014), and these anecdotal impressions are backed up by the strongest and most consistent scientific results ever published on any wildlife management issue (Hutto, 1995, 2006; Morissette et al., 2002; Nappi et al., 2004; Hutto and Gallo, 2006; Koivula and Schmiegelow, 2007; Hanson and North, 2008; Cahall and Hayes, 2009; Saab et al., 2009; Rost et al., 2013). One look at (Figure 3.14), or one walk through, a salvage-logged forest after knowing

f0075 **FIGURE 3.14** A vivid view of what can only be described as an ecological disaster following this postfire salvage logging operation, which took place after the 1988 Combination fire in Montana. *(Photograph by Richard Hutto.)*

something about the biological wonder associated with a severely burned forest should be enough to convince any thinking person that there is no justification for this kind of land management activity.

p0210 It is bad enough that forests logged after fire are made unsuitable for black-backed woodpeckers and other early postfire specialists, but much worse is that postfire logging and shrub removal through mechanical or chemical means may also act as an "ecological trap" (Robertson and Hutto, 2006). This can occur when birds are attracted to burned areas that seem to be suitable and then those areas are suddenly transformed by logging or shrub removal into unsuitable habitat in an unnaturally rapid period of time. This is the most reasonable explanation for why black-backed woodpeckers are more abundant in dense, burned forests that are logged after fire than they are in burned forests that are logged before fire—birds are not attracted to the latter, where tree densities are too low and sizes are too small to provide suitable habitat, but they are attracted to the former before the trees are unexpectedly removed (Hutto, 2008). Similarly, the disproportionate use of recently logged, unburned, old-growth forests in Canada (Tremblay et al., 2009) suggests that black-backed woodpeckers sometimes make the best of a marginal situation, not that they "prefer" recently logged forests.

p0215 Although the ecological responses of birds to postfire salvage logging may differ among globally different ecosystems (Rost et al., 2012), there is absolutely no ecological justification for this kind of logging in the mixed-conifer forests of the western United States, nor is there an economic justification to salvage log after fire, because there are always better places to harvest timber without anywhere near the negative ecological consequences associated with postfire salvage logging. This is a matter of setting priorities for timber harvest, and burned forests should be at the bottom of the list. Burned forests not only provide unique ecological value, they also set the stage for the development of a variety of future forest conditions—conditions that are much more varied than those associated with development after artificial disturbance from logging. Forests have their own rules and timetables associated with the natural process of ecological succession, and we should embrace that variety and complexity. What could be done differently? Postfire rehabilitation should focus on roads, culverts, and other infrastructure issues, and nothing else. We need to recognize that new forest conditions get created after fire, and a disturbance-dependent forest does not need to be "fixed" after disturbance takes place.

s0085 *We Can Do more Harm Than Good Trying to "Mimic" Nature*

p0220 Prescribed burning, forest thinning, and the use of other forms of artificial disturbance in an effort to mimic nature are often poor substitutes for natural disturbance processes. Prescribed burning is usually done out of season, too frequently, and in a manner that is far too mild to have the necessary effects in most systems that evolved with fire (England, 1995; Tucker and

B978-0-12-802749-3.00003-7, 00003

Robinson, 2003; Penman and Towerton, 2008; Peters and Sala, 2008; Arkle and Pilliod, 2010; Rota et al., 2014a). Thinning forests in a manner thought to mimic disturbance effects is also likely to be problematic because natural disturbance (the process of fire itself) produces effects that cannot be emulated through artificial means (Schieck and Song, 2006; Reidy et al., 2014). Moreover, a thinned forest that subsequently burns in a natural fire event will not be suitable as postfire habitat for early postfire specialists because of the reduction in tree densities and sizes (Hutto, 2008). Finally, the use of forest thinning in the name of forest restoration is inappropriately applied to relatively mesic mixed-conifer forests that are unlikely to be in need of restoration, as indicated by a lack of posttreatment change in bird communities toward what one would expect if the forests were actually outside the historical range of natural variation (Hutto et al., 2014).

p0225 Except in the case of an endangered species, the worst management approach is one that focuses narrowly on creating *artificial* conditions needed by a single species. This is "single-species management," which is not the same thing as using a "management indicator approach." Management indicators are not meant to be tools that enable land managers to artificially modify land conditions to benefit a single species. Instead, a management indicator species should be used as an indication of a particular kind of "natural" condition that needs to be maintained on the landscape and as a check that the land condition is indeed acceptable to a species that requires such conditions. Even for an endangered species, we should always be thinking about maintaining the "natural" conditions that historically maintained its population. Thus, although artificial tree plantations may provide conditions used by Kirtland's warbler (Spaulding and Rothstein, 2009), the bird historically nested beneath the canopy of young trees born of fire. Therefore we should create conditions safe enough to allow natural severe fire events to unfold throughout most of its historical range. As clearly stated in the Endangered Species Act (ESA, Section 2), "the purposes of this act are to provide a means whereby the *ecosystems upon which endangered species and threatened species depend* may be conserved . . ." (our italics). Conservation should be about the larger system (e.g., maintaining a fire disturbance-based jack pine forest system), not about ~~a~~ finding a way to maintain a species through artificial means. Thus the black-backed woodpecker is an "indicator" or "focal species" that should be used to inform us about a critically important "natural" disturbance process and vegetation condition we need to maintain—severely burned forests and all the associated organisms that thrive within them.

p0230 What could we be doing differently? We need to trust that disturbance-dependent systems need severe disturbance (yes, that means a lot of tree death) to stimulate ecological succession in a manner that is indeed natural. We also need to appreciate that modeled *means and standard deviations* associated with measures of forest structure are not the same things as historical *ranges of variation* associated with the same measures. While some places have tree densities that exceed some estimated historical average value, it does not mean they fall outside the historical range of natural variation. Land managers need to relax in response to severe fire. As long as we can reduce the frequency of human-caused fires and remain safe during naturally ignited fire events, a management option that lets nature take its course will work just fine (Gill, 2001; Bradstock, 2008). In this context, noting that safety is best achieved through mechanical treatments in small areas immediately adjacent to structures (Cohen, 2000; Cohen and Stratton, 2008; Winter et al., 2009; Stockmann et al., 2010; Gibbons et al., 2012; Syphard et al., 2014), and not through mechanical treatments in more remote wildlands, is important. Given this fact, why treatments in relatively remote, publicly owned wildlands have become the tactic most commonly used to reduce wildfire risk is puzzling (Schoennagel et al., 2009).

s0090 *Concluding Remarks*

p0235 The most important ecological lessons we can take away from the bird research described in this chapter are that (1) many species have evolved to the point where they now require severe fire to create the conditions they need, and (2) even though some ecological systems may have departed significantly from what are believed to be historical conditions (e.g., tree plantations in the Pacific Northwest), birds are telling us (through their behavior and distribution patterns) that the vast majority of fire-dependent ecosystems are still well within the historical range of natural variation, are plenty “resilient,” and are fully capable of proceeding quite naturally through the process of succession following a severe-fire event. Therefore, thinning forests in the name of restoration is largely unnecessary. If this were not true, the world would be full of places that experienced a severe fire disturbance and then underwent an unnatural transformation or “type conversion” following the disturbance event, never to return to what was there before disturbance. It is most telling that those kinds of places are rare indeed.

p0240 For those who would like to read, view, or hear more about the relationship between birds and severe fire, there are excellent children’s books (e.g., Peluso, 2007; Collard, 2015); several informative videos, including a field trip that illustrated many of the patterns discussed here (listed in the Preface); and a Fire Ecology Lab Facebook page (https://www.facebook.com/FireEcologyLab) devoted to building an appreciation for the role of severe fire in our forests.

Abstract

Important lessons emerge from studies of birds in ecosystems born of, and maintained by, mixed- to high-severity fire. Specifically, (1) the effect of fire on any one species is context dependent. It depends on the time since the fire, the fire severity, and vegetation type and condition. (2) Bird species respond differently to any given postfire condition and, given an appropriate time since the fire and postfire vegetation conditions, most benefit from severe fire. (3) Some bird species (the black-backed woodpecker being iconic) seem to *depend* on conditions created by severe fire, as evidenced by their distribution patterns, territory sizes, nest success, and other adaptations. (4) Given these facts, current management practices designed to prevent fire, suppress fire, mitigate fire severity, “restore” or “rehabilitate” burned forests after fire, and mimic the effects of severe fire are incompatible with the maintenance of bird populations and, therefore, ecosystem integrity.

Keywords: Adaptation; Bird; Disturbance; Fire severity; Forest restoration; Salvage logging; Severe fire.

CONSERVATION

A global map of roadless areas and their conservation status

Pierre L. Ibisch,[1,2]* Monika T. Hoffmann,[1] Stefan Kreft,[1,2] Guy Pe'er,[2,3,4] Vassiliki Kati,[2,5] Lisa Biber-Freudenberger,[1,6] Dominick A. DellaSala,[7,8] Mariana M. Vale,[9,10] Peter R. Hobson,[1,2,11] Nuria Selva[12]*

Roads fragment landscapes and trigger human colonization and degradation of ecosystems, to the detriment of biodiversity and ecosystem functions. The planet's remaining large and ecologically important tracts of roadless areas sustain key refugia for biodiversity and provide globally relevant ecosystem services. Applying a 1-kilometer buffer to all roads, we present a global map of roadless areas and an assessment of their status, quality, and extent of coverage by protected areas. About 80% of Earth's terrestrial surface remains roadless, but this area is fragmented into ~600,000 patches, more than half of which are <1 square kilometer and only 7% of which are larger than 100 square kilometers. Global protection of ecologically valuable roadless areas is inadequate. International recognition and protection of roadless areas is urgently needed to halt their continued loss.

The impact of roads on the surrounding landscape extends far beyond the roads themselves. Direct and indirect environmental impacts include deforestation and fragmentation, chemical pollution, noise disturbance, increased wildlife mortality due to car collisions, changes in population gene flow, and facilitation of biological invasions (*1*–*4*). In addition, roads facilitate "contagious development," in that they provide access to previously remote areas, thus opening them up for more roads, land-use changes, associated resource extraction, and human-caused disturbances of biodiversity (*3*, *4*). With the length of roads projected to increase by >60% globally from 2010 to 2050 (*5*), there is an urgent need for the development of a comprehensive global strategy for road development if continued biodiversity loss is to be abated (*6*). To help mitigate the detrimental effects of roads, their construction should be concentrated as much as possible in areas of relatively low "environmental values" (*7*). Likewise, prioritizing the protection of remaining roadless areas that are regarded as important for biodiversity and ecosystem functionality requires an assessment of their extent, distribution, and ecological quality.

Such global assessments have been constrained by deficient spatial data on global road networks. Importantly, recent publicly available and rapidly improving data sets have been generated by crowd-sourcing and citizen science. We demonstrate their potential through OpenStreetMap, a project with an open-access, grassroots approach to mapping and updating free global geographic data, with a focus on roads. The available global road data sets, OpenStreetMap and gROADS, vary in length, location, and type of roads; the former is the data set with the largest length of roads (36 million km in 2013) that is not restricted to specific road types (table S1). OpenStreetMap is more complete than gROADS, which has been used for other global assessments (*7*), but in certain regions, it contains fewer roads than sub-global or local road data sets [see the example of Center for International Forestry Research data for Sabah, Malaysia (*8*); table S1]. Given the pace of road construction and data limitations, our results overestimate the actual extent of global roadless areas.

The spatial extent of road impacts is specific to the impact in question and to each particular road and its traffic volume, as well as to taxa, habitat, landscape, and terrain features. Moreover, for a given road impact, its area of ecological influence is asymmetrical along the road and can vary among seasons, between night and day, according to weather conditions, and over longer time periods. We conducted a comprehensive literature review of 282 publications dealing with "road-effects zones" or including the distance to roads as a covariate, of which 58 assessed the spatial influence of the road (table S2). All investigated road impacts were documented within a distance of

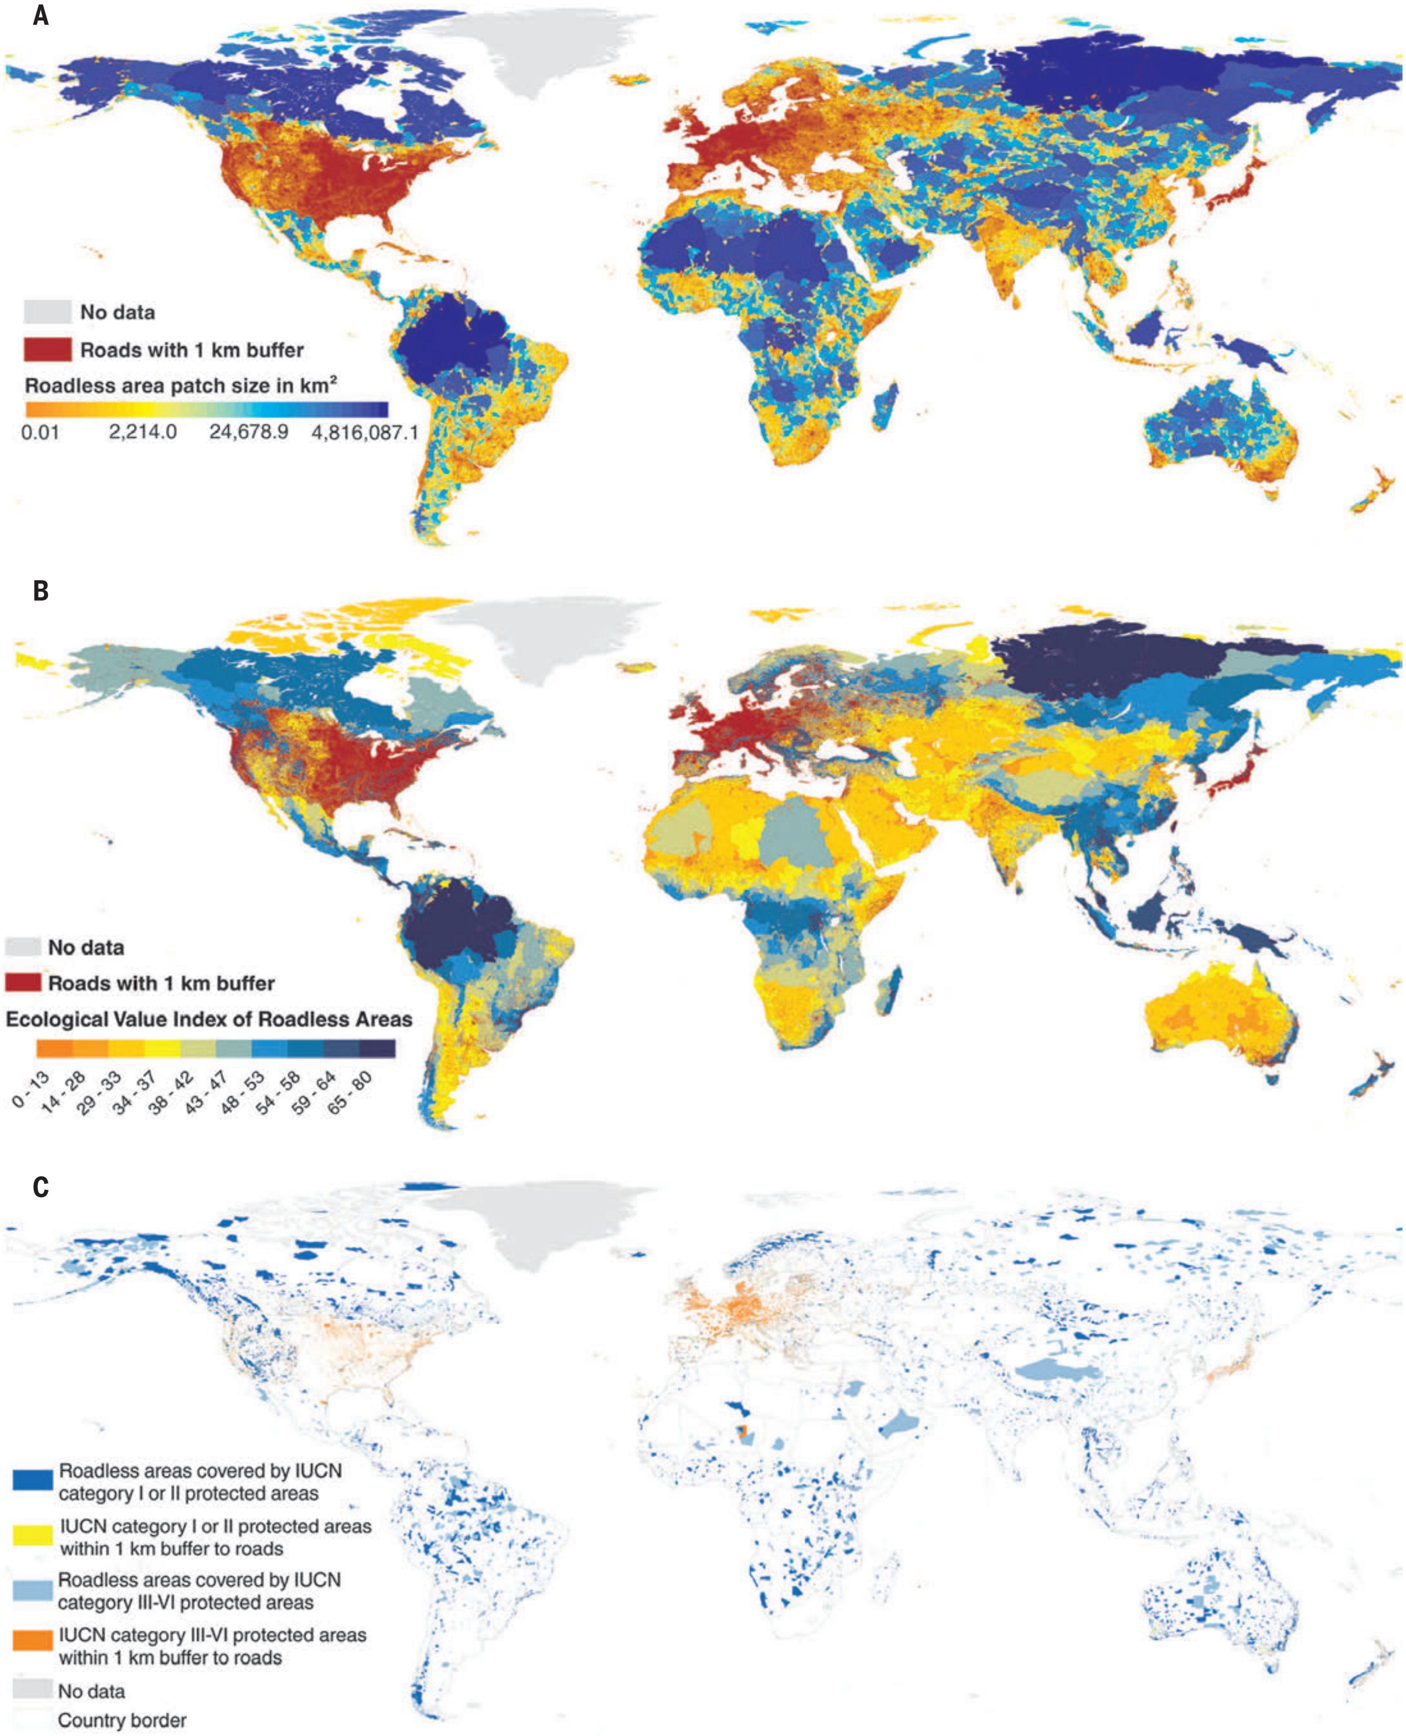

Fig. 1. The global distribution of roadless areas, based on a 1-km buffer around all roads. The distribution is depicted according to (**A**) size classes, (**B**) the ecological value index of roadless areas (EVIRA; based on patch size, connectivity, and ecosystem functionality), and (**C**) representation in protected areas (*8*).

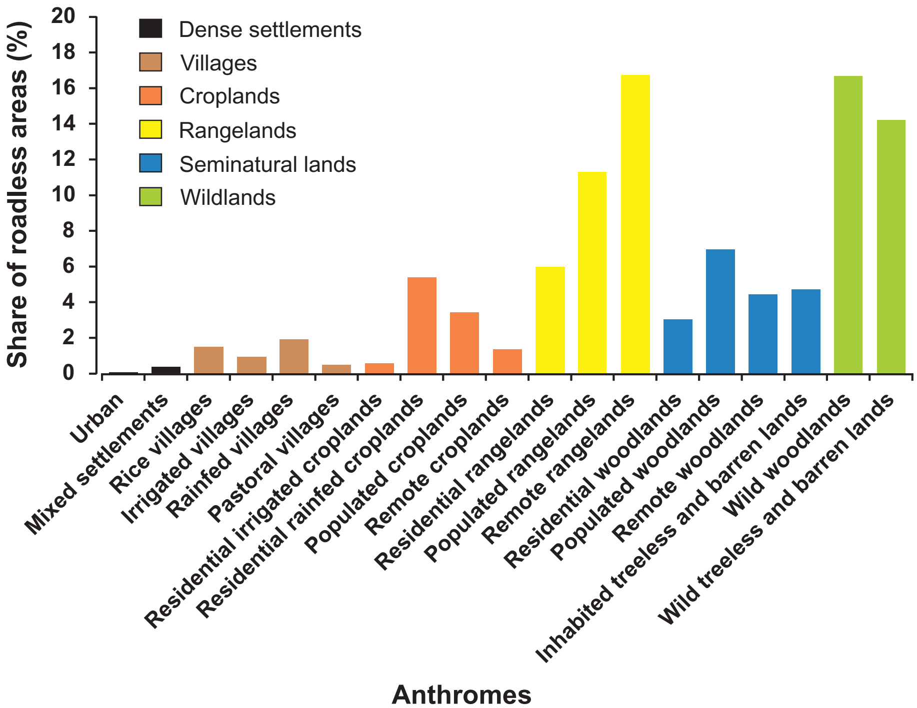

Fig. 2. Extent of roadless areas (1-km buffer) across anthromes. The majority of the world's roadless areas are in remote and unmodified landscapes, but they also occur in anthropogenically modified landscapes. The so-called anthromes were mapped according to (*10*).

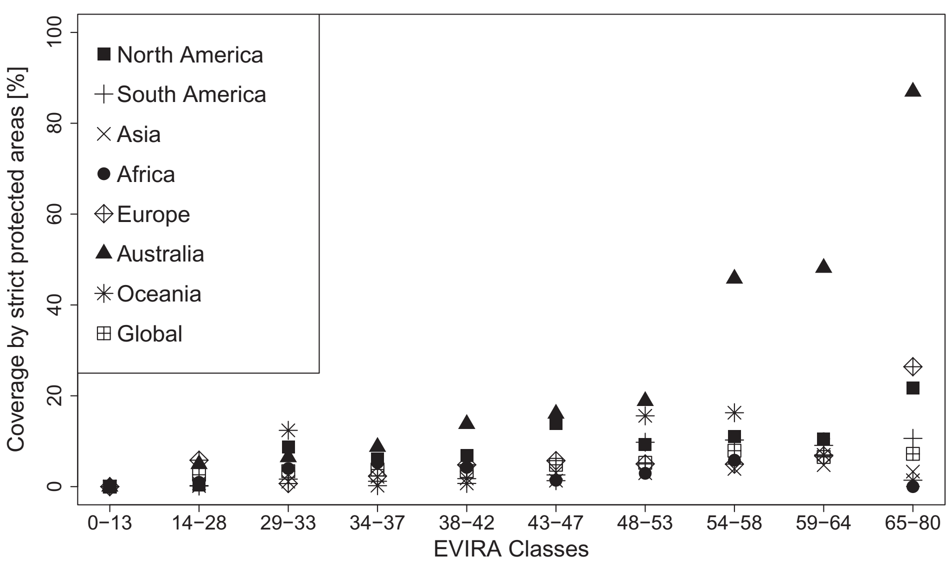

Fig. 3. Coverage of roadless areas by strictly protected areas (IUCN categories I and II) compared with global and continental EVIRA values. If priority were given to protecting roadless areas with high ecological functionality, we should see a positive correlation, with higher coverage associated with higher EVIRA values.

1 km from the road, 39% reached out to 2 km from the road, and only 14% extended out to 5 km from the road (fig. S1). Because the 1-km buffer along each side of the road represents the zone with the highest level and variety of road impacts, we defined roadless areas as those land units that are at least 1 km away from all roads and, therefore, less influenced by road effects. We compared results from using this criterion with the outcomes from using an alternative 5-km buffer (see fig. S2 and table S3). We excluded all large water bodies, as well as Greenland and Antarctica, which are mostly covered by ice, from the analyses.

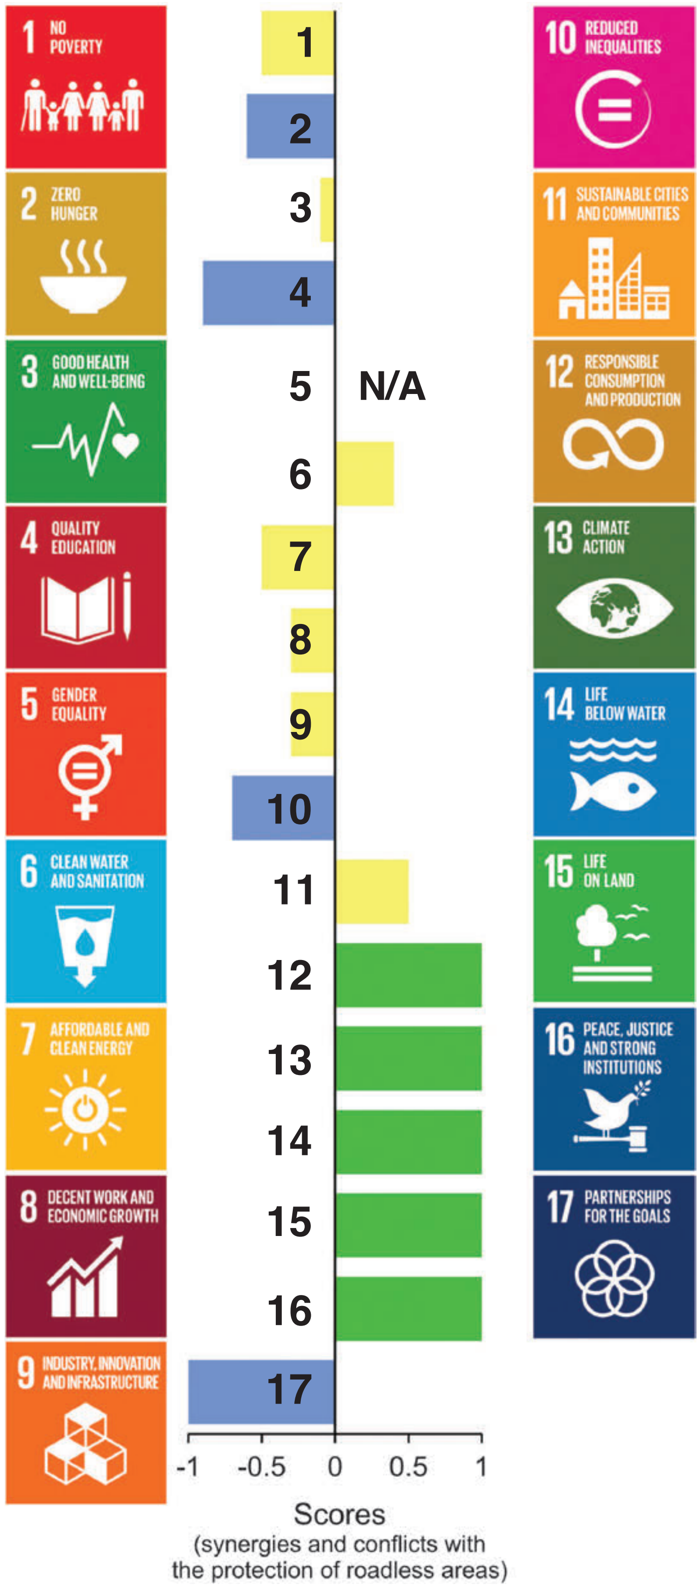
Roadless areas with a 1-km buffer to the nearest road cover about 80% of Earth's terrestrial surface (~105 million km^2). However, these roadless areas are dissected into almost 600,000 patches. More than half of the patches are <1 km^2; 80% are <5 km^2; and only 7% are >100 km^2 (table S4 and fig. S3). If the buffer is extended to 5 km, there is a substantial reduction in roadless areas to about 57% of the world's terrestrial surface (~75 million km^2), dissected into 50,000 patches (fig. S2 and table S3). The occurrence, distribution, and size of roadless areas differ considerably among continents (Fig. 1A and fig. S4). For instance, the mean size of roadless patches (1-km buffer) is 48 km^2 in Europe, compared with >500 km^2 in Africa. Because of comparatively large gaps in available spatial data on roads in many segments of the tropics, the number and size of roadless areas are overestimated and should be treated with caution (e.g., Borneo; table S1).

All identified roadless areas were assessed for a set of ecological properties that were selected to reflect their relative importance to biodiversity, ecological functions, and ecosystem resilience: patch size, connectivity, and ecosystem functionality (*9*) (table S5). We normalized these three indicators to between 0 and 100 to calculate an additive and unitless index of the ecological value of each roadless area identified (termed the ecological value index of roadless areas, or EVIRA) [Fig. 1B and fig. S5; the specific rationale and technicalities of the chosen indicators are described in table S5 (*8*)]. The EVIRA values range from 0 to 80. A sensitivity analysis shows that ecosystem functionality and patch size are the best single indicators for the final index values (table S6 and figs. S6 to S8). Areas with relatively high index values tend to have a lower coefficient of variation (fig. S9).

We used the International Union for Conservation of Nature (IUCN) and UN Environment Programme–World Conservation Monitoring Centre data set of global protected areas to determine the extent of roadless areas that are protected (*8*) (Fig. 1C). The roadless areas distribution across human-dominated landscapes was determined following the classification of so-called anthromes, defined as biomes shaped by human land use and infrastructure (*10*) (Fig. 2 and table S7).

When examining the density of roads within different biomes, large discrepancies in distribution are apparent. The tundra and rock and ice-covered biomes are nearly entirely roadless, whereas temperate broadleaf and mixed forests have the lowest share of roadless areas (41%; figs. S9 and S10). Boreal forests of North America and Eurasia still retain large tracts of roadless areas (figs. S10 and S11). In the tropics, large roadless landscapes (>1000 km^2) remain in Africa, South America, and Southeast Asia, with the Amazon having the single largest roadless segment. In relation to the anthromes (*10*), about two-thirds of the world's roadless areas can be described as remote and unmodified landscapes [26% uninhabited or sparsely inhabited treeless and barren lands; 21% natural and remote seminatural woodlands, with 17% wild woodlands therein (*8*); Fig. 2 and table S7]. The remaining one-third consists of rangelands, indicating that roadless areas can also occur in anthropogenically modified landscapes.

Fig. 4. Synergies and conflicts between conservation of roadless areas and the United Nations' Sustainable Development Goals. Scores <–0.5 (blue bars) indicate that conflicts with the goal prevail; scores between –0.5 and 0.5 (yellow) indicate a mixture of synergies and conflicts with the goal; and scores >0.5 (green) indicate prevailing synergies with the goal [for details, see table S11 (*8*)]. The scores reflect substantial imminent conflicts between various Sustainable Development Goals and conservation of roadless areas (table S11).



About one-third of the world's roadless areas have low EVIRA values. Patches with relatively low EVIRA values (ranging from 0 to 37; namely, <50% of the maximum value) account for 35% of the overall roadless area distribution, because most are small, fragmented, isolated, or otherwise heavily disturbed by humans. Some large tracts of roadless areas, such as arid lands in northern Africa or central Asia, occur in areas of sparse vegetation and low biodiversity and, thus, have low index values for ecosystem functionality (*9*) (Fig. 1B). High EVIRA values occur both in tropical and boreal forests. The relative conservation value of roadless areas is context-dependent. Comparatively small or moderately disturbed roadless areas have higher conservation importance in heavily roaded environments, such as most of Europe, the conterminous United States, and southern Canada.

Although the world's protected areas cover 14.2% of the terrestrial surface, only 9.3% of the overall expanse of roadless areas is within protected areas (all IUCN categories; Fig. 1C and table S8). There is no major difference in the coverage of roadless areas by strictly protected areas (IUCN categories I and II) versus the coverage of the overall landscape by strictly protected areas (3.8% roadless versus 4.2% overall). Only in North America, Australia, and Oceania are more than 6% of roadless areas under strict protection (table S8). If conservation efforts were to prioritize functional, ecologically important roadless areas, we would find a positive relation between strict protection coverage and EVIRA values of roadless areas. However, with the exception of Australia, this is not the case (Fig. 3 and table S9). Asia and Africa have particularly low protection coverage for roadless areas with high EVIRA values. For instance, we found gaps in the Asian tropical southeast, as well as in boreal biomes.

The recent Global Biodiversity Outlook (*11*) gives a bleak account of the progress made toward reaching the United Nations' biodiversity agenda as specified in the 20 Aichi Targets of the Convention on Biological Diversity (*12*). Governments have failed on several accounts to keep their use of natural resources well within safe ecological limits (target 4); to halt or at least halve the rate of habitat loss and substantially reduce the degradation and fragmentation of natural habitats (target 5); and to appropriately protect areas of particular importance for biodiversity and ecosystem services (target 11). To achieve global biodiversity targets, policies must explicitly acknowledge the factors underlying prior failures (*13*). Despite increasing scientific evidence for the negative impacts of roads on ecosystems, the current global conservation policy framework has largely ignored road impacts and road expansion. Furthermore, key policies on road infrastructure and development, such as the Cohesion Policy of the European Union, fail to take into account biodiversity.

In the much wider context of the United Nations' Sustainable Development Goals, conflicting interests can be seen between goals intended to safeguard biodiversity and those promoting economic development (*14*). We analyzed how roadless areas relate to the global conservation and sustainability agendas. As a transparent synthesis, we calculated simple scores of conflicts versus synergies of Sustainable Development Goals and Aichi Targets with the conservation of roadless areas (tables S10 and S11). Roads are explicitly mentioned in the Sustainable Development Goals only for their contribution to economic growth (goal 8), promoting further expansion into remote rural areas, and consideration is given neither to the environmental nor the social costs of road development. The resulting scores reflect substantial imminent conflicts (Fig. 4 and table S10); only in five Sustainable Development Goals do synergies with conservation of roadless

areas prevail, and four Sustainable Development Goals are predominantly in conflict with conservation of roadless areas. Maybe even more surprisingly, several of the Aichi Targets are ambivalent with respect to conserving roadless areas, rather than being in synergy entirely [six conflicting versus 11 synergistic targets (*8*); table S11].

There is an urgent need for a global strategy for the effective conservation, restoration, and monitoring of roadless areas and the ecosystems that they encompass. Governments should be encouraged to incorporate the protection of extensive roadless areas into relevant policies and other legal mechanisms, reexamine where road development conflicts with the protection of roadless areas, and avoid unnecessary and ecologically disastrous roads entirely. In addition, governments should consider road closure where doing so can promote the restoration of wildlife habitats and ecosystem functionality (*4*). Our global map of roadless areas represents a first step in this direction. During planning and evaluation of road projects, financial institutions, transport agencies, environmental nongovernmental organizations, and the engaged public should consider the identified roadless areas.

The conservation of roadless areas can be a key element in accomplishing the United Nations' Sustainable Development Goals. The extent and protection status of valuable roadless areas can serve as effective indicators to address several Sustainable Development Goals, particularly goal 15 ("Protect, restore and promote sustainable use of terrestrial ecosystems, sustainably manage forests, combat desertification, and halt and reverse land degradation and halt biodiversity loss") and goal 9 ("Build resilient infrastructure, promote inclusive and sustainable industrialization and foster innovation"). Enshrined in the protection of roadless areas should be the objective to seek and develop alternative socioeconomic models that do not rely so heavily on road infrastructure. Similarly, governments should consider how roadless areas can support the Aichi Targets (see tables S10 and S11). For instance, the target of expanding protected areas to cover 17% of the world's terrestrial surface could include a representative proportion of roadless areas.

Although we acknowledge that access to transportation is a fundamental element of human well-being, impacts of road infrastructure require a fully integrated environmental and social cost-benefits approach (*15*). Still, under current conditions and policies, limiting road expansion into roadless areas may prove to be the most cost-effective and straightforward way of achieving strategically important global biodiversity and sustainability goals.

PLANT PATHOLOGY

Regulation of sugar transporter activity for antibacterial defense in *Arabidopsis*

Kohji Yamada,[1,2]* Yusuke Saijo,[3,4] Hirofumi Nakagami,[5]† Yoshitaka Takano[1]*

Microbial pathogens strategically acquire metabolites from their hosts during infection. Here we show that the host can intervene to prevent such metabolite loss to pathogens. Phosphorylation-dependent regulation of sugar transport protein 13 (STP13) is required for antibacterial defense in the plant *Arabidopsis thaliana*. STP13 physically associates with the flagellin receptor flagellin-sensitive 2 (FLS2) and its co-receptor BRASSINOSTEROID INSENSITIVE 1–associated receptor kinase 1 (BAK1). BAK1 phosphorylates STP13 at threonine 485, which enhances its monosaccharide uptake activity to compete with bacteria for extracellular sugars. Limiting the availability of extracellular sugar deprives bacteria of an energy source and restricts virulence factor delivery. Our results reveal that control of sugar uptake, managed by regulation of a host sugar transporter, is a defense strategy deployed against microbial infection. Competition for sugar thus shapes host-pathogen interactions.

Plants assimilate carbon into sugar by photosynthesis, and a broad spectrum of plant-interacting microbes exploit these host sugars (*1*, *2*). In *Arabidopsis*, pathogenic bacterial infection causes the leakage of sugars to the extracellular spaces (the apoplast) (*3*), a major site of colonization by plant-infecting bacteria. Although leakage may be a consequence of membrane disintegration during pathogen infection, some bacterial pathogens promote sugar efflux to the apoplast by manipulating host plant sugar transporters (*4*, *5*). Interference with sugar absorption by bacterial and fungal pathogens reduces their virulence, highlighting a general

Editor's Summary

Too many roads

Roads have done much to help humanity spread across the planet and maintain global movement and trade. However, roads also damage wild areas and rapidly contribute to habitat degradation and species loss. Ibisch *et al*. cataloged the world's roads. Though most of the world is not covered by roads, it is fragmented by them, with only 7% of land patches created by roads being greater than 100 km^2. Furthermore, environmental protection of roadless areas is insufficient, which could lead to further degradation of the world's remaining wildernesses.

Abstract. We use the historical presence of high-severity fire patches in mixed-conifer forests of the western United States to make several points that we hope will encourage development of a more ecologically informed view of severe wildland fire effects. First, many plant and animal species use, and have sometimes evolved to depend on, severely burned forest conditions for their persistence. Second, evidence from fire history studies also suggests that a complex mosaic of severely burned conifer patches was common historically in the West. Third, to maintain ecological integrity in forests born of mixed-severity fire, land managers will have to accept some severe fire and maintain the integrity of its aftermath. Lastly, public education messages surrounding fire could be modified so that people better understand and support management designed to maintain ecologically appropriate sizes and distributions of severe fire and the complex early-seral forest conditions it creates.

Key words: early succession; ecological integrity; ecological system; fire management; fire regime; forest resilience; forest restoration; severe fire; wildfire.

Introduction

The spatiotemporal expression of fire events over time in any landscape produces a "fire regime" that influences ecosystem dynamics in that area (Heinselman 1981, Kilgore 1981). Even though the various characteristics of a fire regime (Table 1) are continuous in nature, the traditional approach in representing this variation has been to create a small number of discontinuous categories. Fire regimes in western North America, for example, are often classified into as few as three categories: (1) low-severity, (2) mixed-severity, and (3) high-severity or stand-replacement (Agee 1998, Brown 2000). Our attempt to categorize fire regimes is ". . . an oversimplification…for the convenience of humans" (Sugihara et al. 2006; p. 62), and has had the unfortunate consequence of minimizing rather than emphasizing variation in fire behavior and fire outcomes among vegetation types and across spatial scales (Morgan et al. 2014). In reality, relatively few forest types fit entirely within either of the two extremes—the low-severity (e.g., some interior ponderosa pine) or the stand-replacement (e.g., Rocky Mountain lodgepole pine) categories. Instead, as a simple analysis

Table 1. Characteristics or descriptors often used to describe disturbance regimes (from Keane 2013).

Disturbance Characteristic	Description	Example
Agent	Factor causing the disturbance	Fire is an agent that can kill trees
Source, Cause	Origin of the agent	Lightning is a source for wildland fire
Frequency	How often the disturbance occurs or its return time	Years since last fire (scale dependent)
Intensity	A description of the magnitude of the disturbance agent	Wildland fire heat output
Severity	The level of impact of the disturbance on the environment	Fuel consumption in wildland fires; change in biomass
Size	Spatial extent of the disturbance	Tree kill can occur in small patches or across entire landscapes
Pattern	Patch size distribution of disturbance effects; spatial heterogeneity of disturbance effects	Fire can burn large regions but weather and fuels can influence fire intensity and therefore the patchwork of tree mortality
Seasonality	Time of year of that disturbance occurs	Spring burn vs. fall burn
Duration	Length of time of that disturbances occur	Fires can burn for a day or for an entire summer
Interactions	Disturbance types may interact with each other, or with climate, vegetation and other landscape characteristics	Mountain pine beetles may create fuel complexes that facilitate or exclude wildland fire
Variability	The spatial and temporal variability of the above factors	Each of the above characteristics has variation associated with it

using LANDFIRE data (Rollins 2009, <http://www.landfire.gov>) reveals, roughly 85% of all forested lands within the western US fit within the mixed-severity category, which includes proportions of low-, moderate-, and high-severity (lethal to more than 70% of all trees) fire that vary widely across vegetation types and biophysical settings.

Agee (1993) captured the essence of this important idea in a graph depicting the proportion of low-, moderate-, and high-severity fire across the range of fire regimes (Fig. 1). Note that change from one fire regime to the next (movement along the x-axis) is accompanied not by the sudden appearance of a different fire severity, but by continuous changes in the proportions of each fire severity category. Thus, fire regimes blend imperceptibly into one another. More importantly, except for the two end points on the graph where the proportion of high-severity fire would be either 0% or 100%, most fire regimes consist of a mix of fire severities so, technically speaking, they fit best within a mixed-severity regime (Fig. 2). It is not the presence of a particular fire severity, but the proportion (and, presumably, the distribution and patch sizes) of each severity component that distinguishes regimes. Indeed, empirical

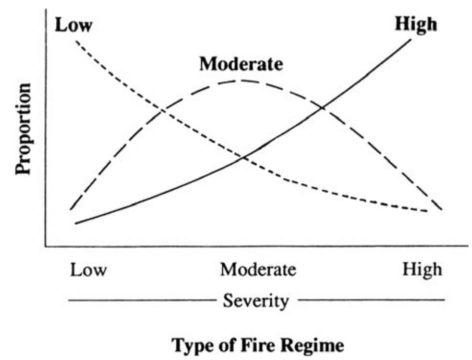

Fig. 1. This graph (from Agee 1993) illustrates that fire regimes are not characterized by the presence of only one kind of fire. Rather, it is the relative frequency of low-, moderate-, and high-severity fire in an average burn that varies among fire regimes.

data drawn from recent fires across the western United States between 1984 and 2008 (Fig. 3) reveal this continuous variation in proportions of different fire severities among fires. Thus, a more continuous view of fire regimes might be a better way to appreciate the infinite variability in fire behavior among forest types and geographic locations, and it might also promote a greater appreciation of severe fire as an integral

Fig. 2. Mixed-severity fires (fires that leave recognizable patches of low-severity, medium-severity, and high-severity effects) typify the majority of mixed-conifer forest systems in the western United States. The brown-needled and blackened areas harbor unique sets of plant and animal species found in no other forest conditions. This photograph of the North Fork of the Blackfoot River was taken 10 months after the 1988 Canyon Creek fire in Montana. Many fire-dependent plant and animal species were present in the more severely burned areas until they were helicopter logged, suggesting that unburned forests might be a better alternative for timber harvest.

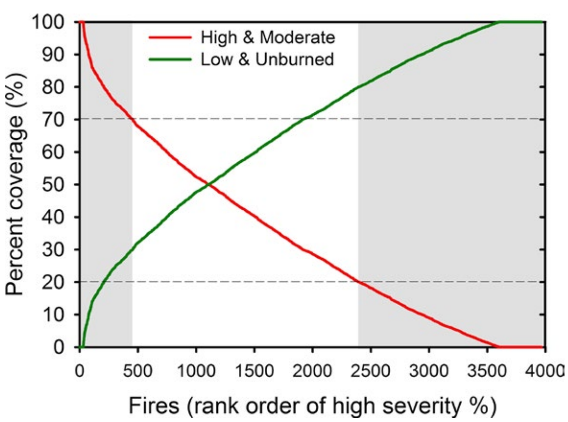

Fig. 3. The percent area within a fire perimeter that burned at low (green line) and at moderate to high (red line) severity is shown for a series of 3696 fires that burned in the western United States between 1984 and 2008 (after Belote 2015). The figure shows that the proportions of each severity category are continuously variable and that high-severity fire is a natural part of most forest fires in the West.

part of mixed- and high-severity conifer forest fire regimes.

Accordingly, we highlight the need for better information on the historical patterns and abundances of high-severity patches in different forest types. This is an important discussion because, even though our National Cohesive Wildland Fire Management Strategy (Wildland Fire Executive Council 2014) acknowledges that many fire regimes exist and that management needs to accommodate that variation and the variety of habitat such variation produces, contemporary fire management is focused heavily on the exclusion (prevention and suppression, collectively) or mitigation of severe fire. When either of those fails, management efforts seem to shift toward speeding the "recovery" of the forest after severe fire. With respect to the latter, there are repeated attempts to introduce legislation designed to expedite logging after fire (salvage logging). Although the removal of dead trees is justified near roads and structures for safety reasons, and although postfire logging can capture economic value of wood that would otherwise be lost, such logging has been shown to carry significant ecological costs (Hutto 2006, Lindenmayer and Noss 2006, Swanson et al. 2011, Lindenmayer and Cunningham 2013, DellaSala et al. 2015). The ecological benefits and necessity of severe fire (and its aftermath) has widespread implications for the flora and fauna that depend on the presence of burned forest conditions. Ecologically sound fire management includes land management designed to ensure the maintenance of ecologically appropriate mixes of fire severities within the forested landscapes of western North America while protecting homes and lives at the same time (Perry et al. 2011). An ecologically informed view of severe fire requires recognition that it is a natural component of many western conifer forests (Heinselman 1981, Arno 2000). Moreover, the severe-fire component must have been large enough and frequent enough to have favored the evolution of specialization by various plant and animal species to conditions that occur in the aftermath of severe fire. We offer the following points in an effort to better recognize and include severe fire as an integral part of fire management in mixed-conifer forest systems:

Severely burned forests create biologically unique conditions that cannot be created by other kinds of disturbances or through artificial means

Patterns in the habitat associations of plant and animal species can provide definitive evidence that severe fire plays an essential role in the ecology of mixed-conifer forests (Hutto et al. 2008). Specifically, if a plant or animal species occurs only in burned forest conditions created by severe fire events, then it cannot be using burned forest conditions merely opportunistically. Instead, the species must have evolved to depend on such conditions because it occurs rarely, if ever, in unburned habitat (Swanson et al. 2011, DellaSala et al. 2014). For example, some moss and lichen species are relatively restricted to severely burned forest conditions (Ahlgren and Ahlgren 1960), as are the fire morel mushroom (*Morchella elata*) and Bicknell's geranium (*Geranium bicknellii*) in forests throughout the West (Heinselman 1981, Pilz et al. 2004). The black-backed woodpecker (*Picoides arcticus*) is emblematic of a species that is relatively restricted to early successional conditions created by high-severity fire (Hutto 1995, Dixon and Saab 2000, Hoyt and Hannon 2002). Black-backed woodpeckers are attracted to postwildfire conditions because of the abundance of larvae of a number of wood-boring beetle species that are attracted to the fire-killed trees (Murphy and Lehnhausen 1998, Rota et al. 2015). Several of these beetle species are themselves relatively restricted to recently burned forests (Saint-Germain et al. 2004*a,b*, Boucher et al. 2012). Importantly, black-backed woodpeckers are significantly more likely to occur in the more severely burned portions of a mixed-severity fire (Hutto 2008, Latif et al. 2013). Although black-backed woodpeckers are known to occur outside severely burned forests on rare occasions, detailed study of survival and reproductive success shows that they exhibit growing populations only in forests recently burned by summer wildfires (Rota et al. 2014). The adaptations of thick bark, branch shedding, and serotiny in *Pinus* are thought to have evolved in response to a period of more intense crown fires in the mid-Cretaceous (He et al. 2012), and those adaptations also reflect the severe-fire backdrop against which pine, Douglas-fir, and larch are thought to thrive.

Many additional animal species, while not as narrowly restricted to burned forest conditions, clearly benefit from the burned forest conditions created by severe fires in mixed-conifer forests throughout the West (Hutto et al. 2015). For example, nest survival of white-headed woodpeckers is significantly higher in burned (wildfire) compared to unburned forest (Hollenbeck et al. 2011, Lorenz et al. 2015). In aquatic systems, severe fire events can rejuvenate stream habitats by causing large amounts of gravel, cobble, woody debris, and nutrients to be imported, resulting in increased production and aquatic insect emergence rates (Benda et al. 2003, Burton 2005, Malison and Baxter 2010, Ryan et al. 2011, Jackson et al. 2015). These changes can, in turn, affect food web dynamics in a way that results in higher growth rates in young trout, including young coastal cutthroat trout (*Oncorhynchus clarkii clarkii*) (Heck 2007) and rainbow trout (*Oncorhynchus mykiss*) (Rosenberger et al. 2011). Indeed, nonnative fish populations declined and native trout densities increased 3 yr after a severe fire in the Bitterroot River watershed, Montana, indicating that severe fire may help ensure ecological integrity of some western streams (Sestrich et al. 2011). In addition, native amphibians such as boreal toads (*Bufo boreas*) thrive in areas that burn severely (Dunham et al. 2007, Hossack and Corn 2007) and use severely burned areas more than expected due to chance (Hossack and Corn 2007, Guscio et al. 2008), as do some bat species (Buchalski et al. 2013).

These strong associations between organisms and severely burned forest patches suggests that many plant and animal species have evolved to rely on recurring severe wildfire events, and further indicates that severe fire events are a natural and important part of the fire regimes associated with many western mixed-conifer forest types. In other words, if one or more species occupy severely burned forests to the exclusion of other forest types (and if they do not tend to occupy forests disturbed through artificial means), then a severely burned forest would have to be considered natural, and would necessarily lie within the historical range of variation (Hutto et al. 2008). Moreover, a more intimate understanding of the biology of those plants and animals (e.g., knowledge of dispersal processes and patterns, foraging ecology, home-range sizes) can provide insight into the historical spatial scales at which severe fire operated across the broader landscape.

Fire history studies suggest that severe fire is an integral component of most fire regimes

In addition to the definitive evidence provided above, a growing body of fire history information points to the same conclusion—severe fire was historically, and is currently, an important component of many western conifer forest systems. At one end of the fire regime spectrum, conifer forests in the warmer, drier geographic areas in western North America are commonly characterized by frequent, low-severity fires that killed primarily juvenile trees historically, resulting in the maintenance of open pine forests with low densities of mature trees (Covington and Moore 1994*a,b*). Nevertheless, mixed and stand-replacement fires were possible even in these forest types after long inter-fire intervals, such as after an especially cold, wet period similar to what occurred during the Little Ice Age (Brown et al. 1999, Sherriff and Veblen 2007, Williams and Baker 2012, Odion et al. 2014, Hanson et al. 2015). At the other end of the fire regime spectrum, cooler, moister forest types, such as lodgepole pine forests, support fire regimes dominated by severe fire events (Brown and Smith 2000), although mixed- and low-severity fires are known to occur in these types as well (Barrett et al. 1991).

Between these two extremes lie the vast majority of mixed-conifer forest types in western North America. These include everything from the xeric, low-elevation, mixed ponderosa pine and Douglas-fir forest types to mesic, high-elevation, spruce-fir forest types. Unlike the forest types that are dominated by either the absence or presence of severe fire, mixed-conifer forests are best characterized by fire regimes of variable, or mixed severity (see Baker 2009: fig. 7.1), which means that the presence of sizable proportions of the three classes of fire severity characterize the fires that burn in those forest systems (Sherriff and Veblen 2006, 2007, Baker et al. 2007, Hessburg et al. 2007, Klenner et al. 2008, Perry et al. 2011, Schoennagel et al. 2011). Importantly, extreme weather (e.g., high temperature, low humidity, high wind speed) rather than quantity of woody fuels often exerts the greatest influence on fire severity and extent across that broad range of mixed-conifer forest types (Johnson et al. 2003, Schoennagel et al. 2004, Lydersen et al. 2014, Williams et al. 2015). This means that, in contrast with the situation in low-elevation or xeric-type ponderosa pine forests in some areas of the southwestern United States (Keane et al. 2008), the amount of high-severity fire in other mixed-conifer forest types is less likely to have departed significantly from historical ranges of variability, even though those forests may have experienced measurable twentieth century changes in fuels due to fire exclusion, timber harvest, and cattle grazing (e.g., Baker et al. 2007, Dillon et al. 2011, Marlon et al. 2012, Miller et al. 2012, Odion et al. 2014, Sherriff et al. 2014). We recognize the lack of relevant historical information on landscape-level distributions and spatial scales of different classes of fire severity for many forest types and regions, but severely burned forest patches have probably always occurred naturally, even in pure ponderosa pine forests of the Southwest, as Cooper (1961) and Weaver (1943) described long ago. We also know that, at least throughout the northern half of the western United States, the extent of severe-fire patches must have been both substantial enough in area and frequent enough to support those plant (e.g., lodgepole pine) and animal (e.g., wood-boring beetle and woodpecker) species that evolved to depend on severe fire itself or on the resulting severely burned forest conditions.

Maintaining ecological integrity means accommodating a broad spectrum of fire severities, including severe fire and its aftermath, in most mixed-conifer forests

We have now established two important facts: severe fire (moderate-to-high burn severity) is a natural agent of disturbance in many mixed-conifer forest types, and such fire is thought to be ecologically necessary for the presence or success of many plant and animal species. These two facts make it clear that management to maintain the ecological integrity of any ecosystem that harbors species that depend on severe fire as a disturbance agent will have to integrate severe fire and its effects into management goals. Moreover, if we better considered distribution patterns, home range sizes, movement patterns, and other animal adaptations that reflect the environment within which they evolved (e.g., Hutto et al. 2008), we could gain considerable insight into historical spatial scales under which severe fire operated as well. We are not questioning or attempting to discredit the evidence that some forest systems were historically dominated by low-severity fire; rather, we are encouraging land managers to also pay close attention to maintaining amounts and distributions of higher severity fire consistent with ecological integrity in our western mixed-conifer forests. The current science, management, and policy challenge for ecosystem managers is to estimate and incorporate amounts of low-, moderate-, and high-severity fire in a manner that maintains ecological integrity (Hessburg et al. 2007, Perry et al. 2011, Baker 2015).

While many fire ecologists understand the importance of more severe fire in forest ecosystems, politicians and the public at large have yet to reach the same understanding. Recent increases in the amount of forested area burned by wildfire over the past three decades in western North American forests (Westerling et al. 2006, Dennison et al. 2014) signaling what many believe to be the emergence of a new age of megafires (Attiwill and Binkley 2013), has created increased movement toward pre and postfire land management activities designed to reduce fire severity, mimic fire effects without the use of fire, or speed the recovery of a forest after fire. These activities may provide some societal benefits, but they can have real costs in terms of the way they negatively affect the ecological integrity of mixed-conifer forests born of mixed-severity fire. Removed from locations that pose a clear and immediate threat to human lives and property, the ecological costs associated with forest thinning may outweigh stated benefits by large margins. We highlight two types of land management (beyond fire suppression itself) that can have significant negative effects on fire-dependent species and, therefore, can interfere with our ability to maintain the ecological integrity of fire-dependent conifer forests: prefire fuel treatments and postfire salvage logging.

Prefire harvest treatments

We know a great deal about the effects of fuel treatments and restoration harvests on forest structure and vegetation recovery, but we know little about the ecological effects of such treatments on the prefire responses of most plant and animal species, and virtually nothing about postfire responses of the most fire-dependent plant and animal species after a treatment subsequently burns in a wildfire. This is because such treatments are rarely accompanied by "ecological effects monitoring," which, in contrast with implementation monitoring (evaluating whether a management activity was implemented) and effectiveness monitoring (evaluating whether the management activity achieved the stated goal), is specifically designed to address whether there are unforeseen negative ecological consequences of a management treatment (Hutto and Belote 2013).

Fuel treatments designed to restore fire-prone ecosystems should do so in the proper fire regime context; more specifically, they should produce appropriate postfire plant and animal responses when fire returns to the forest. Thus, treatments appropriate for dry forests that were historically maintained by a low-severity fire regime may be inappropriate for forests maintained by a mixed-severity fire regime. One serious negative consequence of canopy fuel reduction in forests that evolved with mixed-severity fire could be that fire-dependent species requiring high densities of large standing-dead trees created by the severe-fire component may not recruit after a subsequent fire. For example, the fire-dependent black-backed woodpecker was found to be even less abundant in mixed-conifer forests that were thinned before fire than in the same forest types logged after fire, even though the two pathways support similar standing dead tree densities. This is probably because birds rarely colonize thinned forests that burn, but they still make the best of a bad situation when trees are removed after they have already colonized a densely stocked, severely burned forest (Hutto 2008). Recent research on postfire soil conditions shows that soil C and N response following wildfire also depends on whether there have been fuel treatments, so the assessment of fuel treatment effects needs to include postfire response and not simply postharvest response (Homann et al. 2015). It has been suggested (e.g., Franklin and Johnson 2014) that variable-retention harvests could be designed to emulate early-seral conditions following natural disturbance events in forests born of mixed-severity fire, thereby avoiding the negative consequences associated with other tree harvesting methods. Unfortunately, that strategy is unlikely to satisfy the needs of those fire-dependent animal species that require high densities of fire-killed trees immediately following severe fire (Schieck and Song 2006, Hutto 2008, Reidy et al. 2014).

Postfire salvage logging

Salvage logging after fire is intended to recover economic value of timber that would otherwise be lost, to ensure human safety, and to reduce the risk of future fires. Unfortunately, salvage harvesting activities undermine the ecosystem benefits associated with fire (Lindenmayer et al. 2004, Lindenmayer and Noss 2006, Swanson et al. 2011). For example, postfire salvage logging removes dead, dying, or weakened trees, but those are precisely the resources that provide nest sites and an abundance of food in the form of beetle larvae and bark surface insects (Hutto and Gallo 2006, Koivula and Schmiegelow 2007, Saab et al. 2007, 2009, Cahall and Hayes 2009). No fire-dependent bird species has ever been shown to benefit from salvage logging (Hutto 2006, Hanson and North 2008). The ecological effects of salvage logging on aquatic ecosystems are also largely negative (Karr et al. 2004). In fact, the demonstrated negative ecological effects associated with postfire salvage logging are probably the most consistent and dramatic of any wildlife management effects ever documented for any kind of forest management activity (Hutto 2006). Therefore, because the National Forest Management Act and other legal mandates require public land managers to maintain the integrity of the larger ecological system, burned forests should perhaps be given special consideration compared with green-tree forests. Specifically, they could receive a low priority ranking when it comes to timber harvest decisions (with the obvious exception of small harvests associated with roads and other areas where safety or infrastructure are legitimate concerns). Timber can be harvested from many green-tree forests in a manner that imposes relatively little ecological cost in comparison with the costs associated with logging in burned forest (Lindenmayer and Cunningham 2013).

How do we move toward a more ecologically informed view of forest fires?

The ecological costs associated with some of the more commonly employed pre and postfire management activities in the western United States probably increase substantially as one moves from the low-elevation or xeric ponderosa pine or woodland forest types, where trees were widely spaced and severe fire historically played a spatially restricted role, to the broad array of more densely stocked mixed-conifer forest types, where severe fire historically played a major role. Therefore, a thorough understanding of the historical fire regime associated with any particular vegetation type or land area (as determined from multiple lines of evidence concerning regionally specific fire history) is critically important for land managers who concern themselves with the issues of wildfire risk, ecological restoration, or maintenance of the diversity of native species (Schoennagel and Nelson 2011). More specifically, quantification of appropriate fire rotations and proportions of low-, moderate-, and high-severity fire for any given forest landscape is critical for enlightened land management. For example, in some xeric ponderosa pine forest types, ecosystem restoration activities designed to decrease the severity of wildfire may be ecologically appropriate. The same management activities are not likely to be ecologically appropriate in many mixed-conifer forests, however, because key indicator species evolved to depend on significant amounts of severe fire in those forest types (Schoennagel et al. 2004, Hutto 2008, Klenner et al. 2008, Baker 2012, 2015, Williams and Baker 2012, Odion et al. 2014).

Land and fire managers are now facing future fires that many hypothesize will become larger and contain larger proportions of more severely burned patches under warming climate conditions (Rocca et al. 2014). Problems associated with climate change, however, must be solved through efforts directed toward the causes of climate change and not toward the symptoms of climate change. Any perceived problem with future changes in fire behavior cannot be solved by redoubling our effort to treat this particular climate change symptom by installing widespread fuel treatments that do nothing to stop the warming trend, and do little to reduce the extent or severity of weather-driven fires (Gedalof et al. 2005). Therefore, fuel management efforts to reduce undesirable effects of wildfires outside the xeric ponderosa pine forest types could be more strategically directed toward creating fire-safe communities (Calkin et al. 2014, Kennedy and Johnson 2014). A management emphasis directed toward altering conditions in and immediately adjacent to human communities is very different from an emphasis directed toward treating massive amounts of fuel on more remote public lands. Fuel treatment efforts more distant from human communities may carry the negative ecological consequences we outlined earlier and do little to stop or mitigate the effects of fires that are increasingly weather driven (Rhodes and Baker 2008, Franklin et al. 2014, Moritz et al. 2014, Odion et al. 2014).

Public land managers face significant challenges balancing the threats posed by severe fire with legal mandates to conserve wildlife habitat for plant and animal species that are positively associated with recently burned forests. Nevertheless, land managers who wish to maintain biodiversity must find a way to embrace a fire-use plan that allows for the presence of all fire severities in places where a historical mixed-severity fire regime creates conditions needed by native species while protecting homes and lives at the same time. This balancing act can be best performed by managing fire along a continuum that spans from aggressive prevention and suppression near designated human settlement areas to active "ecological fire management" (Ingalsbee 2015) in places farther removed from such areas. This could not only save considerable dollars in fire-fighting by restricting such activity to near settlements (Ingalsbee and Raja 2015), but it would serve to retain (in the absence of salvage logging, of course) the ecologically important disturbance process over most of our public land while at the same time reducing the potential for firefighter fatalities (Moritz et al. 2014). Severe fire is not ecologically appropriate everywhere, of course, but the potential ecological costs associated with prefire fuels reduction, fire suppression, and postfire harvest activity in forests born of mixed-severity fire need to considered much more seriously if we want to maintain those species and processes that occur only where dense, mature forests are periodically allowed to burn severely, as they have for millennia.

Another integral part of moving toward an ecologically informed perspective of forest fire involves getting the public, politicians, and policy-makers to better recognize and appreciate the critical role that severe fire plays in many forest systems. This has been difficult, and this difficulty has been exacerbated by public messages about severe fire that are uniformly negative. Progress toward allowing fires to burn is difficult unless the public begins to receive a message that differs markedly from the message that Smokey the Bear is sending them now. Fires in our wildlands are fundamentally natural and beneficial, so we must learn to live in a way that allows naturally occurring fires, including severe fires, to burn while minimizing risk to human property and lives (Calkin et al. 2014). That is a vastly different message from one that says severe fires are fundamentally bad and that we have to do everything in our power to prevent and suppress them, or from one that says severely burned forests are places where we should expedite efforts to capture residual economic value through "salvage" logging. We challenge ecologists and managers to pay greater attention to the degree of variation in fire regimes within mixed-conifer forests and to recognize that prefire thinning and postfire "restoration" activities may not always be compatible with maintenance of the ecological integrity of conifer forests that depend on complex mixed-severity fire disturbance.

Acknowledgments

The ideas presented here emerged from a special session that each of us participated in at the 2014 Large Wildland Fires Conference held in Missoula, MT; all authors participated in writing and re-writing drafts of the manuscript. We thank the organizers for the opportunity to pull these ideas together, and we thank anonymous reviewers for numerous helpful suggestions.

ABSTRACT

The use of fire as a land management tool is well recognized for its ecological benefits in many natural systems. To continue to use fire while complying with air quality regulations, land managers are often tasked with modeling emissions from fire during the planning process. To populate such models, the Landscape Fire and Resource Management Planning Tools (LANDFIRE) program has developed raster layers representing vegetation and fuels throughout the United States; however, there are limited studies available comparing LANDFIRE spatially distributed fuel loading data with measured fuel loading data. This study helps address that knowledge gap by evaluating two LANDFIRE fuel loading raster options—Fuels Characteristic Classification System (LANDFIRE-FCCS) and Fuel Loading Model (LANDFIRE-FLM) layers—with measured fuel loadings for a 20 000 ha mixed

RESUMEN

El uso del fuego como herramienta de manejo de tierras es bien reconocido por sus beneficios ecológicos en varios ecosistemas naturales. Para continuar con el uso del fuego y a su vez cumplir con las regulaciones referidas a la calidad del aire, los gestores de tierras deben frecuentemente cumplir con tareas de modelado de emisiones durante el proceso de planificación de las quemas. Para alimentar tales modelos, el programa denominado *Landscape Fire and Resource Management Planning Tools* (LANDFIRE) ha desarrollado capas raster, que representan vegetación y combustibles a lo largo de todos los EEUU; desde luego, son limitados los estudios disponibles que puedan comparar los datos de carga de combustibles espacialmente distribuidos derivados del LANDFIRE, con datos similares producto de mediciones de carga de combustible en el terreno. Este estudio ayuda a dilucidar este vacío en el conocimiento mediante la evaluación de carga de combustible usando dos opciones del programa LANDFIRE—el *Fuels Characteristic Classification System* (LANDFIRE-FCCS) y el *Fuel Loading Model* (LANDFIRE-FLM) *layers*—

conifer study area in northern Idaho, USA. Fuel loadings are compared, and then placed into two emissions models—the First Order Fire Effects Model (FOFEM) and Consume—for a subsequent comparison of consumption and emissions results. The LANDFIRE-FCCS layer showed 200%* higher duff loadings relative to measured loadings. These led to 23% higher total mean total fuel consumption and emissions when modeled in FOFEM. The LANDFIRE-FLM layer showed lower loadings for total surface fuels relative to measured data, especially in the case of coarse woody debris, which in turn led to 51% lower mean total consumption and emissions when modeled in FOFEM. When the comparison was repeated using Consume model outputs, LANDFIRE-FLM consumption was 59% lower relative to that on the measured plots, with 58% lower modeled emissions. Although both LANDFIRE and measured fuel loadings fell within the ranges observed by other researchers in US mixed conifer ecosystems, variation within the fuel loadings for all sources was high, and the differences in fuel loadings led to significant differences in consumption and emissions depending upon the data and model chosen. The results of this case study are consistent with those of other researchers, and indicate that supplementing LANDFIRE-represented data with locally measured data, especially for duff and coarse woody debris, will produce more accurate emissions results relative to using unaltered LANDFIRE-FCCS or LANDFIRE-FLM fuel loadings. Accurate emissions models will aid

comparados con la medición de la carga para 20 000 ha de un área de bosques mixtos de coníferas en el norte de Idaho, EEUU. Las cargas de combustibles fueron comparadas, y luego ubicadas dentro de dos modelos—el *First Order Fire Effects Model* (FOFEM) y el *Consume*—para su subsecuente comparación de los resultados del consumo de combustibles y sus emisiones. El LANDFIRE-FCCS mostró una estimación 200%* superior en la carga del mantillo comparado con la carga medida a campo. Esto llevó a un valor 23% más alto en la media total de consumo y emisiones del combustible cuando fue modelado mediante el modelo FOFEM. El modelo LANDFIRE-FLM layer mostró menores cargas para combustibles de superficie relativo a datos medidos a campo, especialmente en el caso de restos de combustible leñoso grueso (*coarse woody debris*), que a su vez llevó a un 51% menos en el consumo y emisiones promedio cuando fueron modeladas por el modelo FOFEM. Cuando la comparación fue repetida usado el *Consume model outputs*, el consumo estimado por el LANDFIRE-FLM fue un 59% menor en relación a lo determinado en las parcelas medidas, con un 58% menos que las emisiones modeladas. Aunque ambos modelos de LANDFIRE y las cargas efectivamente medidas se ubican dentro de los rangos observados por otros investigadores en los ecosistemas mixtos de coníferas de los EEUU, la variación dentro de las cargas de combustible determinadas por las distintas fuentes fue alta, y las diferencias en carga de combustible llevan a diferencias significativas en consumo y emisiones, dependiendo éstos del modelo elegido. Los resultados de este estudio de caso son consistentes con aquellos obtenidos por otros investigadores, e indican que suplementando datos de LANDFIRE con datos locales obtenidos de mediciones a campo, especialmente para el mantillo y restos de combustible leñoso grueso, producirá resultados de consumo y emisiones más precisos que aquellos que usan solamente datos de carga provistos por LANDFIRE-FCCS o LANDFIRE-FLM. Los modelos de emisiones preci-

INTRODUCTION

The use of fire as a land management tool is widely recognized for its ecological benefits, and as a historic disturbance that has driven succession across many ecosystems (Agee 1996, Hardy and Arno 1996, Rothman 2005). While fire science and policy has advanced in the last 50 years to better allow for the use of fire in managing wildlands (van Wagtendonk 2007), increasingly stringent air quality regulations (US EPA 1990, Hardy *et al.* 2001, US EPA 2015,) and an increased awareness of the health impacts from smoke (Liu *et al.* 2015) can make the use of fire as a management tool difficult. In a recent United States survey, prescribed fire practitioners expressed that smoke and air quality issues are the third greatest impediment to prescribed burning, following low work capacity and unfavorable weather conditions (Melvin 2012). To continue using fire as a management tool, land managers must plan to meet management objectives, while also limiting the impact of smoke on public health and keeping smoke levels within regulatory thresholds (NWCG 2014). Such planning may often require the use of models to determine the quantity of emissions generated by fire; these models require many pieces of information, including expected fire size, fuel loading characteristics, and fuel consumption. Of these, fuel loading has been identified as the most critical step in obtaining accurate smoke predictions (Drury *et al.* 2014). Unfortunately, in many areas there may be little or no measured data on fuel loading; this creates a major difficulty in estimating fuel consumed and emissions produced.

To address the lack of fuel loading information in planning, geospatial Fire Effects Fuel Model (FEFM) layers developed by the Landscape Fire and Resource Management Planning Tools (LANDFIRE) program are often used. LANDFIRE data layers were developed for the contiguous United States, Alaska, and Hawaii to provide consistent geospatial data describing the vegetation type, structure, fuel loading, and disturbances, regardless of land ownership boundaries (Rollins 2009). LANDFIRE is principally intended to inform management and planning decisions made by land management agencies in the United States. It is also the only resource available that provides the geospatial information outlined above across as wide an area as the continental US. To populate models for smoke production, LANDFIRE FEFMs describe fuel loading for duff, litter, woody fuels from timelag size classes ranging from one hour (≤0.6 cm) to 1000 hours (≥7.62 cm), and live herb and shrub loading. Currently, there are two FEFM choices available through LANDFIRE: one represents fuel loading based on the Fuel Loading Model (FLM) categories developed by Lutes *et al.* (2009), and the other based on Fuels Characteristics Classification System (FCCS) categories developed by Ottmar *et al.* (2007). Both methods are derived from extensive measured datasets; however, FCCS is stratified to represent fuel loading by vegetation type (Ottmar *et al.* 2007), while FLM is stratified to represent fuel loadings by their potential fire effects (Lutes *et al.* 2009). The two LANDFIRE FEFMs are different not only in how they stratify fuels, but also in their reported fuel loadings.

There have been few studies that detail the differences between these two LANDFIRE FEFMs. One study evaluated their mapping performance across the western United States (Keane *et al.* 2013), and another compared their loadings and resulting emissions as part of a broader comparison of factors affecting smoke predictions in Washington, USA (Drury *et al.* 2014). When Keane *et al.* (2013) compared fuel loading and mapping accuracy of FCCS and FLM LANDFIRE layers throughout the western United States to data from the Forest Inventory and Analysis (FIA) program, they found poor correlations between FIA and LANDFIRE represented loadings, mainly due to the high variability in fuel loadings. Drury *et al.* (2014) compared FLM and FCCS FEFM data with other local datasets and found the landscape fuel loadings to range from 2.7 million Mg to 8.8 million Mg for their research area in Washington, USA, depending on which fuel loading dataset they used.

Studies such as these are extremely valuable for documenting the complexity and variation within fuel loading data, and identifying the importance and challenges of applying FEFM fuels data to model emissions. Our study builds on the few evaluations of LANDFIRE FEFMs to date by comparing FEFM surface fuel loading with measured fuel loadings, and using these loadings in two popular consumption and emissions models—the First Order Fire Effects Model (FOFEM) and Consume—to compare the resulting differences in fuel consumption and emissions production, while holding the site and environmental conditions constant. This provides insight into the degree of fuel loading differences possible at smaller scales relative to the national or sub-regional scales that LANDFIRE was developed to represent. Yet this 20 000 ha area is large enough to fall within the range of fire management units that land managers are tasked to manage (USDI NPS 2005, USDA FS 2008). We compared duff, litter, herb, shrub, and woody fuel loadings measured in forest inventory plots to those shown on both LANDFIRE Fuel Loading Models (LANDFIRE-FLM) and LANDFIRE Fuels Characterization Classification System (LANDFIRE-FCCS) maps. Subsequent differences in modeled consumption and emissions using FOFEM and Consume are reported.

METHODS

Study Area

To evaluate potential differences in predicted fuel loadings and fire effects, we selected a 20 000 ha study area centered on Moscow Mountain in Latah County, Idaho, USA (Figure 1). The mountain lies in the Palouse Range of northern Idaho, with elevations ranging from 770 m to 1516 m. Moscow Mountain is dominated by mixed conifer forest tree species including ponderosa pine (*Pinus ponderosa* C. Lawson var. *scopulorum* Engelm.), Douglas-fir (*Pseudotsuga menziesii* [Mirb.] Franco var. *glauca* [Beissn.] Franco), grand fir (*Abies grandis* [Douglas ex D. Don] Lindl.), western red cedar (*Thuja plicata* Donn ex D. Don), western hemlock (*Tsuga heterophylla* [Raf.] Sarg.), and western larch (*Larix occidentalis* Nutt.). Ponderosa pine and Douglas-fir habitat types occur on the xeric southern and western aspects, grand fir and cedar-hemlock habitat types occur on the mesic northern and eastern aspects (Cooper *et al.* 1991). The majority of the land is owned by private timber companies, private non-commercial landowners, and public land holdings. Recent disturbances recorded between 2003 and 2009 were predominantly the result of forest man-

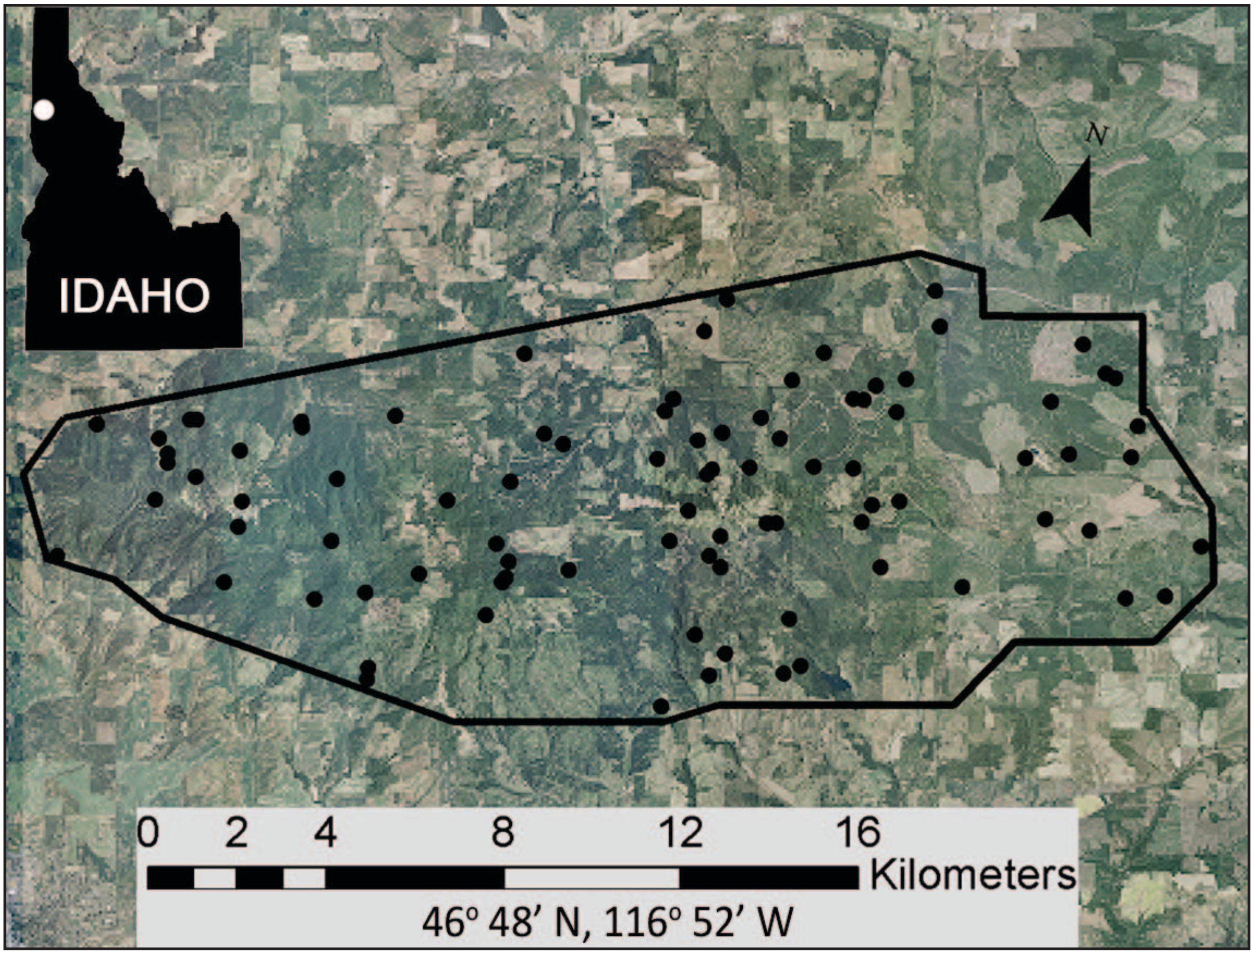

Figure 1. 2009 orthoimagery of the Moscow Mountain, Idaho, USA, study area (outlined) from the United States Geological Survey. The white dot in the inset is the study area. Plot locations are indicated with black dots.

agement practices including thinning, timber harvesting, and prescribed burning (Hudak *et al.* 2012). These activities have resulted in a forest with varying stand ages and structures that occur over a variety of biophysical settings (Falkowski *et al.* 2009, Martinuzzi *et al.* 2009, Hudak *et al.* 2012).

Plot Fuel Loadings

Plot data used in this study were collected in 2009, with information on plot placement and methodologies described in detail in Hudak *et al.* (2012). Following a stratified random sampling design of the study area, 0.04 ha fixed-radius field plots were placed randomly within strata based on elevation, slope, aspect, and percent forest cover. Plots that randomly fell within agricultural areas were subsequently excluded, leaving 87 forested plots for this analysis. Within each plot, duff; litter; coarse woody debris (CWD) in the ≥1000 hour (≥7.62 cm) size class; and fine woody debris in one hour (<0.635 cm), ten hour (0.635 cm to 2.54 cm), and 100 hour (2.54 cm to 7.62 cm) size classes were measured and loading was determined as described by Hudak *et al.* (2009), briefly summarized as follows: fuel loading was determined using two parallel 15 m Brown's transects (Brown 1974) centered 2.5 m upslope and downslope from plot center. On each transect, one hour and ten hour fuels were tallied over a 1.8 m segment, 100 h fuels over a 4.6 m segment, and 1000 h fuels over the entire length of both transects. Shrub and herbaceous cover were estimated ocularly and translated to loadings using equations from Brown (1981) and Smith and Brand (1983). Duff and litter depths were measured once at a set distance along each transect (Brown 1981), and loading was derived from relationships presented in Brown *et al.* (1982) with bulk densities from Woodall and Monleon (2008).

LANDFIRE Fire Effects Fuel Model Loadings

LANDFIRE FEFM map layers are available for both FCCS and FLM fuel classification systems. The FCCS system is composed of fuel loading data organized by vegetation type; each vegetation type is represented by loadings derived from field data collected from that vegetation type (Ottmar *et al.* 2007). FLM fuel loadings are the result of several field-collected datasets, which are grouped into statistically distinct groups based on fuel loading and modeled fire effects (i.e., emissions and soil heating; Lutes *et al.* 2009). In-depth comparisons of these approaches have been addressed by Keane (2013).

For this study, we compared LANDFIRE Refresh 2008 FEFMs to measured fuel loadings. LANDFIRE-FCCS and LANDFIRE-FLM layers were generated using different methodologies. LANDFIRE-FCCS layers were derived by matching FCCS fuelbeds to LANDFIRE vegetation communities (Comer *et al.* 2003) and vegetation type (McKenzie *et al.* 2012, LANDFIRE Team 2014*a*). LANDFIRE-FLMs were derived by a series of database queries that matched LANDFIRE data to the appropriate FLMs (Hann *et al.* 2012). More specifically, Forest Inventory and Analysis (FIA) data (Woudenberg *et al.* 2010) were keyed to FLMs (Lutes *et al.* 2009) and these FLMs were systematically matched to LANDFIRE vegetation types and cover. We should note that the scope of our study focuses on the surface fuel loadings represented in LANDFIRE map layers, not the FCCS and FLM fuel classification systems that the layers are intended to represent.

Generating Emissions within FOFEM and Consume

Consumption and emissions were generated using two common fire effects models: Consume version 4.2 (FERA Team 2014) and the Fire Order Fire Effects Model (FOFEM) version 6.0 (Lutes 2012). Consume calculates consumption and emissions based on empirical algorithms from many studies (Prichard *et al.* 2005). The FOFEM model generates consumption based on equations from the BURNUP model (Albini and Reinhardt 1997) and emission factors from Ward *et al.* (1993). Evaluating results in both models is important as FOFEM and Consume are both commonly used in fire management and are integrated into planning tools such as the Interagency Fuels Treatment Decision Support System (IFTDSS 2015). Consume is also integrated into the BlueSky Framework that is used for emissions calculations (AirFire 2015). For this study, we included the major compounds emitted by wildland fire that could be of concern for reasons of human health effects, regulatory impacts, or greenhouse gas emissions: carbon dioxide (CO_2), carbon monoxide (CO), methane (CH_4), and particulate matter 2.5 μm and 10 μm ($PM_{2.5}$ and PM_{10}). Nitrogen oxides (NO_x) and sulfur dioxide (SO_2) were also modeled using only FOFEM, and non-methane hydrocarbons (NMHC) were modeled using only Consume as these options are specific to each model. To parameterize these models we used the values in Table 1 to simulate summer fire conditions under which past fires in the region have ignited (McDonough 2003).

Table 1. Environmental parameters used to populate FOFEM and Consume under default 'Low' moisture conditions to simulate an early summer fire.

Parameter	Input
Moistures	
Duff	40 %
10 hour	10 %
CWD	15 %
Soil	10 %
Fuel type	Natural
Region	Interior West
Season	Summer

Statistical Comparison of Fuel Loadings

All analyses were conducted using R Statistical Software (R-Project 2013). We initially tested fuel loading differences using Bartlett's test for equal variance (Bartlett 1937). This indicated that the data did not meet the assumption of homoscedasticity required for parametric regression analysis. Therefore, we used non-parametric statistical methods. Analysis of variance was chosen and performed using the Anova test from the "car" package (Fox *et al.* 2014) as this version implemented the test using heteroscedasticity-corrected coefficient covariance matrices. If a significant difference was detected, further analysis was conducted with the Dunnett-Tukey-Kramer pairwise multiple comparison test adjusted for unequal variances and unequal sample sizes (Dunnet 1980) using the DTK package (Lau 2013) at the alpha = 0.05 significance level. This method was used to compare fuel loadings, consumption, and emissions. To examine the influence of different fuels on the total emissions produced, we used Hoffman and Gardner's Importance Index, a ratio of variances between total emissions generated and each individual fuel component (Hoffman and Gardner 1983 , Hamby 1994). Values close to one indicate higher significance than values closer to zero.

RESULTS

Fuel Loadings

In comparing LANDFIRE fuel loadings with measured fuel loadings, all fuel components differed at the alpha = 0.05 significance level with the exception of shrubs (Table 2, Figure 2). LANDFIRE-FCCS loadings over-represented duff and herbs; under-represented litter, 10 h, and 100 h fuels; and did not differ for 1 h fuels or CWD. LANDFIRE-FLM under-represented duff, litter, fine (1 h, 10 h, and 100 h), and CWD fuel loadings; over-represented herb loadings; but duff loading did not

Table 2. Mean fuel loads (Mg ha^{-1} and SD in parentheses) on measured plots and as modeled by LANDFIRE-FCCS and LANDFIRE-FLM. Asterisks indicate statistically significant difference relative to measured loading data at the $P < 0.05$ significance level.

	Mean plot loading		
Fuel	**Measured**	**LANDFIRE-FCCS**	**LANDFIRE-FLM**
Duff	10.55 (10.20)	31.89 (17.80)*	7.76 (12.19)
Litter	5.86 (4.13)	4.199 (1.37)*	3.66 (3.40)*

differ. Duff and CWD fuel components showed the most pronounced difference in loadings, with LANDFIRE-FCCS duff loadings 200 % higher than measured loadings, and 300 % higher than LANDFIRE-FLM loadings. LANDFIRE-FLM CWD loading was 9 times lower than measured or LANDFIRE-FCCS loadings. When comparing LANDFIRE FEFMs to each other, only duff, CWD, and 1 h fuel loadings differed, with LANDFIRE-FCCS having the greater loadings.

Modeled Consumption and Emissions in FOFEM

The statistical relationships for fuel consumption mirrored those for fuel loading (Figures 2 and 3, Tables 2 and 3). Relative to measured consumption, the mean total surface consumption from LANDFIRE-FCCS was 23 % higher, and LANDFIRE-FLM was 51 % lower. It is apparent that the high LANDFIRE-FCCS duff loading led to the higher

overall consumption, and that the low CWD loading in the LANDFIRE-FLM contributed to less consumption. This in turn had a direct effect on the emissions modeled. All modeled emissions, with the exception of NO_x, were significantly higher when modeled using LANDFIRE-FCCS loadings, and lower when using LANDFIRE-FLM loadings, while emissions derived from measured fuel loadings fell in between (Table 4, Figure 4).

The relative importance of CWD and duff to total emissions was reaffirmed and quantified using the importance index (Table 5). Duff and CWD stood out as the primary con-

tributors to total emissions in all cases, with the exception of LANDFIRE-FLM data, in which duff and shrub loadings were the primary contributors. Although shrub loadings did not statistically different in our study, shrub loadings tended to be higher in LANDFIRE-FLMs compared to other sources.

Modeled Consumption and Emissions in Consume

With the exception of duff, the relationships between fuel loading and modeled consumption when using Consume remained the same as with FOFEM; modeled duff consumption was much lower when using Consume (Table 3). Duff consumption using LANDFIRE-FCCS loadings did not significantly differ from consumption generated from measured loadings. Because of this, the overall modeled fuel consumption from LANDFIRE-FCCS did not significantly differ from the fuel consumption generated by measured loadings. However, the modeled consumption from LANDFIRE-FLM was significantly lower than consumption from measured loadings, with mean total surface fuel consumption 59% less than that derived from measured fuel loadings.

The importance index for the consumption and total emissions in Consume was similar to the FOFEM emissions importance index (Table 5). Duff consumption was still an important component with regard to emissions production, even though it did not statistically differ between measured and modeled fuel datasets when modeled with Consume. When emissions were evaluated, the LANDFIRE-FLM generated emissions were significantly lower than those generated using measured fuel loadings. Emissions generated using LANDFIRE-FCCS and measured fuel loadings did not differ from each other (Table 4).

DISCUSSION

Measured Versus Modeled Fuel Loading

Duff and CWD led to the most significant differences in modeled consumption and emissions. LANDFIRE-FLMs contained higher shrub loadings, although this number did not result in a statistically significant difference, nor was it great enough to influence the total surface fuel loading when consumption and emissions were modeled. While the cause for these LANDFIRE-FLM shrub values to be so much higher is not known, the FLM system itself was developed with very little available shrub data (Lutes *et al.* 2009). This likely influenced which FLMs were available to assign

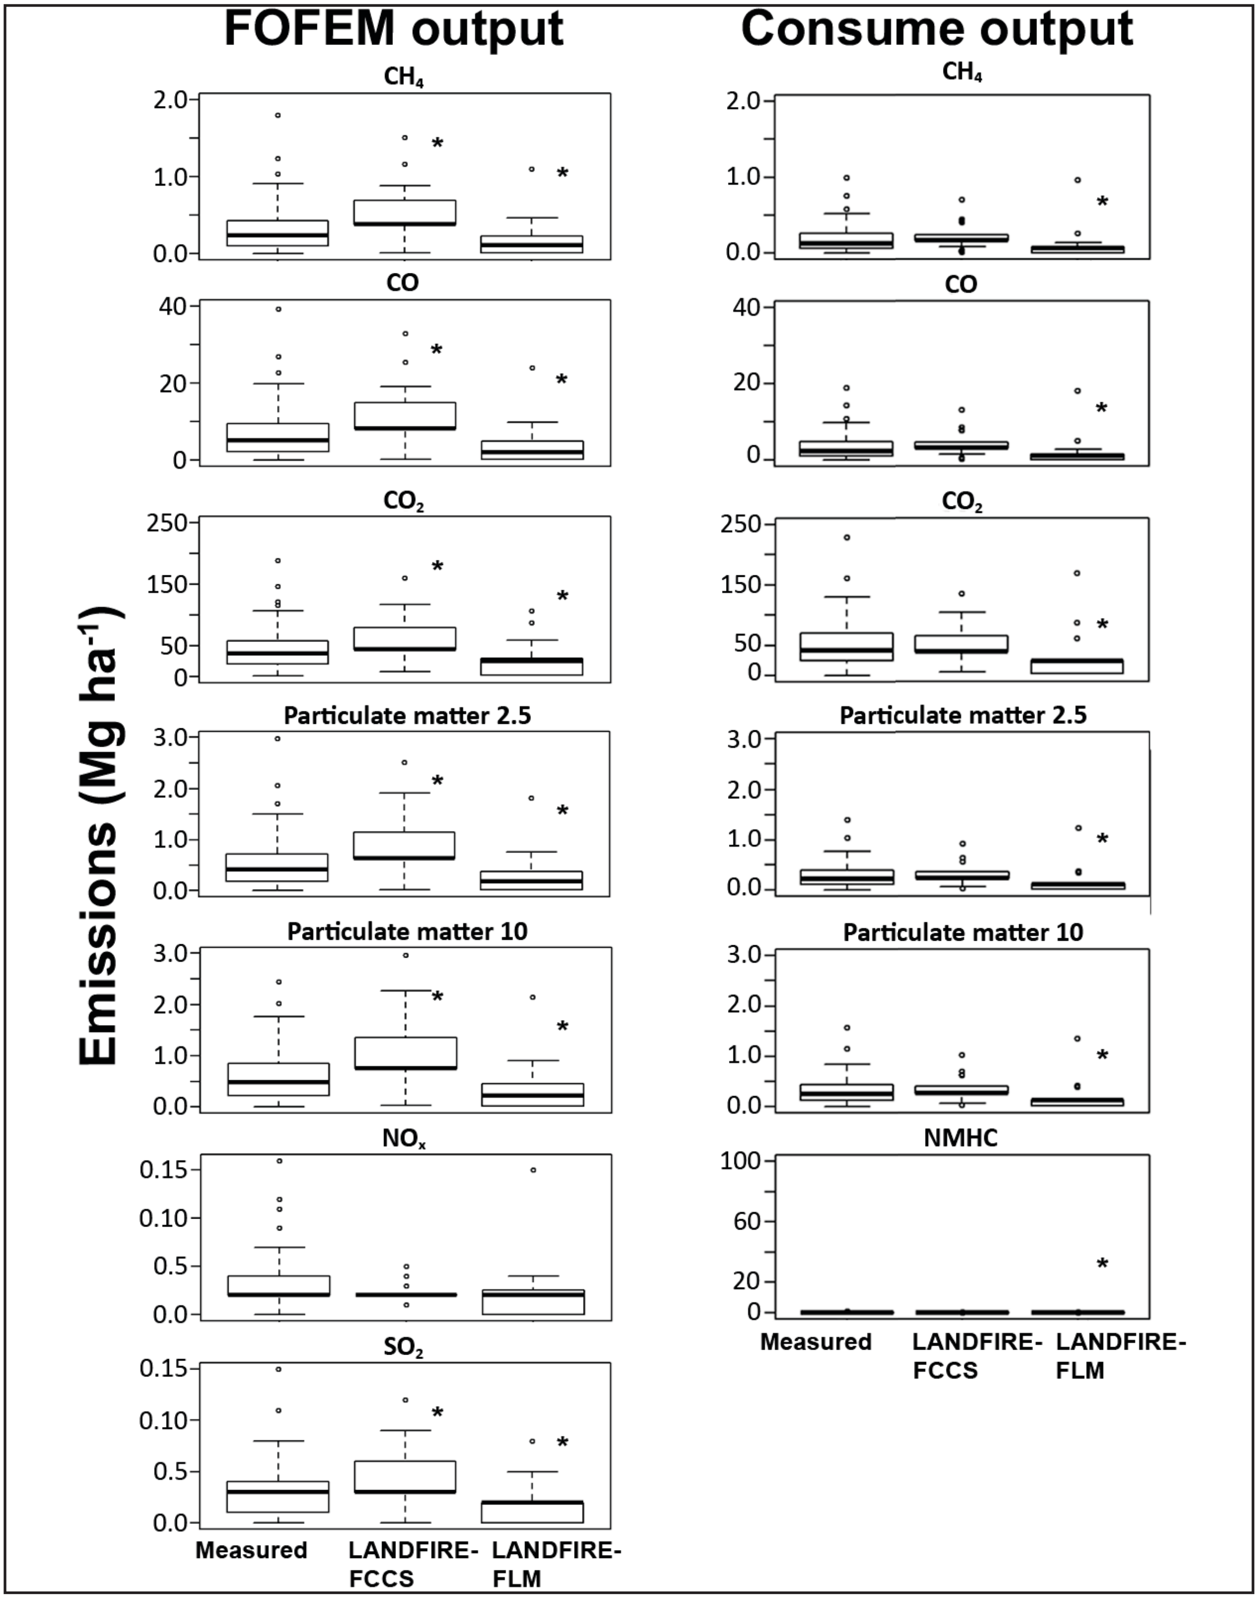

Figure 4. Differences in modeled emissions for measured, LANDFIRE-FLM, and LANDFIRE-FCCS fuel loadings. Bold horizontal lines indicate median values, asterisks represent significant differences relative to results derived from measured loadings.

Table 5. Hoffman and Gardner Importance Index for each FEFM and each fuel type shows that the fuel of relative importance to the total emissions produced varied depending by FEFM. Emissions from measured data and FCCS fuelbeds were most influenced by CWD and duff, and FLM by duff and shrubs, respectively. Highest values are indicated in bold.

to LANDFIRE maps when the LANDFIRE-FLM was created. Because the scope of this study focused on a mixed conifer ecosystem, our shrub data were somewhat limited and probably provided little insight in shrub-dominated ecosystems where shrubs are a large fuel component. Further investigation of these LANDFIRE layers in shrub-dominated systems and further fuel loading data from shrub ecosystems would be beneficial to further refining FLMs and the resulting LANDFIRE-FLM data for shrub ecosystems.

When comparing each fuel component for measured and LANDFIRE-represented loadings with those of other mixed conifer systems, all three of our fuel loading sets fell within the ranges observed by other researchers (Table 6). Focusing on duff and coarse woody debris, we found LANDFIRE-FCCS mean duff loading exceeded our measured values, but more closely resembled the ranges found in other mixed conifer forests. Thus, it is possible that our study area may have had less duff loading than other mixed conifer forests. When evaluating mean CWD loadings, we found the wide range noted in other studies, from 0.5 Mg ha^{-1} to 37 Mg ha^{-1}; LANDFIRE-FLM mean CWD loadings were at the low end of this range averaging 0.53 Mg ha^{-1}, while our measured data and LANDFIRE-FCCS were 10.6 Mg ha^{-1} and 8.6 Mg ha^{-1}, respectively.

Our results support a broader evaluation of the importance of various steps in the emissions modeling process in which Drury *et al.* (2014) compared LANDFIRE-represented loadings to a custom loading map based on measured data. Like our results, their duff loading was higher for LANDFIRE-FCCS relative to loadings represented using measured data, while in our study the LANDFIRE-FCCS total loadings were greater. Drury *et al.* found a wide range in possible fuel loadings depending upon the method chosen, as did we, and concluded that custom fuel loading layers derived from measured data produced the most reliable emissions estimates. Of the two LANDFIRE fuel layers, Drury *et al.* found the LANDFIRE-FCCS layer produced results closer to the custom loading layers. We found this to be true in our study when modeling emissions with Consume, but still found LANDFIRE-FCCS to produce higher emissions values when modeled using FOFEM.

In another study that compared classification, mapping accuracy, and fuel loadings of LANDFIRE-FCCS and LANDFIRE-FLM to Forest Inventory and Analysis (FIA) plot data across the western US, Keane *et al.* (2013) found poor performance in both LAND-

FIRE-represented FEFMs. LANDFIRE-FLM tended to under-predict loadings while LANDFIRE-FCCS tended toward over prediction. However, LANDFIRE-FLM loadings had lower root mean squared errors (Keane *et al.* 2013). Our findings here support the work of Keane *et al.* (2013) and Drury *et al.* (2014) in describing the tendency of LANDFIRE-FCCS to have higher loadings relative to LANDFIRE-FLMs.

Modeled Consumption and Emissions Using FOFEM

Relative differences in consumption values when modeled with FOFEM mirrored those of the loading values. High LANDFIRE-FCCS duff and low LANDFIRE-FLM CWD loading and consumption contributed to the total modeled emissions being highest when using LANDFIRE-FCCS inputs, and lowest when using LANDFIRE-FLM inputs. In examining the fuel loading data (Table 2), there is high variance in all fuel loading categories. This supports the work by Keane *et al.* (2013), who noted the high variance inherent in all categories of fuel loading, and the difficulties caused by spatial variation when trying to represent fuel loadings across large landscapes. Consumption followed the pattern of the total fuel loading values for the landscape, with LANDFIRE-FCCS being the highest, FLM being the lowest, and measured values in the middle. This in turn produced higher emissions from LANDFIRE-FCCS and lower emissions from LANDFIRE-FLM, highlighting the differences in emissions outcomes depending upon the choices made to represent fuel loadings.

Modeled Consumption and Emissions Using Consume

In comparing consumption and emissions from Consume, the choice of model has an effect on emissions generated. In this study, there were similar trends in modeled consumption with both fire effects models, but the lower duff consumption in Consume, relative to FOFEM, led to emissions outputs in which LANDFIRE-FCCS derived emissions did not differ from those derived from measured loadings. This difference in duff consumption is due to the fact that Consume and FOFEM calculate the consumption of duff using different equations, derived from different data sets (Reinhardt 2003, Prichard *et al*. 2005).

Research Implications

In modeling emissions, fuel loadings have been identified as the most crucial variables (Drury *et al.* 2014), yet they represent one of the greatest uncertainties in modeling emissions (French *et al.* 2011). In a detailed discussion on the topic, Keane *et al.* (2013) identified several factors creating difficulties in quantifying fuel loadings. These include lack of data to develop thorough loading maps; the use of classification systems that were developed from discrete plot locations but then applied to large, national-scale areas; and the inherent difficulty of classifying fuels into categories such as hourly size classes and duff, when each of these size classes may have different degrees of variation at different spatial scales (Keane *et al.* 2012, 2013). If existing fuel loading classification maps are to be improved, more data are necessary. The results of our study indicate that data on CWD and duff should be priorities, due to the relative importance of these fuels to overall emissions in mixed conifer forests (Table 5). While consumption didn't statistically differ for the specific case of shrubs, shrub loading accounted for a great deal of variability in emissions from LANDFIRE-FLMs (Table 5), a classification that was developed with little available shrub data (Lutes *et al.* 2009). For the case of LANDFIRE-FLMs, having additional data on shrub loadings would be beneficial.

Despite being represented at a 30 m resolution, LANDFIRE data layers are intended to be used at larger, sub-regional to national scales (LANDFIRE Team 2014*b*). Data from fuel loading maps may work for finer scales; however, there will likely be greater need to supplement that data with local knowledge. Based on our findings in a 20 000 ha area, using measured data, especially for duff and CWD loadings, is preferable relative to unaltered LANDFIRE layers. However, we understand that measured data are often unavailable, may be incomplete, or limited in availability.

Management Implications

If monitoring resources are available, emission estimates will be improved by having more information on duff loading, as differences in duff loading lead to the greatest differences in emissions, followed by CWD. For coarse woody debris, the planar intercept sampling methods have been most commonly used in forests such as in this study, although the Photoload (Keane and Dickinson 2007) method has also performed well (Sikkink and Keane 2008). Duff sampling is often performed via sampling points along a planar intercept to gather both loading and depth (Brown 1974). The fuel photoseries guides available for many ecosystems provide estimates of duff loading (Ottmar *et al.* 2003), but there are few studies comparing their performance relative to the traditional method. If measured data are not available, one could model with both the LANDFIRE-FLM and LANDFIRE-FCCS derived fuel loadings, and then average the two sets of results.

The use of systems such as the Wildland Fire Decision Support System (WFDSS) and the Interagency Fuels Treatment Decision Support System (IFTDSS) also hold potential for obtaining measured fuel loading information (IFTDSS 2015, WFDSS 2015). These systems provide online access to several models to represent fire behavior and effects (including emissions), but they also provide an easy platform from which data can be shared from user to user. In the future, it would be ideal to see a searchable database of user-provided fuel loadings within these decision support systems, similar to the searchable data available through the Fire Research and Management Exchange System (FRAMES) Resource Catalog (FRAMES 2015).

This study has characterized the potential differences in LANDFIRE-represented fuel loadings in a mixed conifer case study area, and their impact on the emissions modeling. While using measured data provides the most reliable outcome, either by itself or to help supplement the LANDFIRE data, this is not always possible. Web-based systems can aid in finding and sharing data; however, a search for the keywords "duff" and "coarse woody debris" in FRAMES returned 34 and 3 results, respectively. While online systems can be powerful sources of information, there is clearly a need for additional data with which tools such as the LANDFIRE map layers could be strengthened. In the interim, information on the relative differences in fuel loadings from LANDFIRE-represented data may be useful to managers who are tasked with quantifying emissions for fire management planning. Using all of these resources will aid in generating more accurate emissions estimates in a climate where regulatory pressure and the need to accurately represent potential emissions from fire are increasing.

ACKNOWLEDGEMENTS

The authors would like to thank the National Wildfire Coordinating Group's Fuels Committee for providing funding to the National Interagency Fuels Technology Transfer, which made this research possible. Additional thanks go to the USDA Forest Service for providing measured fuel loading, and to forestry technician P. Fekety for data preparation.

CONSERVATION

A global map of roadless areas and their conservation status

Pierre L. Ibisch,[1,2]* Monika T. Hoffmann,[1] Stefan Kreft,[1,2] Guy Pe'er,[2,3,4] Vassiliki Kati,[2,5] Lisa Biber-Freudenberger,[1,6] Dominick A. DellaSala,[7,8] Mariana M. Vale,[9,10] Peter R. Hobson,[1,2,11] Nuria Selva[12]*

Roads fragment landscapes and trigger human colonization and degradation of ecosystems, to the detriment of biodiversity and ecosystem functions. The planet's remaining large and ecologically important tracts of roadless areas sustain key refugia for biodiversity and provide globally relevant ecosystem services. Applying a 1-kilometer buffer to all roads, we present a global map of roadless areas and an assessment of their status, quality, and extent of coverage by protected areas. About 80% of Earth's terrestrial surface remains roadless, but this area is fragmented into ~600,000 patches, more than half of which are <1 square kilometer and only 7% of which are larger than 100 square kilometers. Global protection of ecologically valuable roadless areas is inadequate. International recognition and protection of roadless areas is urgently needed to halt their continued loss.

The impact of roads on the surrounding landscape extends far beyond the roads themselves. Direct and indirect environmental impacts include deforestation and fragmentation, chemical pollution, noise disturbance, increased wildlife mortality due to car collisions, changes in population gene flow, and facilitation of biological invasions (*1*–*4*). In addition, roads facilitate "contagious development," in that they provide access to previously remote areas, thus opening them up for more roads, land-use changes, associated resource extraction, and human-caused disturbances of biodiversity (*3*, *4*). With the length of roads projected to increase by >60% globally from 2010 to 2050 (*5*), there is an urgent need for the development of a comprehensive global strategy for road development if continued biodiversity loss is to be abated (*6*). To help mitigate the detrimental effects of roads, their construction should be concentrated as much as possible in areas of relatively low "environmental values" (*7*). Likewise, prioritizing the protection of remaining roadless areas that are regarded as important for biodiversity and ecosystem functionality requires an assessment of their extent, distribution, and ecological quality.

Such global assessments have been constrained by deficient spatial data on global road networks. Importantly, recent publicly available and rapidly improving data sets have been generated by crowd-sourcing and citizen science. We demonstrate their potential through OpenStreetMap, a project with an open-access, grassroots approach to mapping and updating free global geographic data, with a focus on roads. The available global road data sets, OpenStreetMap and gROADS, vary in length, location, and type of roads; the former is the data set with the largest length of roads (36 million km in 2013) that is not restricted to specific road types (table S1). OpenStreetMap is more complete than gROADS, which has been used for other global assessments (*7*), but in certain regions, it contains fewer roads than sub-global or local road data sets [see the example of Center for International Forestry Research data for Sabah, Malaysia (*8*); table S1]. Given the pace of road construction and data limitations, our results overestimate the actual extent of global roadless areas.

The spatial extent of road impacts is specific to the impact in question and to each particular road and its traffic volume, as well as to taxa, habitat, landscape, and terrain features. Moreover, for a given road impact, its area of ecological influence is asymmetrical along the road and can vary among seasons, between night and day, according to weather conditions, and over longer time periods. We conducted a comprehensive literature review of 282 publications dealing with "road-effects zones" or including the distance to roads as a covariate, of which 58 assessed the spatial influence of the road (table S2). All investigated road impacts were documented within a distance of

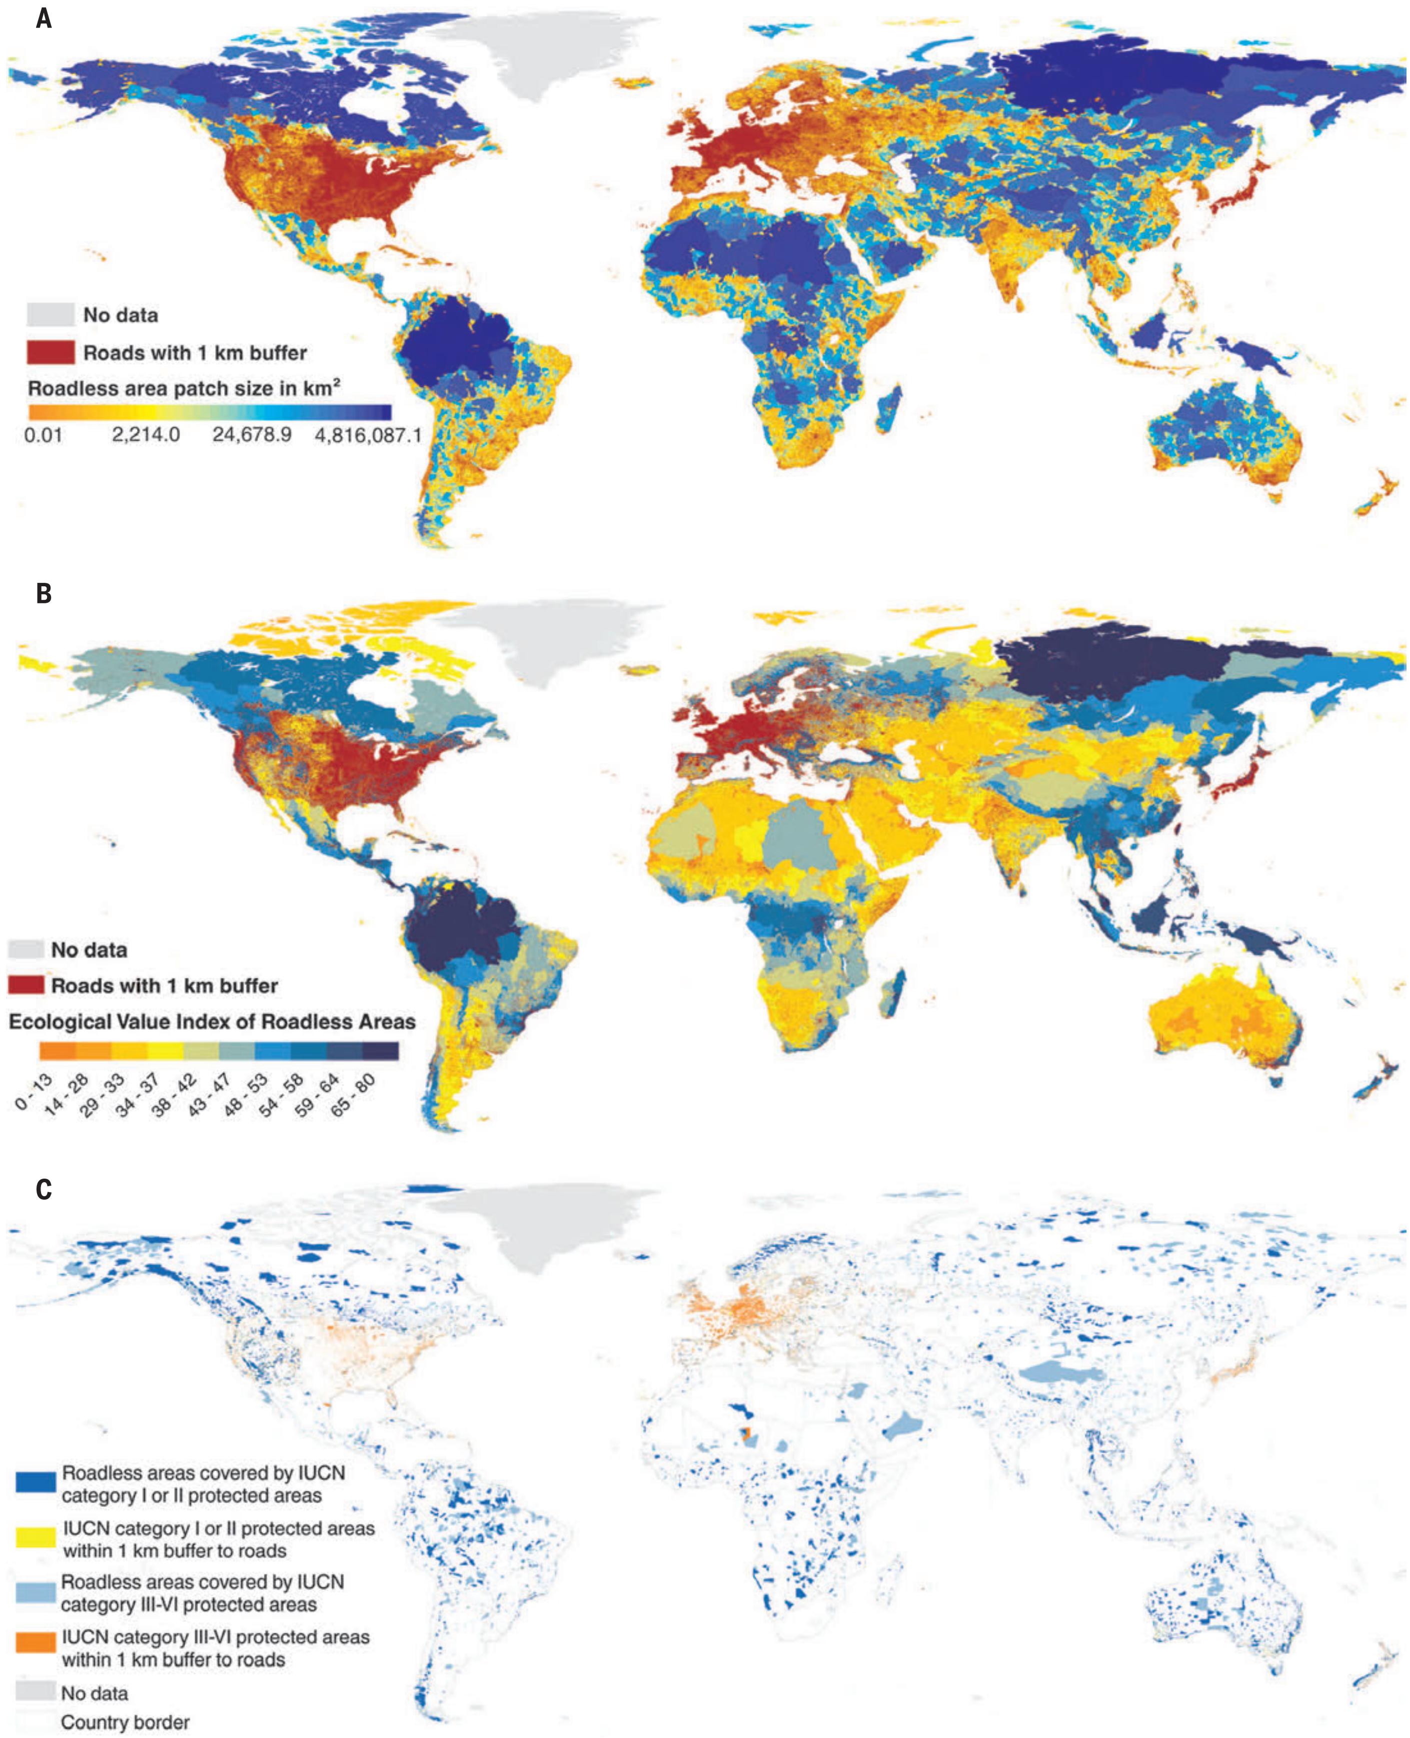

Fig. 1. The global distribution of roadless areas, based on a 1-km buffer around all roads. The distribution is depicted according to (**A**) size classes, (**B**) the ecological value index of roadless areas (EVIRA; based on patch size, connectivity, and ecosystem functionality), and (**C**) representation in protected areas (*8*).

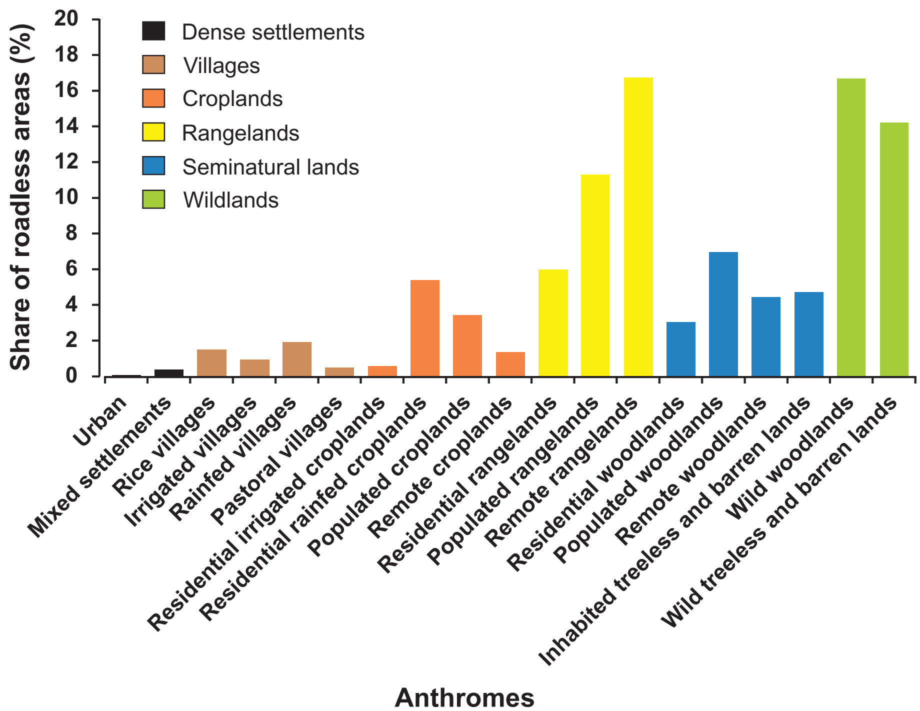

Fig. 2. Extent of roadless areas (1-km buffer) across anthromes. The majority of the world's roadless areas are in remote and unmodified landscapes, but they also occur in anthropogenically modified landscapes. The so-called anthromes were mapped according to (*10*).

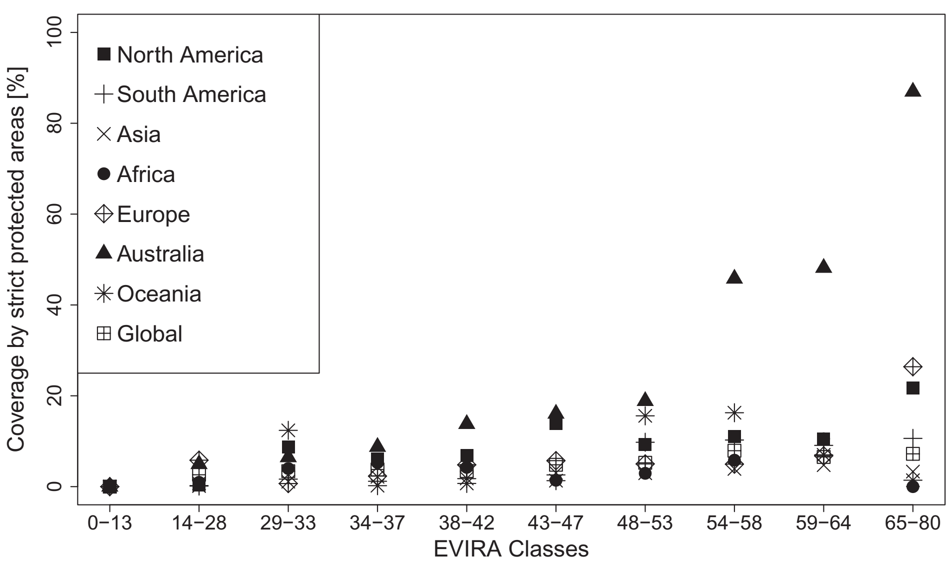

Fig. 3. Coverage of roadless areas by strictly protected areas (IUCN categories I and II) compared with global and continental EVIRA values. If priority were given to protecting roadless areas with high ecological functionality, we should see a positive correlation, with higher coverage associated with higher EVIRA values.

1 km from the road, 39% reached out to 2 km from the road, and only 14% extended out to 5 km from the road (fig. S1). Because the 1-km buffer along each side of the road represents the zone with the highest level and variety of road impacts, we defined roadless areas as those land units that are at least 1 km away from all roads and, therefore, less influenced by road effects. We compared results from using this criterion with the outcomes from using an alternative 5-km buffer (see fig. S2 and table S3). We excluded all large water bodies, as well as Greenland and Antarctica, which are mostly covered by ice, from the analyses.

Roadless areas with a 1-km buffer to the nearest road cover about 80% of Earth's terrestrial surface (~105 million km^2). However, these roadless areas are dissected into almost 600,000 patches. More than half of the patches are <1 km^2; 80% are <5 km^2; and only 7% are >100 km^2 (table S4 and fig. S3). If the buffer is extended to 5 km, there is a substantial reduction in roadless areas to about 57% of the world's terrestrial surface (~75 million km^2), dissected into 50,000 patches (fig. S2 and table S3). The occurrence, distribution, and size of roadless areas differ considerably among continents (Fig. 1A and fig. S4). For instance, the mean size of roadless patches (1-km buffer) is 48 km^2 in Europe, compared with >500 km^2 in Africa. Because of comparatively large gaps in available spatial data on roads in many segments of the tropics, the number and size of roadless areas are overestimated and should be treated with caution (e.g., Borneo; table S1).

All identified roadless areas were assessed for a set of ecological properties that were selected to reflect their relative importance to biodiversity, ecological functions, and ecosystem resilience: patch size, connectivity, and ecosystem functionality (*9*) (table S5). We normalized these three indicators to between 0 and 100 to calculate an additive and unitless index of the ecological value of each roadless area identified (termed the ecological value index of roadless areas, or EVIRA) [Fig. 1B and fig. S5; the specific rationale and technicalities of the chosen indicators are described in table S5 (*8*)]. The EVIRA values range from 0 to 80. A sensitivity analysis shows that ecosystem functionality and patch size are the best single indicators for the final index values (table S6 and figs. S6 to S8). Areas with relatively high index values tend to have a lower coefficient of variation (fig. S9).

We used the International Union for Conservation of Nature (IUCN) and UN Environment Programme–World Conservation Monitoring Centre data set of global protected areas to determine the extent of roadless areas that are protected (*8*) (Fig. 1C). The roadless areas distribution across human-dominated landscapes was determined following the classification of so-called anthromes, defined as biomes shaped by human land use and infrastructure (*10*) (Fig. 2 and table S7).

When examining the density of roads within different biomes, large discrepancies in distribution are apparent. The tundra and rock and ice-covered biomes are nearly entirely roadless, whereas temperate broadleaf and mixed forests have the lowest share of roadless areas (41%; figs. S9 and S10). Boreal forests of North America and Eurasia still retain large tracts of roadless areas (figs. S10 and S11). In the tropics, large roadless landscapes (>1000 km^2) remain in Africa, South America, and Southeast Asia, with the Amazon having the single largest roadless segment. In relation to the anthromes (*10*), about two-thirds of the world's roadless areas can be described as remote and unmodified landscapes [26% uninhabited or sparsely inhabited treeless and barren lands; 21% natural and remote seminatural woodlands, with 17% wild woodlands therein (*8*); Fig. 2 and table S7]. The remaining one-third consists of rangelands, indicating that roadless areas can also occur in anthropogenically modified landscapes.

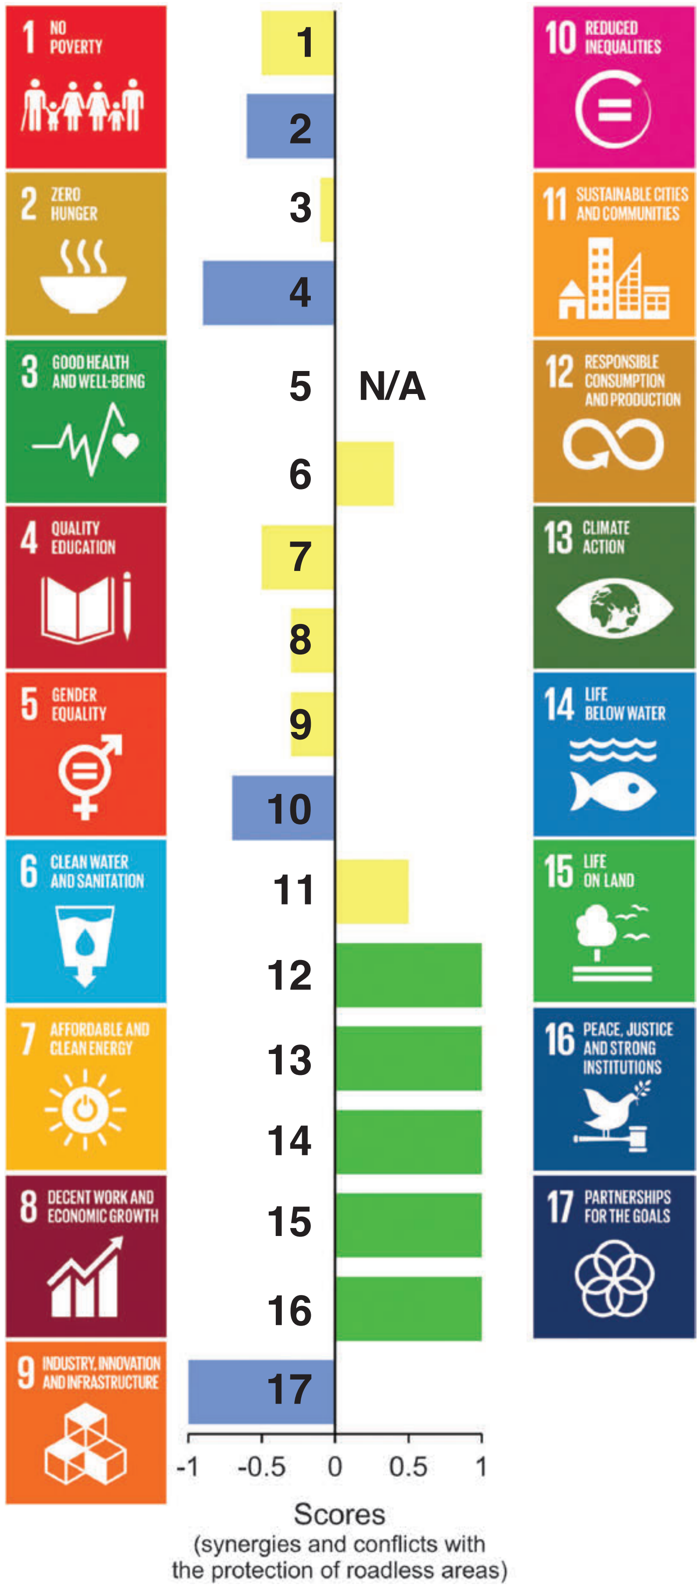

Fig. 4. Synergies and conflicts between conservation of roadless areas and the United Nations' Sustainable Development Goals. Scores <−0.5 (blue bars) indicate that conflicts with the goal prevail; scores between −0.5 and 0.5 (yellow) indicate a mixture of synergies and conflicts with the goal; and scores >0.5 (green) indicate prevailing synergies with the goal [for details, see table S11 (*8*)]. The scores reflect substantial imminent conflicts between various Sustainable Development Goals and conservation of roadless areas (table S11).

About one-third of the world's roadless areas have low EVIRA values. Patches with relatively low EVIRA values (ranging from 0 to 37; namely, <50% of the maximum value) account for 35% of the overall roadless area distribution, because most are small, fragmented, isolated, or otherwise heavily disturbed by humans. Some large tracts of roadless areas, such as arid lands in northern Africa or central Asia, occur in areas of sparse vegetation and low biodiversity and, thus, have low index values for ecosystem functionality (*9*) (Fig. 1B). High EVIRA values occur both in tropical and boreal forests. The relative conservation value of roadless areas is context-dependent. Comparatively small or moderately disturbed roadless areas have higher conservation importance in heavily roaded environments, such as most of Europe, the conterminous United States, and southern Canada.

Although the world's protected areas cover 14.2% of the terrestrial surface, only 9.3% of the overall expanse of roadless areas is within protected areas (all IUCN categories; Fig. 1C and table S8). There is no major difference in the coverage of roadless areas by strictly protected areas (IUCN categories I and II) versus the coverage of the overall landscape by strictly protected areas (3.8% roadless versus 4.2% overall). Only in North America, Australia, and Oceania are more than 6% of roadless areas under strict protection (table S8). If conservation efforts were to prioritize functional, ecologically important roadless areas, we would find a positive relation between strict protection coverage and EVIRA values of roadless areas. However, with the exception of Australia, this is not the case (Fig. 3 and table S9). Asia and Africa have particularly low protection coverage for roadless areas with high EVIRA values. For instance, we found gaps in the Asian tropical southeast, as well as in boreal biomes.

The recent Global Biodiversity Outlook (*11*) gives a bleak account of the progress made toward reaching the United Nations' biodiversity agenda as specified in the 20 Aichi Targets of the Convention on Biological Diversity (*12*). Governments have failed on several accounts to keep their use of natural resources well within safe ecological limits (target 4); to halt or at least halve the rate of habitat loss and substantially reduce the degradation and fragmentation of natural habitats (target 5); and to appropriately protect areas of particular importance for biodiversity and ecosystem services (target 11). To achieve global biodiversity targets, policies must explicitly acknowledge the factors underlying prior failures (*13*). Despite increasing scientific evidence for the negative impacts of roads on ecosystems, the current global conservation policy framework has largely ignored road impacts and road expansion. Furthermore, key policies on road infrastructure and development, such as the Cohesion Policy of the European Union, fail to take into account biodiversity.

In the much wider context of the United Nations' Sustainable Development Goals, conflicting interests can be seen between goals intended to safeguard biodiversity and those promoting economic development (*14*). We analyzed how roadless areas relate to the global conservation and sustainability agendas. As a transparent synthesis, we calculated simple scores of conflicts versus synergies of Sustainable Development Goals and Aichi Targets with the conservation of roadless areas (tables S10 and S11). Roads are explicitly mentioned in the Sustainable Development Goals only for their contribution to economic growth (goal 8), promoting further expansion into remote rural areas, and consideration is given neither to the environmental nor the social costs of road development. The resulting scores reflect substantial imminent conflicts (Fig. 4 and table S10); only in five Sustainable Development Goals do synergies with conservation of roadless

areas prevail, and four Sustainable Development Goals are predominantly in conflict with conservation of roadless areas. Maybe even more surprisingly, several of the Aichi Targets are ambivalent with respect to conserving roadless areas, rather than being in synergy entirely [six conflicting versus 11 synergistic targets (*8*); table S11].
